Notices

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our understanding, changes in research methods, professional practices, or medical treatment may become necessary.

Practitioners and researchers must always rely on their own experience and knowledge in evaluating and using any information, methods, compounds, or experiments described herein. In using such information or methods they should be mindful of their own safety and the safety of others, including parties for whom they have a professional responsibility.

With respect to any drug or pharmaceutical products identified, readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of practitioners, relying on their own experience and knowledge of their patients, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions.

To the fullest extent of the law, neither the Publisher nor the authors, contributors, or editors assume any liability for any injury and/or damage to persons or property as a matter of products liability, negligence or otherwise, or from any use or operation of any methods, products, instructions, or ideas contained in the material herein.

To our families and special friends, for their love and support.

To our clinical colleagues, who have taught us so much along the way.

To our mentors, who have imparted not just knowledge, but inspiration.

To our patients, for always making us work harder to provide the best practice patterns based on the evidence and to provide the best quality care. Our patients have always made us better. Thanks for trusting us with your care.

To our students, Residents, and Fellows, for always asking the "tough questions" with the patient right in front of us. When we discuss what should work, then use the treatment intervention and it doesn't work, then what? It is the clinical problem solving that makes us all better practitioners. We thank them for trusting us to guide them toward becoming outstanding clinicians.

To our academic colleagues, for sharing our passion for teaching and sharing information with students so we can mold the clinicians of tomorrow.

To our research colleagues, for asking the difficult questions, but then facilitating the opportunity to frame the research projects to answer some of those questions. We thank them for helping increase the translational research to improve clinical practice.

To our coauthors, for having the confidence to allow us to share the opportunity to participate in this book and make a significant contribution to the literature.

To our Elsevier colleagues, for their guidance, patience, and outstanding attention to detail needed to get the job done.

Contributors

Christopher S. Ahmad, MD
Professor of Orthopedic Surgery
Department of Orthopedics
New York Presbyterian/Columbia University Medical Center
New York, New York

Amy N. Alexander, PT, DPT
Clinical Director of Rehabilitation
JAG Physical Therapy Union
JAG Physical Therapy
West Orange, New Jersey

PREFACE

Orthopaedic Rehabilitation of the Athlete was designed to be a comprehensive, extensively illustrated textbook about the rehabilitation of common musculoskeletal conditions that affect athletes—from the professional competitor to the occasional participant. The textbook is the first of its kind to bring together surgeons, therapists, and athletic trainers to address injuries from the cervical spine to the foot, and nearly everything in between.

Comprising 45 chapters and 242 internationally renowned authors, the content and organization of this work is unique. All chapters have between three and nine parts (separate sections) with additional authors and experts that tease out the most salient and clinically applicable features and scenarios for our patients. The fundamental issues in the care of each major injury are first introduced in separate chapters. Next, treatment regimens for nonoperative care are given, with guidelines describing the indications for surgical intervention. Each diagnostic section includes an operative portion that explains, in a highly illustrative manner, the surgical technique and intraoperative variations, so that the entire musculoskeletal care team can better understand how the details of surgery may affect the rehabilitative portion of the athlete's care.

For patients undergoing surgery, preoperative "pre-habilitation" and postoperative rehabilitation are described in great detail. All physicians, physical therapists, and athletic trainers who work with competitive athletes face the challenge of returning the athlete to competition as quickly, safely, and completely as possible. In compiling this book, we have emphasized the terminal and transitional phases of rehabilitation necessary to restore the athlete to competition. This includes many chapters with detailed rehabilitation plans customized for sports in which the injuries commonly occur. Many books that include rehabilitation do not emphasize this critical phase of the actual return to sport-specific training and competition. Often there seems to be a gap between traditional rehabilitation programs and the intense requirements of participation in specific sports. Much of this book is dedicated to this transitional phase of returning the athlete back to sports safely, using sport-specific rehabilitation programs and progressive return to training, participation, and competition. Detailed criteria are given to guide the clinician and facilitate the decision to discharge the athlete from rehabilitation and return him or her back to sports.

The textbook was formatted with a post-injury and recover timeline that will facilitate progression through a rehabilitation plan. This original feature is formatted in a timeline "ribbon" of rehabilitation progressions. Simply reviewing the ribbon will provide guidelines for the clinician to use when rehabilitating the patient following each specific injury. The timeline is designed with the "stoplight" concept: The red area of the timeline signifies that extreme caution is needed in the early stages, because of factors including pain, effusion, arthrogenic inhibition, soft tissue healing, and kinesophobia. In the yellow area of the timeline, a moderate degree of caution is still required in the progression of the patient. The green area of the timeline means that the patient can be accelerated and progress to the terminal and transitional phases of the rehabilitation program.

We hope that therapists, athletic trainers, surgeons, students, residents, and fellows, as well as others with an interest in the comprehensive care of the musculoskeletal system, will all find this book informative and useful for their education and practice. To enhance post-injury care, both the print and online versions have dedicated rehabilitation guidelines and exercise prescriptions that will enhance communication within musculoskeletal teams.

We are deeply indebted to our contributors. Without their incredible talent and expertise, this textbook would not have been possible. We are very fortunate to have authors who are leaders in their fields. We would also like to thank the Elsevier team of Ann Ruzycka Anderson, Don Scholz, and Jennifer Moore, who handled a complex and innovative publishing product with the highest level of dedication and professionalism.

Chapter 1

Anterior Shoulder Instability

INTRODUCTION

Ellen Shanley, PhD, PT, OCS, Charles A. Thigpen, PhD, PT, ATC, and Richard J. Hawkins, MD

Epidemiology

Overall Incidence

- Estimates of the initial incidence of anterior glenohumeral instability in the general population range from 8.2 occurrences per 100,000 person years[1] in the rural United States to as high as 24 occurrences per 100,000 person years in Scandinavian countries.[2,3]
- In NCAA athletes the instability incidence at the glenohumeral joint was calculated as 0.12 injuries per 1000 athletic exposures (AE).[4]
- The frequency of instability episodes in a military population over 1 year was calculated as 2.8%.[5]
- The overall injury rate, including both initial and recurrent episodes of shoulder instability, has been documented to significantly increase the total number of episodes.[1,4]

Age

- Owens et al. reported that 80% of shoulder dislocations occur in younger patients.[5] Forty seven percent of patients presenting to U.S. emergency departments with traumatic dislocations were between the age of 15 and 29.[6] A Scandinavian population study reported that the overall peak incidence of shoulder dislocations in males occurred between the ages 21 and 30 and in females between the ages of 61 and 80.[2] Recurrent instability has been reported at highest frequencies in patients younger than 20 years old (66% to 94%).[7,8]

Gender

- Male collegiate athletes (0.15/1000 AE) were 2.7 times more likely to sustain a shoulder instability episode than female (0.06/ 1000 AE) collegiate athletes.[4] In the military, male cadets had a slightly higher frequency of shoulder instability than their female counterparts with 2.9% and 2.5% documented over a 1-year study period, respectively.[5]

Sport

- In collegiate athletes, the rate of shoulder instability was greatest in Spring football at 0.40/1000 AE followed by wrestling (0.21/1000 AE), women's ice hockey (0.18/1000 AE) and fall football (0.18/1000 AEs).[4]
- In high school athletes, dislocations were reported to be higher in male sports (38%) than female sports (29%).[9] However, female basketball players sustained more shoulder dislocations than male basketball players (proportion ratio = 2.7).[9,10]
- Injuries were sustained more in games (0.31/1000 AE) than practices (0.09/1000 AE) and NCAA athletes were 3.5 times more likely to sustain an injury in games than in practice.[4]

Position

- In football, linebackers, wide receivers, and running backs most frequently sustained dislocations.[9]
- Outside hitters reported the highest percentage of shoulder dislocation amongst volleyball players [9]

Pathophysiology

Intrinsic Factors

- Several anatomic factors have been theorized to increase the potential for anterior instability of the

glenohumeral joint. Capsular redundancy, patulousness of the inferior glenohumeral capsule, variations in the capsular and ligament insertion to the glenoid, and laxity of the rotator interval have been identified as risk factors for initial and recurrent instability.[11,12] The glenoid labrum is a static stabilizer of the joint and disruption of this structure yields a decrease in the stability of approximately 10% in all directions.[13] Generalized joint hypermobility (Figure 1-1), as measured by the Beighton scale, has been associated with a 2.5 times increased risk of having reported an episode of glenohumeral instability.[14]

- The loss of osseous integrity by altered inclination or version, as well as bone loss on the glenoid or humeral side of the joint, may affect anterior and inferior joint stability. There is the concept of bone loss inferiorly which may suggest, if significant, a bone block operation rather than an arthroscopic Bankart type of repair.
  - Following failure of an arthroscopic procedure, an open procedure going through the subscapularis might be considered.
  - There may be associated pathology that requires attention such as a superior labrum anterior to posterior (SLAP) lesion. Most surgeons in doing a Bankart repair in the presence of a SLAP, also repair the SLAP for added stability.[15]
  - There is a relationship of the presence of SLAP tears and increased strain on the anterior inferior glenoid humeral ligament. Thus it is related to instability.
- Dynamic stability of the shoulder is dependent on concavity-compression.[16] This phenomenon is related to the centering forces produced by coordinated contraction of the rotator cuff musculature combined with proper position and stabilization of the scapula. [17] A lack of neuromuscular control secondary to interruption of descending neural input,[18-21] rotator cuff inhibition or decreased integrity,[13,22-25] or scapular dyskinesis can lead to shoulder instability.[26,27]

Extrinsic Factors

- The initial incidence of shoulder dislocation was greater in those involved in sport and recreational activities as compared with sedentary individuals in the general population.[2,6] Also, the frequency of recurrent dislocation was greater in athletes (> 80%) than the general population (33%).[7,28]
- Contact has been documented as the most common mechanism of shoulder dislocation.[9,29] In full to partial contact sports, contact with another participant was the most frequent cause of dislocation.[9] Another common mechanism for injury was player contact with equipment and playing surfaces.[9,10]
- In the general population, especially older women, falls on the outstretched arm have been theorized as a frequent cause of dislocation.[2]

Traumatic Factors

- Bankart described the mechanism for shoulder dislocation as a fall on the extended arm causing a forceful extension of the humerus resulting in anterior-inferior dislocation.[30]
- More recently, contact or externally applied energy to the distal upper extremity while the arm is abducted and externally rotated, forcing the shoulder beyond the limits of normal range of motion, has been documented in weight lifters and rugby players sustaining anterior shoulder dislocations.[31-33]

Classic Pathological Findings

- Intraarticular pathology, including disruption of the anterior inferior capsule and labrum associated with anterior dislocation has been classically documented by Perthes (Figure 1-2).[34] Bankart has been credited with describing a shearing disruption of the glenoid labrum naming this the "essential lesion" of any anterior glenohumeral dislocation (Figure 1-3).[30] Previously, Flower in 1861 and Caird in 1887, described the relationship of a defect in the head of the humerus as an associated injury suffered with anterior dislocation.[35]
- Bony injury to the glenoid has been documented as a frequent concomitant injury suffered during a high energy dislocation.[36] The presence of a bony Bankart lesion in association with a Hill-Sachs lesion (often termed an engaging Hill-Sachs lesion) is a risk factor for recurrent dislocation.

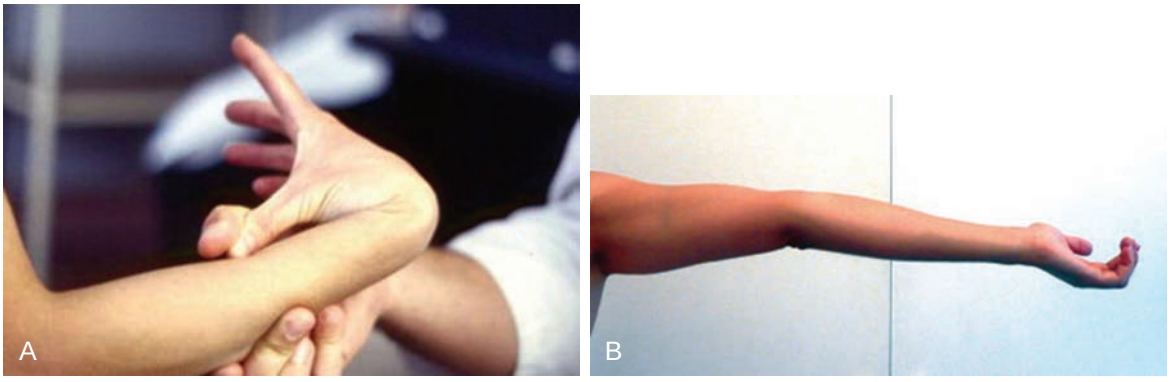

FIGURE 1-1. Hyperlaxity of the wrist (A) and elbow (B).*(Courtesy of Drs. Baujat and Finidori, Necker Hospital, Genetics Department and Pediatric Orthopaedic Surgery Department, Paris, France.) (From Provencher MT, Romeo AA, editors: Shoulder instability: a comprehensive approach. Philadelphia, 2011, Elsevier (Saunders), p. 481) Fig 42-10 and 42-11.*

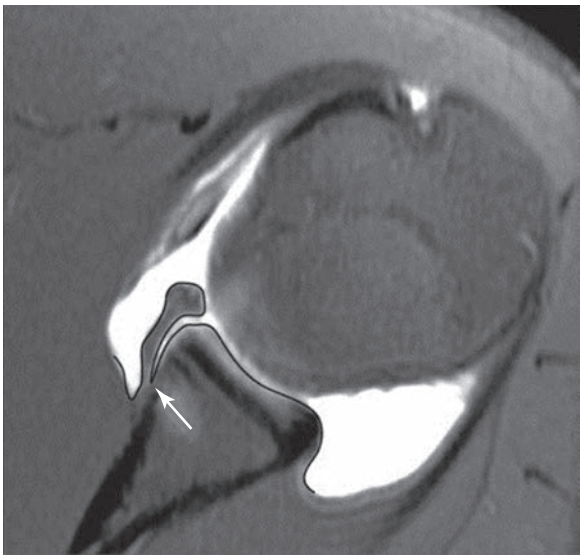

FIGURE 1-2. Axial MRI scan of a Perthes lesion: Incomplete tear of nondisplaced anteroinferior labrum that remains attached to the glenoid neck only through periosteal fibers *(arrow). (From Provencher MT, Romeo AA, editors: Shoulder instability: a comprehensive approach. Philadelphia, 2011, Elsevier (Saunders), p. 98.) Fig 8-10.*

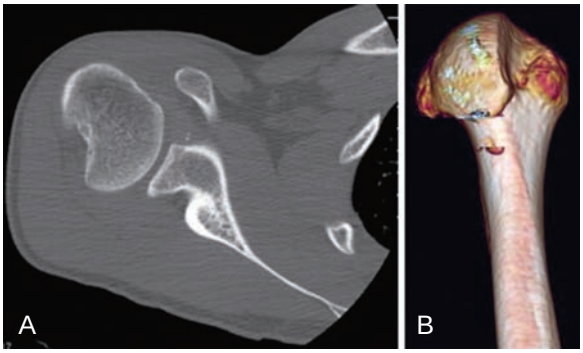

FIGURE 1-3. The axial CT image and associated 3-D reconstruction demonstrate a large Hill-Sachs lesion of the posterosuperolateral humeral head and evaluation of the anterior glenoid rim reveals loss of normal contour consistent with a compression type glenoid injury. *(From Provencher MT, Romeo AA, editors: Shoulder instability: a comprehensive approach. Philadelphia, 2011, Elsevier (Saunders), p. 251.) Fig 21-4.*

FIGURE 1-4. Axial MRA demonstrating an ALPSA lesion *(arrow). (From Provencher MT, Romeo AA, editors: Shoulder instability: a comprehensive approach. Philadelphia, 2011, Elsevier (Saunders), p. 72.) Fig 6-5A.*

FIGURE 1-5. Performance of the anterior apprehension test. An examination is positive when the patient expresses "apprehension" or the feeling of their shoulder slipping out of socket when in this abducted externally rotated position. *(From Provencher MT, Romeo AA, editors: Shoulder instability: a comprehensive approach. Philadelphia, 2011, Elsevier (Saunders), p. 26.) Fig 2-8A.*

- Researchers documenting the prevalence of specific tissue injury after primary and recurrent anterior dislocations reported anterior labrum periosteal sleeve avulsion (ALPSA) (Figure 1-4) lesions (27%) occurred with greater frequency than Bankart lesions (24%) during primary dislocation.[36]

Clinical Presentation

History

- Depending on the timing of presentation, patients presenting for evaluation often complain of pain after an initial episode of traumatic anterior instability. The pain and muscle spasm may accompany prolonged dislocation with a delay in reduction.
- The individual may report impaired sensation, loss of motion, and impaired strength.[37]
- Commonly, patients report feelings of apprehension and instability.[33]

Physical Examination

Abnormal Findings

- Positive anterior apprehension test (+/– relocation test) (Figure 1-5) is suggestive of anterior instability.[37] The relocation test (Figure 1-6) must not be confused with a positive relocation for reduction of pain which would be suggestive of internal impingement.
- Positive results for the combination of all three provocative (apprehension, relocation, and surprise) tests,

FIGURE 1-6. Performance of the anterior relocation test. The addition of a posteriorly directed force to the anterior proximal arm results in relief of patient apprehension in the abducted, externally rotated position. *(From Provencher MT, Romeo AA, editors: Shoulder instability: a comprehensive approach. Philadelphia, 2011, Elsevier (Saunders), p. 26.) Fig 2-10.*

FIGURE 1-7. True anteroposterior (Grashey) radiographic view demonstrating intact glenoid rim. *(From Provencher MT, Romeo AA, editors: Shoulder instability: a comprehensive approach. Philadelphia, 2011, Elsevier (Saunders), p. 90.) Fig 8-2C.*

was highly specific for the presence of anterior instability.[33]

- The athlete may complain of popping or clicking in the shoulder on movement.[38]
- Neurologic assessment including sensory and motor exam might demonstrate impaired sensation over the deltoid [38] and decreased strength for abduction and external rotation[38]. These symptoms are usually found in an individual requiring eduction of the dislocation. Symptoms may be related to neuropraxia and are usually transient axillary nerve injury.[38] There is rarely decreased strength related to a true persistent neurological injury.

Pertinent Normal Findings

- The patient with anterior instability will demonstrate normal to near normal single plane range of motion after an initial recovery.
- Strength will return after a brief period of recovery barring neurological involvement.
- The patient will resume participation at a high level of play with the exception of overhead activities and activities requiring the arm to extend behind the body or adopt a position of abduction and external rotation.
- The provocative position for anterior instability is the maximal cocking position for a thrower.

Imaging

- Radiographic studies routinely consist of a true AP (right angle to the scapula) (Figure 1-7), a lateral scapula, and an axillary view. They often demonstrate the presence of a Hill-Sachs lesion of the humeral head and may demonstrate a loss of bone at the anterior surface of the glenoid. *There can be specialized X-rays such as a west point view (Figure 1-8) to determine anterior glenoid bone involvement and specialized views to identify a Hill-Sachs lesion.*

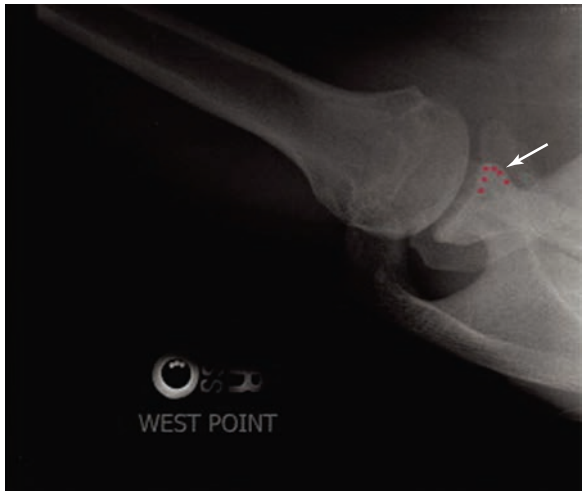

FIGURE 1-8. West Point view. Red dots outline glenoid bone loss (about 15%) *(white arrow). (From Provencher MT, Romeo AA, editors: Shoulder instability: a comprehensive approach. Philadelphia, 2011, Elsevier (Saunders), p. 173.) Fig 14-2B.*

- Magnetic resonance imaging (Figure 1-9) may demonstrate tearing of the anterior inferior glenoid labrum and with less frequency the anterior capsule and anterior aspect of the inferior glenohumeral ligament. Increased signals denoting structural deficits and tissue inflammation are noted on the T2-weighted images. The concomitant rotator cuff tear, in an older patient, can be diagnosed with an MRI.
- Commuted tomography (CT) is utilized to identify bone defects in two dimensions.
- CT reconstructions are three-dimensional studies (Figure 1-10) and are used to quantify bone defects on both the humeral and glenoid surfaces when standard X-ray images fail to specifically define the

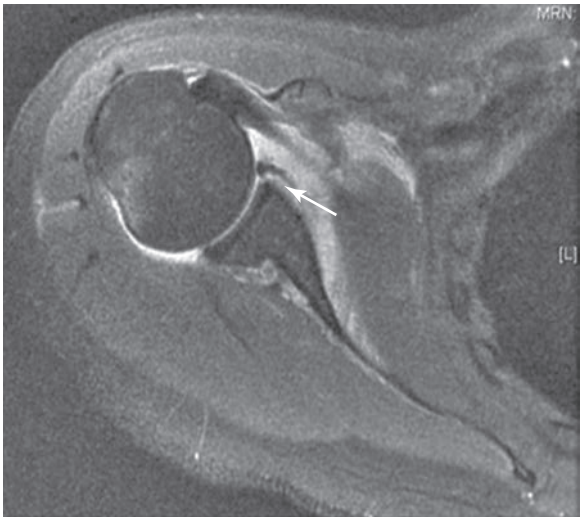

FIGURE 1-9. Axial MR arthrogram demonstrating an anterior labral tear. Note fluid interposed between anterior labrum and glenoid *(arrow). (From Provencher MT, Romeo AA, editors: Shoulder instability: a comprehensive approach. Philadelphia, 2011, Elsevier (Saunders), p. 71.) Fig 6-4A.*

FIGURE 1-11. Commercially available external rotation sling that can be used for immediate postreduction immobilization. *(From Provencher MT, Romeo AA, editors: Shoulder instability: a comprehensive approach. Philadelphia, 2011, Elsevier (Saunders), p. 103.) Fig 9-3.*

FIGURE 1-10. Three-dimensional CT: Arrow indicates the bone fragment detached from the anterior glenoid rim. *(From Provencher MT, Romeo AA, editors: Shoulder instability: a comprehensive approach. Philadelphia, 2011, Elsevier (Saunders), p. 96.) Fig 8-7A.*

lesion. These images are used sparingly as they deliver a fair amount of radiation exposure to the patient.

Differential Diagnosis

- Multidirectional instability of the glenohumeral joint may be confused with anterior glenohumeral joint instability. The differential diagnosis is made by history (chronic episodes of subluxation/dislocations and often laxity in multiple joints), unwanted translation in two or more directions (always inferior and either anterior, or posterior), and positive sulcus sign. Additionally, the athlete may present with decreased dynamic stability and poor muscle control in multiple planes of motion.
- Posterior instability may be misdiagnosed as anterior instability. Patients with decreased force couple/concavity compression, and altered positioning of the humeral head in the glenoid fossa can be misdiagnosed with anterior instability. These patients will appear to have increased anterior translation on examination if the humeral head is not centered prior to conducting the load shift test. The differential diagnosis begins with recognizing the presenting symptoms. The patient will often complain of an inability to bring their arm across their body especially when weight is applied to the distal portion of the upper extremity.
- Superior labrum from anterior to posterior (SLAP) lesions have been documented in patients complaining of anterior instability. Patients with complaints of anterior instability have been documented to present with a variety of labral and bony lesion (ALPSA).[15]

Treatment

Nonoperative Management

- Bracing: Itoi et al. have shown that traumatic anterior instability can be placed in a **sling** (Figure 1-11) with pillow at 45° to 60° of external rotation (ER) and the injury heals. However, compliance and long-term success seem to be problematic, based on follow-up studies.
- A criterion-based, progressive exercise program is thought to be effective for short-term management of traumatic anterior shoulder instability coupled with bracing when the athlete returns to sport. This program focuses on rotator cuff and scapular stability as well as maximizing shoulder proprioception/kinetic awareness in higher ranges of elevation and ER.

Guidelines for Choosing Among Nonoperative Treatments

- Patients with initial, unidirectional, capsular injuries may be appropriate for immediate bracing in slight abduction and ER.
- A progressive rehabilitation program works well for many patients to ensure success.

Surgical Indications

- Disability related to recurrent dislocations.
- First-time dislocations with combinations of specific pathologies (e.g., an older patient with combined dislocation and rotator cuff tear).
- Selected patients presenting with acute dislocation and combined bone loss (humeral and glenoid).

Aspects of History, Demographics, or Exam Findings that Affect Choice of Treatment

- Number of dislocations[39]
- Severity of dislocation
  - Was anesthesia required?
  - Was it a "locked" dislocation?
- Labral involvement
- Bony avulsion
- Percentage glenoid bone loss[39]
- Residual neurological or vascular symptoms
- Rotator cuff involvement
- Concomitant SLAP repair[15]

Aspects of Clinical Decision-Making When Surgery is Indicated

- Number of dislocations and the resultant disability are considered when planning for surgery.
- Patient age and overall health.
- Patients presenting with apprehension concerns are examined carefully to define the size and location of the lesion.
- Patients with engaging lesions require consideration to determine if the engagement occurs prior to attainment of the 90-90 positions.
- Patients presenting to the orthopedic surgeon reporting recurrent dislocations with difficult reduction.
- Sport and occupational requirements (i.e., position played, contact, ROM requirements).
- Associated complications (i.e., axillary nerve or rotator cuff involvement).
- Previous failed reconstruction.

Evidence

Arciero RA, Wheeler JH, Ryan JB, et al: Arthroscopic Bankart repair versus nonoperative treatment for acute, initial anterior shoulder dislocations. *Am J Sports Med* 22:589–594, 1994.

This is a prospective study evaluating the effectiveness of two treatment pathways for anterior dislocation of the shoulder in young athletes. Non-operative treatments verses arthroscopic Bankart suture repair for the dislocation was compared. Thirty-six athletes met the inclusion criteria: first time with a traumatic anterior dislocation, no history of impingement or subluxation, dislocation required manual reduction, and no neurological injury present. Of the two patient groups, Group 1 was immobilized for 1 month followed by rehabilitation and return to full activity at 4 months. Group 2 received arthroscopic Bankart repair before receiving similar rehabilitation as those athletes in Group 1. Twelve of the 15 nonoperative patients developed instability following return to full activity. Seven of these patients required open Bankart repair to correct instability. Eighty-six percent of the patients (18/21) in the arthroscopic Bankart repair group were deemed stabile and only one patient returned for an open procedure. It was determined that Bankart repair significantly reduced recurrent instability in anterior shoulder dislocation sustained in young athletes. (Level I evidence).

Bigliani LU, Kelkar R, Flatow EL, et al: Glenohumeral stability. Biomechanical properties of passive and active stabilizers. *Clin Orthop Relat Res* 330:13–30, 1996.

The article focuses on the stability of the glenohumeral joint. The anatomy of the joint is evaluated to analyze how osseous stability is achieved and the mechanics of arthrokinematic motion within the joint. The function of the joint capsule and ligaments are detailed regarding static and dynamic stability. The author recommends conducting studies to elucidate motion and biomechanics under abnormal conditions, such as rotator cuff pathology, and shoulder degeneration. (Level V evidence).

Buss DD, Lynch GP, Meyer CP, et al: Nonoperative management for in-season athletes with anterior shoulder instability. *Am J Sports Med* 32:1430–1433, 2004.

This is a prospective study of 30 athletes sustaining an episode of anterior shoulder instability. The athletes were treated conservatively without a sling and with physical therapy, if necessary, to restore range of motion and strength to symmetrical limits. The athletes were returned to full participation in their sport with a brace and were monitored for the number of recurrent instability episodes, additional injuries, and the ability to complete their season. (Level III evidence)

Cameron KL, Duffey ML, DeBerardino TM, et al: Association of generalized joint hypermobility with a history of glenohumeral joint instability. *J Athl Train* 45:253–258, 2010.

This study enrolled a cohort of 1050 incoming West Point freshman evaluated to identify risk factors for glenohumeral joint instability. The Beighton Scale was used to access generalized joint hypermobility. Those freshmen with a history of glenohumeral joint instability had higher total Beighton Scale scores than did those with no history of instability. Freshmen with a Beighton score greater than 2 were 2.5 times more likely to have an associated history of shoulder instability than those without a history of instability. (Level II evidence).

Griffith JF, Antonio GE, Yung PS, et al: Prevalence, pattern, and spectrum of glenoid bone loss in anterior shoulder dislocation: CT analysis of 218 patients. *AJR Am J Roentgenol* 190:1247–1254, 2008.

This cohort study quantified bone loss via CT scan in 218 patients to determine the prevalence and severity of glenoid bone loss in patients presenting after anterior dislocation. The CT scans were compared with 55 patients without a history of shoulder dislocation. The study determined that glenoid bone loss is common but generally mild. The severity of bone loss was maximally recorded at 33% of surface area. The

number of dislocations was only moderately correlated with the amount of glenoid bone loss. (Level II evidence).

Hantes ME, Venouziou AI, Liantsis AK, et al: Arthroscopic repair for chronic anterior shoulder instability: a comparative study between patients with Bankart lesions and patients with combined Bankart and superior labral anterior posterior lesions. *Am J Sports Med* 37:1093–1098, 2009.

Sixty-three patients with a diagnosis of chronic anterior shoulder instability were studied. Evaluation was performed to determine which of two groups each person should be assigned: Bankart/ALPSA lesion (n = 38), or a combined Bankart/ALPSA lesion and type II SLAP lesion (n = 25). Groups were matched for age, gender, activity level, apprehension and ROM. Arthroscopic examination, preparation, and repair of all injured tissues were performed for each patient. The patients received identical rehabilitation protocols. Patients in the second group displayed significantly more preoperative instability episodes and required on average an additional suture anchor for fixation. Similar results for postoperative success and function were documented between groups. (Level III evidence).

Kralinger FS, Golser K, Wischatta R, et al: Predicting recurrence after primary anterior shoulder dislocation. *Am J Sports Med* 30:116–120, 2002.

This study was a retrospective analysis of records and radiologic follow up of 241 patients treated after episodic anterior instability. Risk factors including: Rowe score, demographics, athletic activity, clinical (ROM, apprehension sign) and radiologic features (Hill-Sachs lesion, glenoid bone loss) were analyzed. The authors found that age (21 to 30) was the most accurate factor predicting recurrence of dislocation. The authors recommended that individuals in this age group participating in high levels of activity should undergo primary stabilization. (Level IV evidence).

Nelson BJ, Aciero RA: Arthroscopic management of glenohumeral Instability. *Am J Sports Med* 28:602–614, 2000.

Over the last 20 years there have been new developments in arthroscopic shoulder techniques, especially in the area of shoulder instability. The article discusses the various arthroscopic surgical techniques used to treat the unstable glenohumeral joint. The article looks at arthroscopic stabilization techniques for primary anterior glenohumeral instability, recurrent anterior instability, and multidirectional instability. The wide ranges of results are also discussed. (Level V evidence).

Owens BD, Duffey ML, Nelson BJ, et al: The incidence and characteristics of shoulder instability at the United States Military Academy. *Am J Sports Med* 35:1168–1173, 2007.

This is a prospective study, which looked at 4141 students at the United Military Academy to determine how many experienced a new traumatic shoulder instability event. Between September 1, 2004 and May 31, 2005; 117 students with a mean age of 20 experienced a traumatic shoulder instability event. Each instability event used the following methods to evaluate the injury: physical examination, plain radiographs, and magnetic resonance imaging. Subluxations where present in 85% of the instability events. Direction, chronicity, and whether it was a subluxation or dislocation were recorded. (Level II evidence).

Simonet WT, Melton LJ, 3rd, Cofield RH, et al: Incidence of anterior shoulder dislocation in Olmsted County, Minnesota. *Clin Orthop Relat Res* 186–191, 1984.

The study retrospectively analyzed the incidence of traumatic anterior shoulder dislocations among all Olmsted County, Minnesota residents during a 10 year period. The history of incidence was reviewed for the 124 patients who had been treated for an anterior dislocated shoulder. Of the 124, 116 had complete follow-up evaluation records. It was determined that the incidence rates were higher among men than women. According to the author, young males have the highest frequency of shoulder dislocations. No significant differences in incidence rates were found between urban and rural communities. (Level IV evidence).

Multiple-Choice Questions

QUESTION 1. Overall in high school athletes, males are at a higher risk of sustaining at traumatic anterior shoulder dislocation when compared to females. However, when comparing which two sports females are at higher risk than males:

A. Boys' baseball to girls' softball
B. Boys' to girls' basketball
C. Boys' to girls' ice hockey
D. Boys' to girls' soccer

QUESTION 2. Generalized joint hypermobility, as measured by the Beighton scale, has been associated with a ____ times increased risk of having reported an episode of glenohumeral instability.

A. 1.5
B. 2.0
C. 2.5
D. 3.0

QUESTION 3. When documenting specific tissue injury after primary and recurrent anterior dislocations, researchers have reported:

A. ALPSA lesions occurred with greater frequency than Bankart lesions during primary dislocation
B. Concomitant intraarticular pathology occurs with increasing frequency with recurrent dislocations
C. Bony Bankart lesions occurred with greater frequency than Hill-Sachs lesions during recurrent dislocation
D. Glad lesions occurred with greater frequency than Bankart lesions during primary dislocation

QUESTION 4. Which of the following modalities is the best choice for an older patient presenting after initial dislocation episode presenting with complaints of weakness and inability to lift their arm overhead?

A. Computed tomography
B. Computed tomography with 3D reconstruction
C. Magnetic resonance imaging
D. Specialized radiographs (West Point view)

QUESTION 5. Neuropraxic symptoms in a patient presenting after anterior dislocation are most often related to:

A. Axillary nerve injury
B. Musculocutaneous nerve injury
C. Radial nerve injury
D. Suprascapular nerve injury

Answer Key

QUESTION 1. Correct answer: **B** (see Overall Incidence—Sport)

QUESTION 2. Correct answer: **C** (see Pathophysiology)

QUESTION 3. Correct answer: **A** (see Pathophysiology)

QUESTION 4. Correct answer: **C** (see Clinical Presentation)

QUESTION 5. Correct answer: **A** (see Clinical Presentation)

NONOPERATIVE REHABILITATION FOLLOWING ANTERIOR CAPSULOLABRAL INJURY

Charles A. Thigpen, PhD, PT, ATC, Ellen Shanley, PhD, PT, OCS, and Richard J. Hawkins, MD

Overview of Goals, Important Milestones, and Guidelines

- Conservative management of anterior shoulder instability is often considered for patients diagnosed with traumatic anterior shoulder instability.
- The rehabilitation process is not dependent on time as clearance for return to sport is not based on assumed tissue healing.
- The rate of recurrence following traumatic anterior shoulder instability is significant and should be considered during the counseling and rehabilitation process. In general, the younger the patient and the more tissues involved (capsule/ligament, labrum, glenoid), the greater the recurrence rate. Therefore, we recommend limiting the number of recurrent episodes as they may lead to increased incidence of intrarticular pathology and long-term complications.
- Rehabilitation following traumatic anterior instability is therefore based on criteria alone with a strong emphasis on maximizing dynamic stability about the shoulder girdle.
- The suggested treatment progressions should be constantly within the context of risk of reinjury based on age, sport, and involved pathology.

GUIDING PRINCIPLES OF NONOPERATIVE REHABILITATION

- Gradual, pain-free restoration of range of motion (ROM) avoiding the sensation of instability
- Muscle guarding/spasm must first be resolved before dynamic stability can be restored
- Correct application of manual techniques and therapeutic exercises to promote static balance in glenohumeral joint mobility and optimum dynamic stabilization from the rotator cuff and associated shoulder girdle muscles.
- Return to sport is not appropriate until the athlete demonstrates dynamic stability in the functional ROM in which they are expected to participate.

Phase I

Goals

- Educate the patient about restrictions, pain management, and activities of daily living (ADLs).
- Protect the anterior shoulder by avoiding positions/movements that are likely to increase stress on the anterior/inferior capsulolabral structures.
- Minimize shoulder pain to normalize muscle tone.
- Gradually restore frontal plane elevation, abduction, and external rotation (ER) above 45°, as suggested in Table 1-1.
- Restore scapular control.

Clinical Pearls

- Modalities and soft tissue mobilization are often helpful to decrease guarding and allow gradual increase in muscle function.
- Restore isometric, then positional, isometric muscle function before progressing to full ROM concentric activities

Protection

- We recommend initial sling use for dislocations with gradual progression to no sling based on pain, available ROM, muscle performance, and activity level.

Management of Pain and Swelling

- Oral pain medications as needed
- Electrical stimulation (Transcutaneous Electrical Neural Stimulation, TENS) is recommended to manage pain and muscle guarding.
- Intermittent cryotherapy for pain and inflammation reduction[1]

Table 1-1 Staged Range of Motion Goals Following Arthroscopic Anterior Capsulolabral Injury

	PFE	PER at 20° abd	PER at 90° abd	AFE
Phase I	90°	10°–30°	Contraindicated	NA
Phase II	155°	50°–65°	75°	145°
Phase III	WFL	WFL	WFL	WFL

AFE, Active forward elevation in the scapular plane; *NA*, not appropriate; *PER*, passive external rotation; *PFE*, passive forward elevation; *WFL*, within functional limits.

- Patient positioning: patients are encouraged to use pillows or bolsters to find a "position of comfort," usually slightly abducted (20° to 30°) in a neutral or slight internal rotation (IR), especially at night. This position is recommended to reduce stress on repaired structures as well as to "unload" the surrounding muscles.

Techniques for Progressive Increase in Range of Motion

- The initial phase is resolving pain, decreasing swelling, and allowing the acute, postinjury shoulder to recover.
- Supported Codman's pendulum exercises for gentle motion and joint distraction, supported forward elevation (FE) (<90°), and ER to 0° at the side (<20° abduction) can be performed immediately to maintain joint mobility but should not reproduce symptoms. We suggest all of these motions be performed with support to minimize rotator cuff activity due to incorrect technique.[2-4]

Manual Therapy Techniques

- Gentle joint distraction and grade I-II joint oscillations may be helpful before performing supervised passive/active assisted range of motion (P/AAROM) by the rehabilitation professional to decrease muscle guarding and prepare the joint for ROM exercise. We recommend these treatments to be performed in the scapular plane in approximately 30° of elevation, and neutral rotation to limit the stress on the capsulolabral injury.[5]

Soft Tissue Techniques

- Shortening, parallel techniques (such as positional release/strain-counterstrain) may be helpful to reduce protective guarding especially for the subscapularis, posterior rotator cuff, teres major, latissimus dorsi, and pectoralis major/minor.

Stretching/Flexibility Techniques for the Musculo-Tendinous Unit

- Stretching/flexibility exercises are not recommended at this time due the need to protect the repair. Cervicothoracic, elbow, hand, and wrist.

Other Therapeutic Exercises

- Lower extremity and cardiovascular exercises may begin immediately as long as there is no reproduction of instability symptoms. This is crucial especially for the in-season management with the goal to return to play in season.

Activation of Primary Muscles Involved

- Isometric exercises may begin day 1 as tolerated. We recommend performing these exercises in the "safe zone" of 20° to 30° abduction in the plane of the scapula in neutral rotation first with the elbow supported then gradually removing support.
- Gradual progression to positional isometrics can begin day 1.

Open and Closed Kinetic Chain Exercises

- Closed chain activities are often less painful and help to provide compression of the GH joint, thereby increasing the static stability of the joint (Figure 1-12).

Neuromuscular Dynamic Stability Exercises

- Exercises to emphasize rotator cuff balance and co-contraction should be emphasized during Phase I (Figure 1-13).

Milestones for Progression to the Next Phase

- Minimal to moderate pain (Numeric Pain Rating Scale [NPRS]: 2 to 4/10) with minimal pain at rest (2/10)

FIGURE 1-12. Closed kinetic chain perturbations in quadruped. Patient is positioned in quadruped loading affected arm as tolerated. Perturbations can then be applied manually or using an unstable surface.

TIMELINE 1-1: Nonoperative Rehabilitation Following Anterior Capsulolabral Injury

PHASE I	PHASE II	PHASE III
• Sling • PT modalities • ROM wk 3—forward elevation to 90° • ROM wk 3—external rotation to 10°–30° • TBS/TAS/TLS activities as recommended & tolerated • Scapular exercises • AAROM exercises within functional range • Wk 4—submaximal isometrics for GH joint muscles	• Sling • PT Modalities • ROM wk 3—forward elevation to 90° • ROM wk 3—external rotation to 10°–30° • TBS/TAS/TLS activities as recommended & tolerated • Scapular exercises • AAROM exercises within functional range • Wk 4—submaximal isometrics for GH joint muscles	• Sling • PT Modalities • ROM wk 3—forward elevation to 90° • ROM wk 3—external rotation to 10°–30° • TBS/TAS/TLS activities as recommended & tolerated • Scapular exercises • AAROM exercises within functional range • Wk 4—submaximal isometrics for GH joint muscles

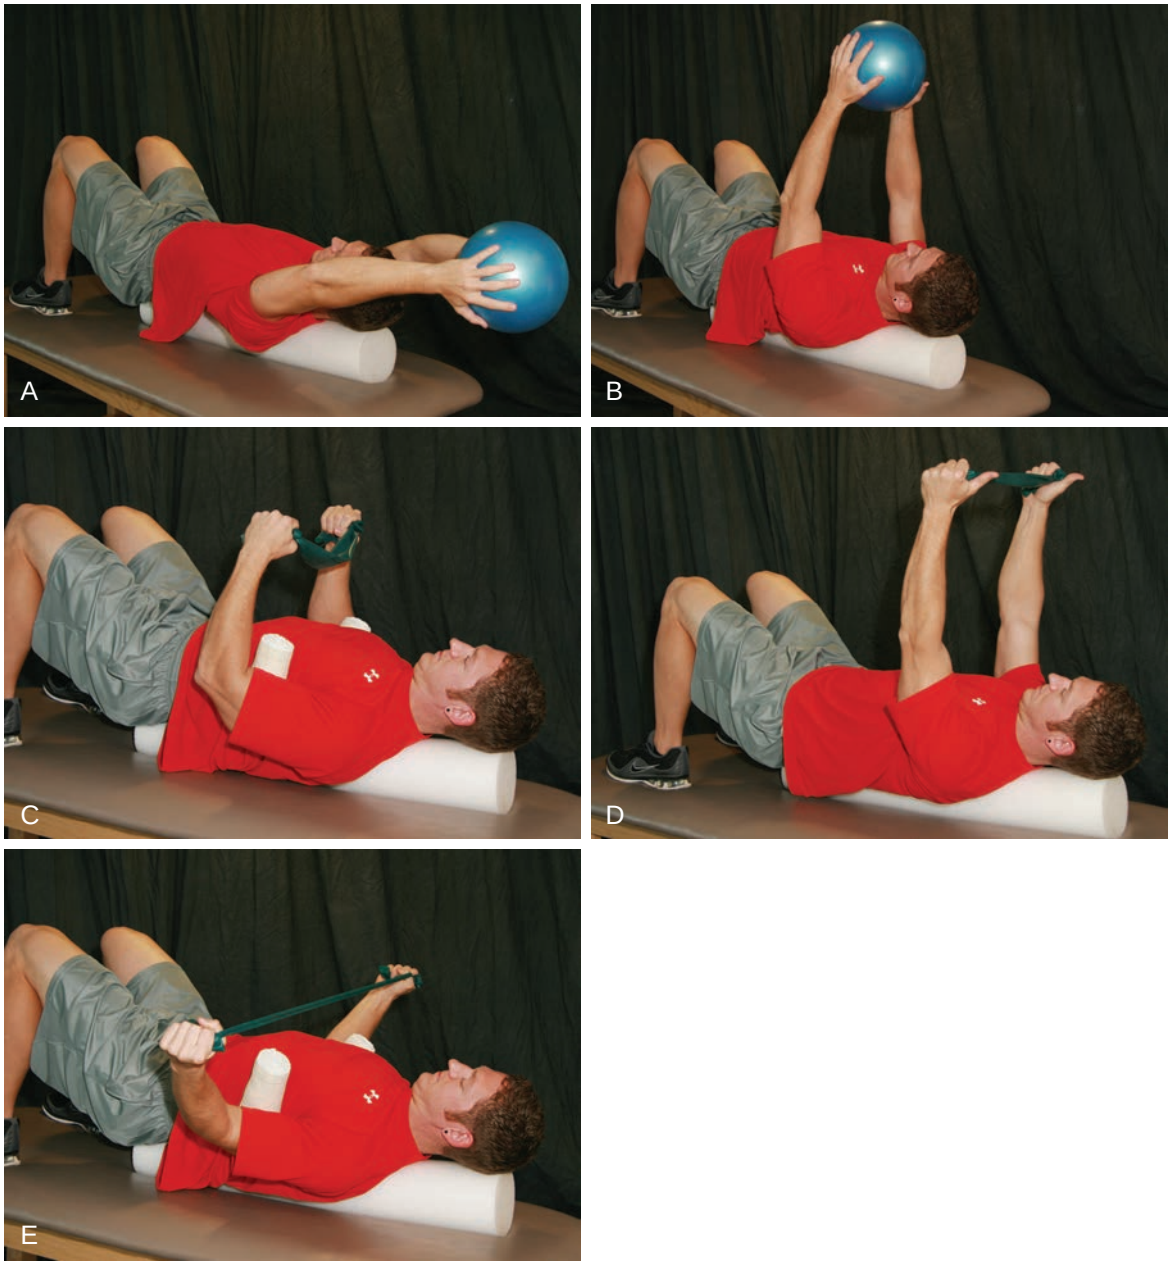

FIGURE 1-13. Cuff co-contraction during elevation: **A, B,** Patient squeezes ball into internal rotation/adduction while elevating arm as tolerated. **C-E,** Patient maintains ER while elevating arm as tolerated.

- Stage I ROM goals achieved but not significantly exceeded

Phase II

Goals

- Minimize shoulder pain (<2/10)
- Achieve staged ROM goals to normalize passive ROM and active ROM.
- Normalize rotator cuff guarding and neuromuscular control
- Normalize scapular position and control

Clinical Pearls

- Normalize subscapularis muscle function to provide dynamic stability for the anterior shoulder.
- Avoid scapular protraction with coronal plane shoulder motion to limit stress on the anterior capsulolabral structures.[6,7]
- Follow up soft tissue work with proprioceptive neuromuscular facilitation (PNF), positional isometrics, and proprioceptive activities to maximize neuromuscular facilitation during early phases after injury.

Patient-Oriented Outcomes

- Best clinical practice uses patient-rated measures of function and disability to comprehensively assess patient response to treatment.
- There are many available scales for measuring functional loss and disability in patients with instability and one measure is likely not superior to another.[8,9]
- We recommend two measures, a general measure of shoulder function that includes pain, function, and patient satisfaction similar to the American Shoulder and Elbow Surgeons' (ASES), the Pennsylvania Shoulder Score (PSS) and a measure specifically for instability, such as the Western Ontario Instability Index (WOSI).[10-14]

Protection

- Treatment for pain/analgesia oral pain medications
- Electrical stimulation (TENS) is recommended to manage pain and muscle guarding. TENS units at home are often helpful to control pain, especially shortly after surgery.
- Intermittent cryotherapy for pain and inflammation reduction.[1] We recommend 20 minutes per hour for the first week following surgery.

Techniques for Progressive Increase in Range of Motion

Manual Therapy Techniques

- Gentle joint distraction and grade I-III joint oscillations may be helpful before performing supervised PROM by the rehabilitation professional to decrease muscle guarding, restore capsular balance, and prepare the joint for ROM exercise. Anterior-inferior or inferior glides should not be performed. We recommend these positions to be performed in the scapular plane in approximately 30° of elevation, and neutral rotation to limit the stress on the capsulolabral repair.[5]

Soft Tissue Techniques

- Shortening, parallel techniques such as (Positional Release/Strain-Counterstrain) may be helpful to reduce protective guarding especially for the subscapularis, posterior rotator cuff, teres major, latissimus dorsi, and pectoralis major/minor.
- Passive ROM and active assist ROM exercises may be initiated after POW 2 for ER and FE (see Table 1-1).

Stretching/Flexibility Techniques for the Musculo-Tendinous Unit

- Should not be performed as these are end ROM exercises.

Other Therapeutic Exercises

- Gradual introduction of total body strengthening (TBS), total leg strength (TLS), core stability, uninvolved total arm strength (TAS), and cardiovascular conditioning can be initiated with attention to the safety of the activity. All exercises should be performed so that the patient does not have symptoms of instability during activity.

Activation of Primary Muscles Involved

- Scapular retraction and proprioceptive neuromuscular facilitation (PNF) patterns should be emphasized and positions based on patient tolerance. We recommend first achieving stability in a retracted position then progressing to scapular protraction to minimize increased stress on the anterior capsulolabral structures.[6,7] Although scapular elevation and retraction are safe we suggested limited resistance because of the load placed through the glenohumeral joint for most exercises.
- Active ROM and rotator cuff strengthening within the staged ROM goals in Table 1-1. The recommended procedure is to begin with submaximal isometric strengthening of the shoulder and elbow with the arm adducted to the side in neutral rotation first, then to progressively increase the angle of arm elevation and ER. As the patient demonstrates improved rotator cuff endurance and absence of pain or other symptoms it is recommended to progress to dynamic isometrics, then concentric/eccentric exercises, then AROM exercises within the ROM restrictions.

Sensorimotor Exercises

- Angular reposition, rhythmic stabilization, and repeated contractions within staged ROM limits may be implemented during Phase II.

Open and Closed Kinetic Chain Exercises

- Closed kinetic chain (CKC) exercises may be implemented below 90° of elevation during Phase II. These exercises should begin in a modified weight-bearing position and progressed to full weight-bearing as tolerated.[15]

Techniques to Increase Muscle Strength, Power, and Endurance

- See above w/AROM

Milestones for Progression to the Next Phase

- Appropriate healing of the surgical repair by adhering to the precautions and immobilization guidelines.
- Staged ROM goals achieved but not significantly exceeded
- Minimal to no pain (NPRS: 0—2/10) with ROM
- PSS greater than 60% and WOSI less than 50%. These are estimates based on reported normative data and our experience. This combined with other objective criteria provides clear communication between the patient and medical professionals on how the patient perceives their shoulder function, and gives potential insight as to how care can be improved upon.

Phase III

Goals

- Achieve staged ROM goals to normalize passive ROM and active ROM. DO NOT significantly exceed especially for ER at 90° of abduction

- Minimize shoulder pain (0/10 at rest and <2/10 following exercises or activity)
- Begin to increase strength and endurance
- Increase functional activities as evidenced by PSS > 80% and WOSI < 30%.

Clinical Pearls

- Nearly full active elevation in the plane of the scapula should be achieved before progressing to elevation in other planes or initiating resistive elevation exercises.
- Ensuring posterior rotator cuff performance and scapular stability below 90° of abduction before progressing to higher elevation and difficulty of exercises.
- Posterior-inferior glides are often helpful to gain full ER and FE. Addition of posterior shoulder flexibility exercises in conjunction with these mobs before and after exercise is helpful in the stiff shoulder.
- In our opinion, rapid gain of ER towards 90° of abduction should be avoided (before 8 weeks). If the athlete must return to overhead, throwing sports and the involved shoulder is their throwing arm, then more aggressive stretching of ER towards 90° of abduction may begin at 8 weeks.
- Functional exercises may begin toward the end of this phase. Simple patient instruction to *"keep their hands where they can see them"* will allow the patient to resume desired activities without risking reinjury.

Protection

- No sling use
- Avoid positions of max ER towards 90° of abduction, especially with a posteriorly directed load. (e.g., NO push-ups, bench press, pectoral flys)

Management of Pain and Swelling

- Pain should not be a limiting factor at this point. If pain is limiting progression of activities rest and reevaluation of all aspects of the shoulder should be performed in consultation with the referring surgeon
- Cryotherapy as needed.
- NSAIDS as needed.

Patient Education

- Counsel about using the upper extremity for appropriate ADLs in the pain-free ROM (starting with waist level activities and progressing to shoulder level and finally to overhead activities over time)
- Continue education regarding avoidance of heavy lifting or quick sudden motions
- Education to avoid positions which place stress on the anterior inferior capsule during ADLs

Techniques for Progressive Increase in Range of Motion

- FE should be progressed from active-assistive exercises (e.g., rope and pulley, wall walks), to active, to resistive upright exercises, then finally to prone exercises as per reported electomyography (EMG) activity of the shoulder.[3,4] Although protection of the rotator cuff is not needed, the EMG activity reflects overall stress to the shoulder and is a good guide to exercise progression.

Manual Therapy Techniques

- Grade I-III joint mobilizations (up to tissue resistance) are most often all that is required especially for anterior/inferior directions. If ROM is greater than 50% less than staged ROM goals as compared with the uninvolved extremity then gentle joint mobilizations may be performed. However they should be done only into the limited directions and only until staged ROM goals are achieved. It is crucial in the patients that appear "tight" to discern if there is capsuloligamentous tightness/stiffness, musculotendinous, pain limitation, or some combination.

Soft Tissue Techniques

- Deeper soft tissue techniques may be initiated during this phase. More aggressive techniques such as Active Release® or other instrumented soft tissue mobilizations to normalize muscle tone and extensibility. Particular attention should be paid to the subscapularis, latissimus, pectorals, teres major, and posterior rotator cuff. In our experience these techniques often allow for gradual return consistent with the staged goals without aggressive joint mobilizations or excessive end range stretching.

Stretching/Flexibility Techniques for the Musculo-Tendinous Unit

- Total upper quarter mobility should be evaluated with restoration of cervical, thoracic, and scapulothoracic mobility to facilitate optimal return upper extremity ROM.
- End range flexibility exercises may begin in particular for posterior shoulder (horizontal adduction and sleeper stretch beginning at 60° to 70° of elevation on side.[16,17] Pectoralis minor flexibility can begin with attention not to increase stress on anterior shoulder as these have been shown to be effective at increasing pectoralis minor length (Figure 1-14).[18,19] Gradual introduction of latissimus, posterior shoulder, and FE stretches as needed (Figure 1-15).

Other Therapeutic Exercises

- Address core stability deficits as needed beginning in the sagittal plane and progressing to frontal and transverse plane exercises.
- Total leg strengthening exercises may be progressed as tolerated but high loads should be avoided on the shoulder in activities such as power clean, dead lifts, and back squats should be avoided. Front squats during this phase are recommended to allow for safe positioning of the shoulder with large loads.

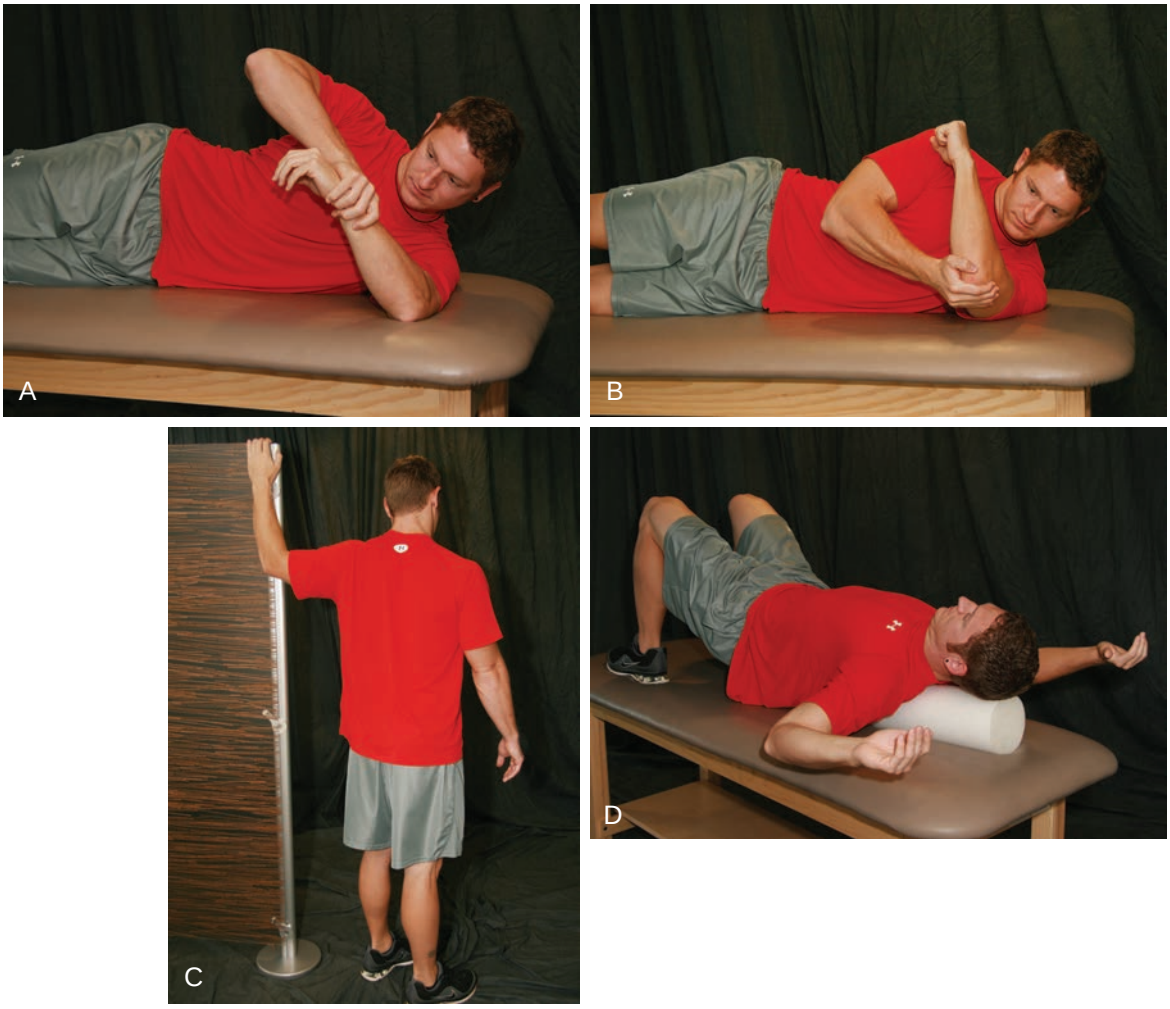

FIGURE 1-14. A, The pectoralis major and minor are stretched by placing the arm at 90° of abduction then leaning forward and rotating away from affected arm while keeping the elbow in line with the scapula and thorax. The patient should report feeling a "stretch" along the anterior shoulder and pectorals, not glenohumeral joint discomfort. **B,** The pectoralis major and minor are stretched by placing the arm at 120° of abduction then leaning forward and rotating away from affected arm the while keeping the elbow in line with the scapula and thorax. The patient should report feeling a "stretch" along the anterior shoulder and pectorals, not glenohumeral joint discomfort. **C, D,** Pectoralis minor flexibility can begin with attention not to increase stress on anterior shoulder as these have been shown to be effective at increasing pectoralis minor length.

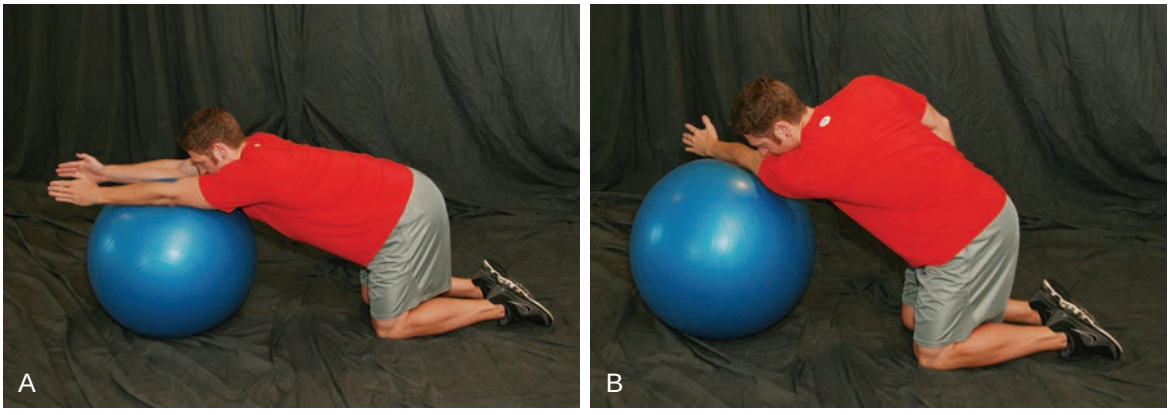

FIGURE 1-15. Latissimus and posterior shoulder flexibility on ball: (A) Patient actively rolls ball away from body and sits back on buttocks maintaining neutral spine then (B) adding trunk rotation away from affected side to change angle of stretch from distal latissimus to posterior cuff and teres major.

- It is also recommended to use this phase of rehabilitation to address kinetic chain deficits using basic functional screens such as the overhead squat, single leg squat, or more in-depth approaches such as the Functional Movement Screen. These approaches will provide areas for improvement for the athlete allowing for total body and lower extremity kinematic chain assessment.

Activation of Primary Muscles Involved

- Elbow flexion/extension strengthening with elbow by the side can begin in this phase
- Exercises and functional activities should be pain free and performed without substitutions or aberrant movement patterns (shrugging, thoracic extension)
- Balanced rotator cuff strengthening to maintain the humeral head centered within the glenoid fossa during progressively more challenging activities
- Should be initially performed in a position of comfort with low stress to the glenohumeral joint such as less than 45° elevation in the plane of the scapula (e.g., elastic band or dumbbell ER, IR, FE)
- Exercises should be progressive in terms of shoulder elevation (e.g., start with exercises performed at waist level progressing to shoulder level and finally overhead activities)
- Depending upon the goals of the exercise (control versus strengthening), rehabilitation activities may also be progressive in terms of speed once the patient demonstrates proficiency at slower speeds

Sensorimotor Exercises

- Activities to improve neuromuscular control of the rotator cuff and shoulder girdle such as use of unstable surfaces, body blade, and manual resistance exercises in conjunction with auditory, visual, or tactile cues or biofeedback.
- PNF patterns are particularly effective for restoring muscle balance and proper coordination patterns. This manual feedback is preferable, especially early during this phase because the clinician controls the load to the extremity and is able to best match the patient's level of performance.

Open and Closed Kinetic Chain Exercises

- Strengthen scapular retractors and upward rotators
- Weight-bearing exercises with a fixed distal segment. Examples: quadruped position while working to maintain proper position of the scapula, quadruped with scapula protraction, progressing from quadruped to tripod position, *no push-ups*[20]

Techniques to Increase Muscle Strength, Power, and Endurance

- Exercises should be progressive in terms of muscle demand. It is suggested to use activities that have muscle activity levels documented with EMG.[2,20-36] In general, increasing elevation increases deltoid and supraspinatus activity, whereas increasing ER at lower levels of elevation increases posterior rotator cuff EMG.[2,20-36] The subscapularis is most active during forward punches (combined scapular protraction and glenohumeral IR) and should be performed at lower and higher levels of elevation.[32]
- Exercises should be progressive in terms of adding stress to the anterior capsule, gradually working towards a position of 90° of ER and 90° of abduction by 12 weeks.
- Rehabilitation should include isolated and complex movement patterns progressing from isolated to complex movement patterns.
- The rotator cuff and scapula stabilizer strengthening program should emphasize high repetitions (typically 30 to 50 reps) and relatively low resistance (typically 1 to 2 kg) during this phase.
- General shoulder strengthening exercises (front/side raises, shoulder presses) may be initiated as full AROM is achieved and rotator cuff and scapular stabilizer strength is adequate for normal movement patterns. This is usually a late Phase III exercise and should begin with 3 to 5 kg and similar reps (15 to 20 for 3 to 4 sets).

Neuromuscular Dynamic Stability Exercises

- Development of dynamic stability is crucial during this phase of rehabilitation following stabilization procedure. Rhythmic stabilization starting at 45° of abduction in the scapular plane in neutral rotation and gradually increasing in elevation and ER as performance increases. Four to five bouts for 30 seconds are recommended before progressing the difficulty of exercises.
- CKC push up plus progression are important exercises as it promotes rotator cuff and scapular stabilizer co-contraction needed for dynamic stability.[30,37]

Plyometrics

- No heavy lifting or plyometrics should be performed during this stage.

Functional Exercises

- Functional exercises may be initiated toward the end of Phase III (weeks 9 to 12); however, we strongly recommend avoiding undue stress on the anterior shoulder.
- Multi-planar exercises should be progressed in a similar fashion as previously described, emphasizing rotational control across each plane of elevation.

Milestones for Progression to the Next Phase

- Staged active ROM goals achieved with minimal to no pain (NPRS 0 to 2/10) and without substitution patterns
- Appropriate scapular posture at rest and dynamic scapular control during ROM and strengthening exercises
- Strengthening activities completed with minimal to no pain (NPRS 0 to 2/10)
- <20% deficit using isokinetic or hand held dynamometer for ER, IR, abduction, and elevation.
- Able to complete 20 hand-taps during modified Davies CKC upper extremity (UE) test.[38] We recommend modifying the Davies test by using biacromial width as in our experience a standard 36″ is too wide for many patients.

- Able to complete 30 reps of ER at <20° of abduction in 30 seconds (1 rep/sec).

Phase IV

- The length of Phase IV will vary dependent upon sport participation. For noncontact sports it may be as simple as a gradual return to sport. For contact athletes it may require a more gradual return to activity in a braced condition.

Goals

- No complaints of pain at rest and minimal to no pain (NPRS 0 to 2/10) following activities
- No or minimal sensation of instability with activities
- Normalize strength, endurance, neuromuscular control, and power as evidenced by:
  - <10% deficit using isokinetic or hand held dynamometer for ER, IR, abduction, and elevation.
  - 30 reps in 30 seconds with blue Thera-Band at 0° and 90° abduction
  - Able to complete 90 hand-taps during modified Davies CKC UE test in 60 seconds.[38]
  - Gradual demonstration of confidence and performance in sports specific positions.
  - Functional improvement in ADLs and sport as evidenced by PSS > 90% and WOSI < 20%.

Clinical Pearls

- A balance of posterior and anterior rotator cuff strength (ER:IR ratio) of 66% before beginning return to sport training is recommended.[39,40]
- Progression of presport training activities should be monitored, re-evaluating the athlete's pain and strength (no >10% advancement as compared to presport).
- We recommend soreness rules avoiding activity postsoreness for 24 to 48 hours.[41]

Management of Pain and Swelling

- Pain should not be a limiting factor at this point. If pain is limiting progression of activities rest and reevaluation of all aspects of the shoulder should be performed in consultation with the referring surgeon
- Cryotherapy as needed
- NSAIDS as needed

Patient Education

- Counsel about using the upper extremity for appropriate ADLs in the pain-free ROM (starting with waist level activities and progressing to shoulder level and finally to overhead activities over time)
- Continue education regarding avoidance of heavy lifting or quick sudden motions
- Education to avoid positions which place stress on the anterior inferior capsule during ADLs

Other Therapeutic Exercises

- Progressing from Phase III there are no limitations to TBS/TLS or TAS. However, unless end range of motion is required for the athlete's sport then we strongly recommend avoiding training that stresses the shoulder in the ABER position as the risk of developing recurrent instability outweighs the benefits of training.

Open and Closed Kinetic Chain Exercises

- Progression of OKC and CKC consistent with principles previously outlined.

Techniques to Increase Muscle Strength, Power, and Endurance

- During this phase the focus of exercises should progress from endurance to strength and power. This will require increasing loads, speed of movements, and type of contraction.
- *Loads*—loads now may be increased appropriate to sport and body weight beginning with 3 to 5 sets of 10 and progressing to 3 to 5 sets of 4 to 6 reps over the next 8 to 10 weeks consistent with a traditional strength training program.
- *Speed of movement*—concentric movements are challenged first beginning with IR, then ER, then punches and complex movements. Punches are last as this as scapular protraction places increased stress on the capsulolabral complex and is a common mode of dislocation.
- *Type of contraction*—eccentric loads can now be initiated beginning with ER (towards IR) and abduction (towards adduction) first then progressing to IR and abduction in preparation for plyometric exercises.
- It is recommended to gradually progress to positions of high stress during this phase as needed. For example, to progress back to bench press begin with the athlete performing a dumbbell bench press on the floor, then barbell on the floor, then dumbbell (Figure 1-16).

Neuromuscular Dynamic Stability Exercises

- Integration of higher loads and greater perturbations are important in particular for athletes returning to sport.

Examples include:

- For football players clap pushups on foam or Dynadisc
- For throwers repeated ER yo-yos (with 1-kg weight on band)

Plyometrics

- Because of the explosive nature of this type of exercise, emphasis of plyometric exercises should be on quality not quantity. Additionally, 2 to 3 weeks of tolerance to high speed multi-planar activities is recommended, which progressively mimics functional demands before initiating plyometric exercises.
- Perform two to three times/week and utilize moderate reps (e.g., 3 to 5 sets of 15 to 20 reps).

FIGURE 1-16. A, B, The bench press progression begins with dumbbells and the athlete on the floor. The arms are shoulder level then the weight is pushed up finishing with scapular protraction. When the athlete can complete 3 sets of 15 without pain or soreness the barbell bench on the floor can be considered. **C,** The barbell progression is performed in the same manner as dumbbell bench press on the floor completing the exercise with full scapular protraction. **D,** Traditional bench press should begin after completing the floor progression. Hands should be shoulder width apart and the elbows should not go behind the body when the bar is to the chest to protect the anterior repair. A towel roll or other que can be used on the chest to help the athlete modify the exercise.

- Begin with unweighted balls and progress to lightly weighted balls (Plyoballs).

Functional Exercises

- Continue as per Phase III.

Sport-Specific Exercises

- Med ball throws against a wall, for distance for OKC sports.
- UE fitter/stepper in prone position for CKC sports (Figure 1-17).
- Dribbling on wall or rebounding with one hand.

Milestones for Progression to Advanced Sport-Specific Training and Conditioning

- Clearance from physician.
- PSS > 90% and WOSI < 10%.
- No complaints of pain at rest and minimal to no pain (NPRS 0 to 2/10) following activities.
- No or minimal sensation of instability with activities.
- Restoration of sufficient ROM to perform desired activities.
- Maintenance of strength and endurance as evidence by the following:
  - <10% deficit using isokinetic or hand held dynamometer for ER, IR, abduction, and elevation.
  - 30 repetitions in 30 seconds with blue Thera-Band at 0° and 90° abduction
  - Able to complete 90 hand-taps during modified Davies CKC UE test in 60 seconds.[38]

Phase V: Return to Sport Progression

- Similar to Phase IV, the length will vary dependent upon sport participation.
- The timing of this phase will be greatly impacted by risk of reinjury and timing relative to competition requirements.
- As risk of reinjury increases, a more conservative approach in return to competition is recommended.

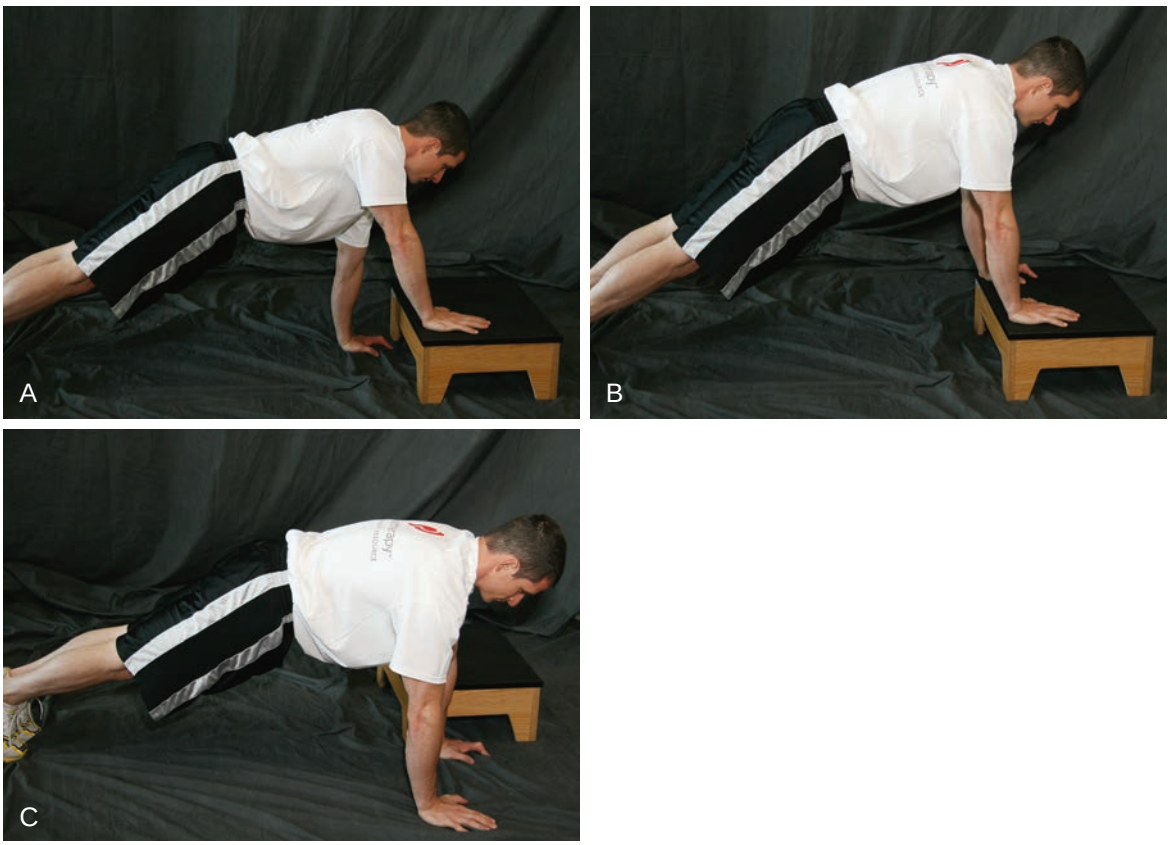

FIGURE 1-17. Hand Walks on Box: Patient "walks" one hand at a time up on box and back down maintaining scapular stability without shrugging and remaining symptom free for 1 rep/sec (both hands up and down) for 30 to 60 seconds.

- As maturity of the athlete and level of competition increase athlete education becomes imperative allowing the sports medicine team (athlete, PT, ATC, and MD) to reach the best decision for that athlete.

Goals

- No complaints of pain at rest and minimal to no pain (NPRS 0 to 2/10) following activities
- No or minimal sensation of instability with activities
- Maintenance of sufficient ROM to perform desired activities
- Maintenance of shoulder strength and endurance as previously described with minimal to no pain (NPRS 0 to 2/10) or difficulty

Clinical Pearls

- Soft tissue and joint mobilizations (once or twice per week) will prevent loss in ROM during the return to sport progression. Careful attention to maintenance of ROM and flexibility will allow for long-term successful return to sport.
- Begin sessions with a complete dynamic warm-up including rotator cuff before complex, functional, and plyometric exercises.
- Continued strengthening of the rotator cuff and scapular stabilization exercises to fatigue should be performed once or twice per week.

Protection

- Use of either a Sully or Donjoy (formerly SaWa) brace is recommended during initial return to sport, in particular for contact athletes. We prefer the SaWa brace-9 (lace up/strap brace) for contact athletes as it is the only brace demonstrated to limit ER and abd ROM.[42] The Sully (neoprene) is recommended for all others as it has been shown to increase proprioception and kinesthetic awareness which are altered in shoulders with anterior instability.[43,44]

Techniques for Progressive Increase in Range of Motion

Manual Therapy Techniques

- As previously described PRN.

Soft Tissue Techniques

- As previously described PRN.

Stretching/Flexibility Techniques for the Musculo-Tendinous Unit

- Regular assessment of ROM/flexibility during the return to sport progression and after return to sport is important for long-term shoulder function.

Other Therapeutic Exercises

- As previously described.

Open and Closed Kinetic Chain Exercises

- As previously described.

Techniques to Increase Muscle Strength, Power, and Endurance

- Care should be taken to ensure that the athlete maintains shoulder-strengthening and dynamic strengthening exercises. We recommend 3 days for 20 to 30 minutes of focused rotator cuff and scapular stabilizing exercises in addition to TBS and TAS that may be apart from normal athletic activities.

Plyometrics

- PRN as previously described.

Sport-Specific Exercises

- PRN as previously described.

Criteria for Return to Sport

- PSS > 95% and WOSI < 10%.
- No complaints of pain at rest and minimal to no pain (NPRS 0 to 2/10) following activities.
- No or minimal sensation of instability with activities.
- Maintenance of sufficient ROM to perform desired activities.
- Maintenance of strength and endurance as evidenced by the following:
  - <10% side-to-side deficit using isokinetic or hand held dynameter for ER, IR, abduction, and elevation.
  - <33% unilateral ER:IR ratio[39,40]
  - 30 repetitions in 30 seconds with blue Thera-Band at 0° and 90° abduction
  - Able to complete 90 hand-taps during modified Davies CKC UE test in 60 seconds.[38]

Evidence

Arciero RA, Wheeler JH, Ryan JB, et al: Arthroscopic Bankart repair versus nonoperative treatment for acute, initial anterior shoulder dislocations. *Am J Sports Med* 22:589–594, 1994.

We will include all varsity, junior varsity, and freshmen baseball and softball players in our study. Players will be excluded from the study if they are being treated for a shoulder or elbow injury at the beginning of the preseason training. Players will be excluded if they are following a physician, therapist or trainer prescribed arm care program. Athletes complaining of pain during flexibility or strength testing will be excluded from the study. (Level IV evidence)

Bankart ASB: The pathology and treatment of recurrent shoulder dislocation of the shoulder. *Br J Surg* 26:23–29, 1939.

The article looks at the condition of recurrent shoulder dislocation and the operation techniques used to repair the disability, causes of the recurrent dislocation, and the recommended operation for most effective repair. Abnormal laxity in the capsule of the joint and weakness of the surrounding muscles have been associated with the condition. Stretching and imperfect healing from too much use early after reduction has said to cause the recurrent dislocation. Two types of operations to fix the problem are described; one which decreases the size of the capsule, and the other which is supposed to give support to the capsule. The problem with the two techniques is that they can limit normal movement and range of motion. The articles suggest an operation that exposes the anterior margin of the glenoid cavity, and repair the defect with sutures that pass through the free edge of the capsule and glenoid ligament. The goal of the technique is to correct the condition and still maintain normal motion. (Level IV evidence).

Buss DD, Lynch GP, Meyer CP, et al: Nonoperative management for in-season athletes with anterior shoulder instability. *Am J Sports Med* 32:1430–1433, 2004.

This is a prospective study of 30 athletes sustaining an episode of anterior shoulder instability. The athletes were treated conservatively without a sling and with physical therapy, if necessary, to restore range of motion and strength to symmetrical limits. The athletes were returned to full participation in their sport with a brace and were monitored for the number of recurrent instability episodes, additional injuries, and the ability to complete their season. (Level III evidence)

Edouard P, Degache F, Beguin L, et al: Rotator cuff strength in recurrent anterior shoulder instability. *J Bone Joint Surg Am* 93:759–765, 2011.

The study analyzes the relationship between internal/external rotator muscle strength and recurrent anterior shoulder instability. The study included 37 patients with recurrent unilateral shoulder dislocation and 11 healthy nonathletic subjects. A Con-Trex dynamometer was used to test internal and external rotator strength with side-to-side comparisons of the effected group as well as comparisons of the control group. Angles of measure were 180°, 120°, and 60° in concentric mode. Findings showed that patients with recurrent anterior shoulder instability also had weakness in the rotator cuff. Side-to-side differences in strength were present and increased depending on which arm was dominant or non-dominant. The strength difference increases when the nondominant arm was involved, and decreased when the dominant arm was involved. The control group was representative of other studies with healthy subjects who had more strength in the dominant arm. It is suggested that further studies be conducted to determine whether weakness contributes to or is a consequence of recurrent instability. (Level III evidence).

Ellenbecker TS, Mattalino AJ: Glenohumeral joint range of motion and rotator cuff strength following arthroscopic anterior stabilization with thermal capsulorraphy. *J Orthop Sports Phys Ther* 29:160–167, 1999.

This descriptive study of 20 patients diagnosed with anterior shoulder instability described their postoperative rehabilitation program following arthroscopic shoulder stabilization. The involved patients experienced return of ROM and scapular/rotator cuff strength at 12 weeks when compared with the uninjured extremity. (Level IV evidence).

Matias R, Pascoal AG: The unstable shoulder in arm elevation: a three-dimensional and electromyographic study in subjects with glenohumeral instability. *Clin Biomech (Bristol, Avon)* 21(Suppl 1):S52–S58, 2006. [Epub 2005 Nov 9];

An altered scapulohumeral rhythm is said to be related to some shoulder dysfunction, but little is known about the shoulder muscle activation patterns in patients with

glenohumeral instability. The study included six subjects with glenohumeral instability who all performed arm elevations in eight positions. A 6 DOF electromagnetic device was used to record the kinematics. The scapulohumeral rhythms were compared among subjects. The most significant differences were seen in the scapular protraction and spinal tilt and no differences were seen in the scapular lateral rotation. The kinematic changes during certain angles of arm elevation may be due to changes in alignment of the humeral head and glenoid and as a result contribute to shoulder instability. The study emphasizes the importance of assessing scapulohumeral rhythms in the rehabilitation process of individuals with shoulder instability. (Level IV evidence).

Myers JB, Ju YY, Hwang JH, et al: Reflexive muscle activation alterations in shoulders with anterior glenohumeral instability. *Am J Sports Med* 32:1013–1021, 2004.

The study looks at the relationship between anterior shoulder instability and muscle activation alterations. Eleven patients with anterior shoulder instability where matched with 11 control subjects. Each subject underwent external humeral rotation apprehension perturbation while muscle activation characteristics were recorded using electromyographic analysis. Patients with instability showed decreased pectoralis major and biceps brachii mean activation along with increased peak activation in the subscapularis, supraspinatus, and infraspinatus when compared with the control subjects. A much slower bicep brachii mean reflex latency as well as suppressed supraspinatus-subscapularis coactivation was seen in the patients with instability. These results may explain recurring episodes of instability in patients with glenohumeral instability. (Level IV evidence).

Paletta GA, Jr, Warner JJ, Warren RF, et al: Shoulder kinematics with two-plane x-ray evaluation in patients with anterior instability or rotator cuff tearing. *J Shoulder Elbow Surg* 6:516–527, 1997.

The study analyzes the relationship of biplanar glenohumeral kinematics and glenohumeral-scapulothoracic motion in normal patients using a two-plane radiograph series and then in patients with either shoulder instability or rotator cuff tear. The measurements were taken before and after surgery and after postoperative rehabilitation. X-rays of normal adults were obtained to have control values. Patients who had anterior instability showed abnormal motion anterior humeral translation in the anterior posterior plane and in the scapular plane. Following open stabilization the results were normal. The abnormal glenohumeral-scapulothoracic motion relationships persisted after open stabilization. Patients with rotator cuff tears also experienced abnormal glenohumeral kinematics, but after repair the problem become normal. It is suggested that further studies be conducted to understand the significance of the results. (Level IV evidence).

Rodosky MW, Harner CD, et al: The role of the long head of the biceps muscle and superior glenoid labrum in anterior stability of the shoulder. *Am J Sports Med* 22:121–130, 1994.

The study analyzes the role of the long head of the biceps muscle and superior glenoid labrum in anterior stability of the shoulder in overhead positions. Seven nonembalmed cadaver shoulders without history of articular disease where dissected for use in the study. The shoulders simulated the forces of the rotator cuff and long head biceps muscle as the glenohumeral joint was abducted and externally rotated by an Intron testing device. The device applied external rotator torque to the humerus. The testing was first completed on a normal shoulder, then the superior glenoid labrum was detached and the testing was repeated. Results showed that the long head of the biceps muscle contributes to the anterior stability of the shoulder through increasing torsional rigidity. This allows for resistance of external rotatory forces which occurs during abducted and externally rotated positions of the shoulder. In addition, the protective role of the biceps muscles helps to lessen the stress of the inferior glenohumeral ligament. Lesions to the superior glenoid labrum decrease the shoulder's torsional rigidity and put added strain on the inferior glenohumeral ligament and therefore lessen anterior shoulder stability. (Level IV evidence).

Rowe CR, Zarins B: Recurrent transient subluxation of the shoulder. *J Bone Joint Surg Am* 63:863–872, 1981.

Transient subluxation of the shoulder may be the causation of the "dead arm syndrome" characterized by sharp paralyzing pain occurring during extreme external rotation. Activities such as throwing and strained positions with the arm above the shoulder can cause the syndrome. The study includes 58 patients (60 shoulders) all with dead arm syndrome caused by transient dislocation. The treated patients were followed up at 2 to 16 years. Group 1 had the sensation of subluxation and group 2 did not have the sensation. Patients without the sensation are difficult to diagnose correctly. To obtain the most accurate physical finding for patients, an apprehension test was performed. Of the 50 shoulders that underwent a Bankart repair, the following grading system results were obtained: 70% excellent, 24% good, and 6% fair. Deficiencies in the shoulder capsule are said to be a factor of anterior subluxation of the shoulder. (Level III evidence).

Multiple-Choice Questions

QUESTION 1. Recurrent episodes following traumatic anterior shoulder instability generally increase

A. The older a patient and less tissues involved.
B. The younger a patient and more tissues involved.
C. The older a patient and more tissues involved.
D. The younger a patient and less tissues involved.

QUESTION 2. Rotator cuff exercises in Phase I are best tolerated

A. In the "safe zone" of 20° to 30° abduction in the plane of the scapula.
B. In neutral abduction and rotation.
C. In supported elevation at 90° of abduction.
D. In 45° of abduction and 20° of IR.

QUESTION 3. Which statement best describes the rationale of why recurrent instability is worrisome?

A. Clearance for return to sport isn't based on number of recurrent episodes.
B. Contact athletes are at risk for rotator cuff tears with recurrent instability.
C. There is no evidence that recurrent instability increases injury risk or long-term disability.
D. Recurrent instability episodes may lead to increased incidence of intraarticular pathology and early onset osteoarthritis.

QUESTION 4. Criteria for initiating resistance exercises above shoulder height include

A. Pain free at rest, full AROM in abduction and ER.
B. Pain free at rest, PROM within functional limits, and negative apprehension test.
C. Pain free after exercise, AROM within functional limits, and tolerance of Phase 2 exercises.
D. Pain free at rest, AROM within functional limits, and tolerance of Phase 2 exercises.

QUESTION 5. A 16-year-old linebacker is 4 weeks s/p a right shoulder dislocation without labral or bony injuries confirmed by MRI. What criteria should they meet to return to play?

A. No sense of instability at end ROM, < 50% ER:IR strength ratio, and 60 hand-taps during CKC UE test.
B. No sense of instability at end ROM, < 50% ER:IR strength ratio, and 90 hand-taps during CKC UE test.
C. Minimal sense of instability at end ROM, < 33% ER:IR strength ratio, and 60 hand-taps during CKC UE test.
D. Minimal sense of instability at end ROM, < 33% ER:IR strength ratio, and 90 hand-taps during CKC UE test.

Answer Key

QUESTION 1. Correct answer: **B**. (see Overview)

QUESTION 2. Correct answer: **A**. (see ROM Guidelines Phase I)

QUESTION 3. Correct answer: **D**. (see Overview/Return to Sport-Phase IV)

QUESTION 4. Correct answer: **C**. (see Phases II and III)

QUESTION 5. Correct answer: **D**. (see Phase IV-Return to Sport)

POSTOPERATIVE REHABILITATION AFTER ARTHROSCOPIC ANTERIOR SHOULDER STABILIZATION

Charles A. Thigpen, PhD, PT, ATC, Ellen Shanley, PhD, PT, OCS, and Richard J. Hawkins, MD

Indications for Surgical Treatment

- Disability related to recurrent shoulder instability.
- Following first time dislocation selected patients combined with certain pathologies (e.g., full thickness rotator cuff tear following dislocation in older patient, large glenoid or humeral defect).

Brief Summary of Surgical Technique

Major Surgical Steps

- Examination under anesthesia for translation in all directions and range of motion.
- Positioning in lateral decubitus or sitting (beach chair) position (Figures 1-18 and 1-19). Either requires some lateral distraction.
- Prepping and draping protecting vulnerable areas and insuring sterility and accessibility.
- Insertion of scope for visualization (establish outflow when necessary) (Figures 1-20 and 1-21).
- Identify pathology and determine approach.
- Prepare anterior glenoid surface.
- Mobilize labrum and capsule (Figures 1-22 and 1-23).
- Secure capsule and labrum to anterior glenoid usually with bone anchors (Figure 1-24).
- Usually three anchors securing capsule and labrum.
- Amount of capsule incorporated varies based on the amount of laxity under exam under anesthesia (EUA), labral/capsular damage, and functional range of motion (ROM) requirements (thrower vs. linebacker)
- Usually three anchors. Anchors at apex or slightly upon the face of glenoid to recreate bumper.
- Remove traction and close portal sites in usual fashion.

Factors That May Affect Rehabilitation

Surgical

- In this section we discuss arthroscopic plication and the Bankart repair. The principles of open surgical reconstruction for anterior instability would be similar if soft tissue in nature (i.e., modified Bankart procedure). Bony procedures if secured by screws may allow earlier mobilization.
- Amount of capsular plication and integrity of the capsule.[2] ROM progression and goals may be delayed for excessive plication to correct excessive capsular redundancy or for patients with a long-standing instability history as their anterior-inferior capsule is often not robust.[2,3]
- Degree of labral repair/reconstruction repairs.[4] Typically, the labrum is detached from the 3 to 6 o'clock position off the glenoid. Tears that extend beyond these borders would require close consultation with the surgeon to modify ROM limits and precautions.
- Amount of glenoid bone loss.[5-7] The degree of glenoid bone loss will influence ROM expectations as well as amount of protection needed postoperatively. Emerging evidence suggests glenoid bone loss as a likely factor in recurrent dislocations. Significant bone loss anteriorly may suggest soft tissue arthroscopic reconstruction inadequate and may require a bony reconstruction (i.e., Latarjet).
- Associated injuries such as a Hill-Sachs lesion, SLAP (superior labral tear from anterior to posterior) tears,

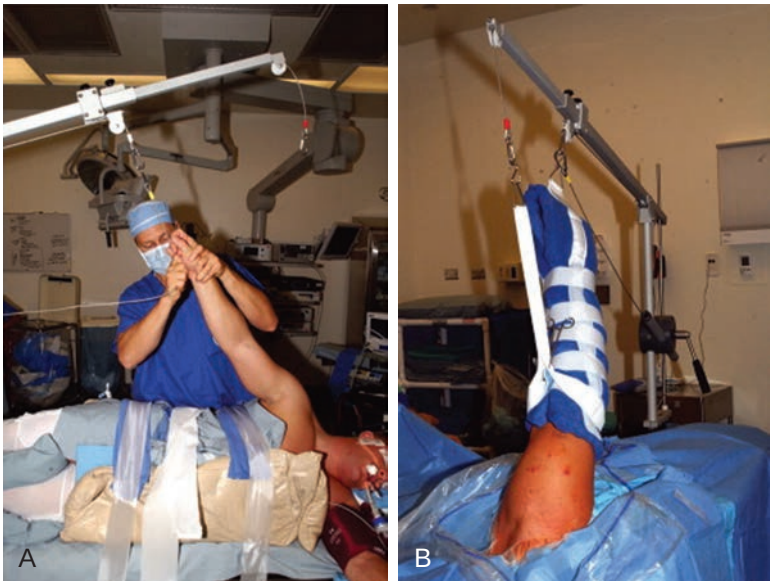

FIGURE 1-18. The lateral decubitus position. (A) Operative setup. The arm is usually abducted between 45 and 60 degrees. (B) Final balanced suspension setup with the arm abducted about 50 degrees and a lateral strap is used to facilitate the visualization of the glenohumeral joint. Care must be taken to ensure the lateral suspension strap is around a padded arm sleeve. *(From Provencher MT, Romeo AA, editors: Shoulder instability: a comprehensive approach, Philadelphia, 2011, Elsevier (Saunders), p. 37.) Fig. 3-10B and 3-12.*

FIGURE 1-19. Beach chair position. Final positioning with the arm reduced to a pneumatic arm positioner. It is easier to reduce the arm to the arm holder that has been previously placed on the pneumatic arm positioner. *(From Provencher MT, Romeo AA, editors: Shoulder instability: a comprehensive approach, Philadelphia, 2011, Elsevier (Saunders), p. 41.) Fig. 3-20C.*

rotator cuff tears, or other osteochondral injuries may also be present.[4] The impact of these concomitant injuries and potential procedures should be accounted for in the rehabilitation plan.

Anesthetic

- Anesthesia interscalene blocks are commonly used postoperatively for short-term pain control.
- Usually, one interscalene injection is appropriate for anterior instability procedures.
- Patients may perform ROM exercises carefully as directed by the surgeon.
- An interscalene block may require careful early mobilization under the direction of a Physical Therapist or Certified Athletic Trainer as directed by the surgeon.

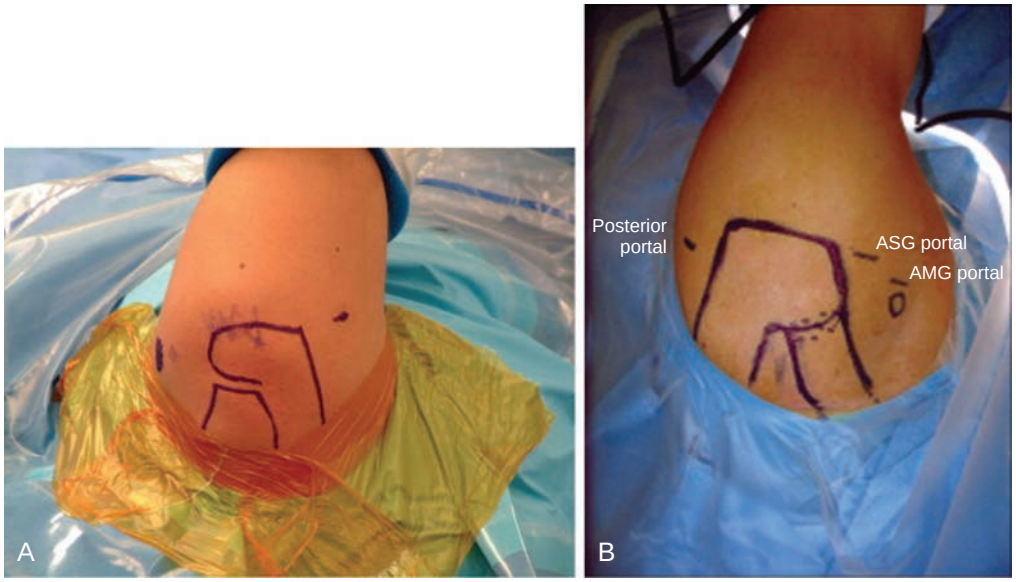

FIGURE 1-20. Surgical skin landmarks. **A,** Initial skin markings showing landmarks. Note lateral position of anticipated portal posteriorly. **B,** Shows portals. *(From Reider B, et al: Operative techniques: sports medicine surgery, Philadelphia, 2010, Elsevier (Saunders)) Fig. 11-14A and B.*

FIGURE 1-21. Outside picture demonstrating arthroscope posterior and 18-gauge needles placed in outside-in fashion. Note anterosuperior portal is adjacent to anterior acromion and anterior mid-glenoid portal is adjacent to coracoid. *From Provencher MT, Romeo AA, editors: Shoulder instability: a comprehensive approach, Philadelphia, 2011, Elsevier (Saunders), p. 135.) Fig. 11-15.*

Other Surgical Techniques and Options

- Major differences in other surgical techniques
  - Open Bankart repair is the same as the arthroscopic Bankart repair with the exception that the subscapularis is either detached or split for accessibility to the anterior labrum, capsule, and glenoid (see Figure 1-29).
  - Open procedures for bone loss or bony defects require secure fixation or a bone block such as a Latarjet (see Figure 1-33) with an associated soft tissue reconstruction. Rehab is much the same but may allow early mobilization. Other grafts may be used such as iliac crest graft or allograft. These are securely fixed to anterior glenoid. These also require subscapularis violation.
- This chapter is dedicated primarily to arthroscopic plication with or without a Bankart repair. The primary difference between the following guidelines and these surgical modifications is rate of ROM return. For the open surgical reconstruction significant attention should be given to external rotation (ER). ER should be limited to 30° with the arm at the side and a measured rate of ROM. We recommend ER to 0 for 3 weeks then gradual stretching with a goal of attaining 30° of ER by 6 weeks. In contrast, bony procedures if secured by screws may allow earlier mobilization with gradual return of ER and ABD ROM.

GUIDING PRINCIPLES OF POSTOPERATIVE REHABILITATION

- Understanding of the surgical procedure and anatomic structures, which require protection.
- Consideration of healing rates of the involved tissues while balancing the stresses needed for tissue proliferation/remodeling and protecting the repaired/reconstructed tissues.[1]
- Gradual restoration of PROM while protecting the anterior-inferior aspect of the glenohumeral joint through initial immobilization and the rate of ROM gain. Emphasizing PROM then AROM then resisted activities.
- Correct application of manual techniques and therapeutic exercises to promote static balance in glenohumeral joint mobility and optimum dynamic stabilization from the rotator cuff and associated shoulder girdle muscles.

Phase I (0 to 14 days): Immediate Postoperative Period

Goals

- Protect the surgical repair (capsule, ligaments, labrum, sutures)

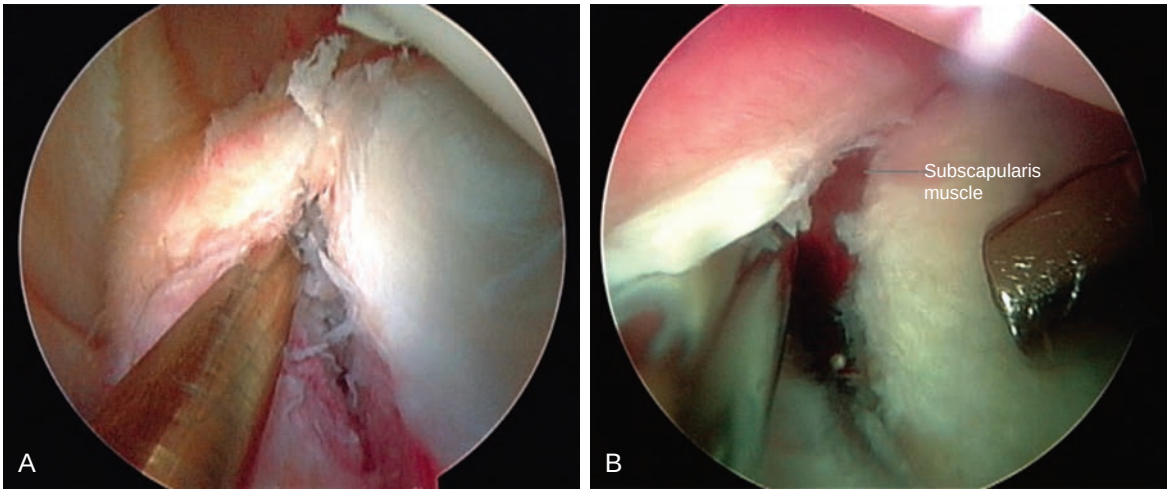

FIGURE 1-22. Preparation of anterior labrum. **A,** Arthroscopic view from anterosuperior portal in a right shoulder showing anterior-inferior capsulolabral avulsion. **B,** Right shoulder showing mobilization of anterior capsulolabral avulsion with subscapularis muscle visible deep to labrum. *From Provencher MT, Romeo AA, editors: Shoulder instability: a comprehensive approach, Philadelphia, 2011, Elsevier (Saunders), pp.136 and 137.) Fig. 11-20 and 11-22.*

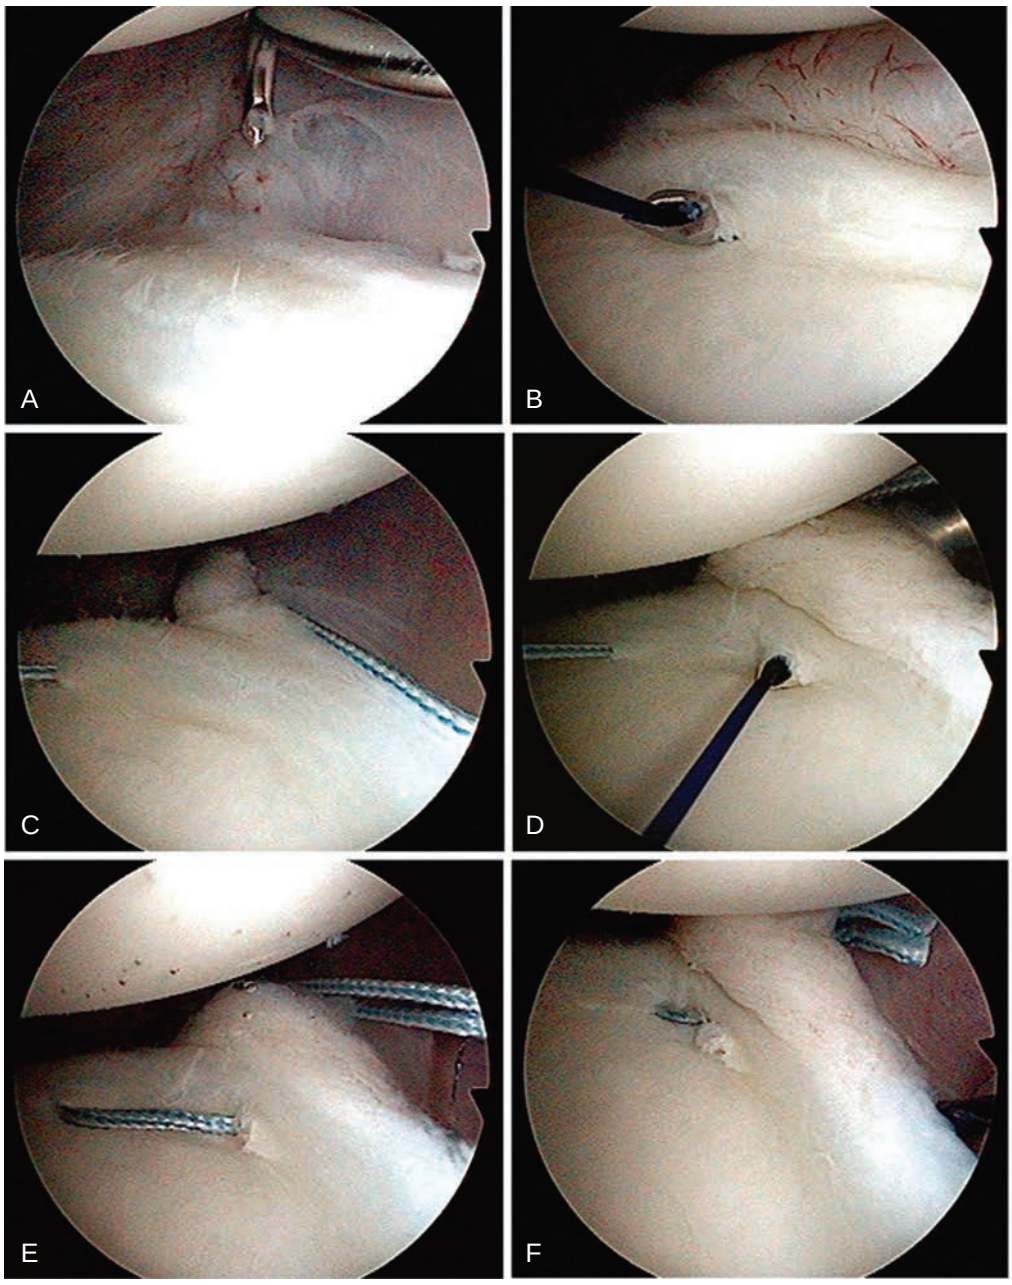

FIGURE 1-23. Mobilization of labrum and capsule. Sequence of performing plication posteroinferiorly as part of the initial phase of the repair in a right shoulder; viewing portal is anterosuperior. **A,** A suture shuttling device pierced capsule about 10 mm lateral to labrum at 6 o'clock position. **B,** The needle is then brought through the labrum and a monofilament suture (0 or No. 1) is passed and retrieved out of the anterior mid-glenoid portal. **C,** A nonabsorbable suture (No. 2) is tied to the monofilament suture outside the anterior mid-glenoid portal, and the monofilament suture acts to shuttle the nonabsorbable suture. **D,** Steps are repeated to shuttle the other limb of the nonabsorbable suture through labrum and capsule. **E,** Mattress plication suture in place posteroinferiorly. **F,** Mattress plication suture tied; note reduction of posteroinferior redundancy. *(From Provencher MT, Romeo AA, editors: Shoulder instability: a comprehensive approach, Philadelphia, 2011, Elsevier (Saunders), p. 138.) Fig. 11-24A-F.*

- Educate the patient in terms of restrictions, pain management, and ADLs
- Minimize shoulder pain
- Achieve staged ROM goals, DO NOT significantly exceed them
- Restore scapular control

Clinical Pearls

- When patients are very painful and guarded reviewing sleeping habits, sling use, and HEP are often helpful in managing pain allowing for gentle restoration of ROM.
- Gradual "weaning" of the sling in 4-hour increments/day provides for gradual introduction of stress to shoulder decreasing likelihood of development of pain and loss of ROM.

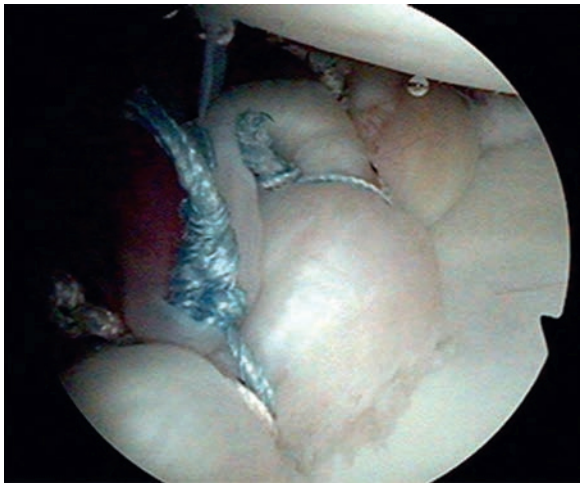

FIGURE 1-24. Securing labrum and capsule. Finished repair with combined plication and labral repair performed anteriorly with each anchor. In this case double-loaded anchors were used. *(From Provencher MT, Romeo AA, editors: Shoulder instability: a comprehensive approach, Philadelphia, 2011, Elsevier (Saunders), p. 142.) Fig. 11-31.*

Protection

- Postoperative immobilization using a sling (with or without a pillow) is recommended for patient comfort and limits stress on the anterior/inferior structures for the first 2 weeks.
  - The sling is to be used at all times, including during sleep
- We recommend gradual progression to no sling from weeks 4 to 6 based on pain, available ROM, muscle performance, and activity level.

Management of Pain and Swelling

- Interscalene pain pumps are often used during postoperative days 1 to 3 to control early postoperative pain.
- Oral pain medications.
- Electrical stimulation (Transcutaneous Electrical Neural Stimulation [TENS]) is recommended to manage pain and muscle guarding.
- Intermittent cryotherapy for pain and inflammation reduction.[8]
- Patient positioning: patients are encouraged to use pillows or bolsters to find a "position of comfort" which is usually slightly abducted (20° to 30°) in a neutral or slight internal rotation. This position is recommended to reduce stress on repaired structures as well as "unload" the surrounding muscles.

Techniques for Progressive Increase in Range of Motion (Table 1-2)

- The initial 2 weeks are essentially quiet with little or no ROM exercises required. The focus of this phase is resolving pain, decreasing swelling, and allowing the postsurgical shoulder to recover.
- Codman's pendulum exercises for gentle motion and joint distraction, supported FE (<90°), and ER to 0° at the side (<20° abd) can be performed 1 to 3 times/day to maintain joint mobility. We suggest all of these motions be performed with support to minimize rotator cuff activity due to incorrect technique.[9-11]
- Manual therapy techniques—gentle joint distraction and grade I-II joint oscillations may be helpful before performing supervised PROM by the rehabilitation professional to decrease muscle guarding and prepare the joint for ROM exercise. We recommend these treatments to be performed in the scapular plane in approximately 30° of elevation, and neutral rotation to limit the stress on the capsulolabral repair.[12]
- Soft tissue techniques—shortening, parallel techniques such as (Positional Release/Strain-Counter-strain) may be helpful to reduce protective guarding especially for the subscapularis, posterior rotator cuff, teres major, latissimus dorsi, and pectoralis major/minor.
- Stretching/flexibility techniques for the musculotendinous unit are not recommended at this time

TIMELINE 1-2: **Postoperative Rehabilitation After Arthroscopic Anterior Shoulder Stabilization**[1]

PHASE I (weeks 1 to 2)	PHASE II (weeks 3 to 6)	PHASE III (weeks 6 to 10)
• Sling • PT modalities • ROM-passive forward elevation to 90° • Active assistive Codman's exercises • TBS/TAS/TLS activities as recommended & tolerated	• Sling • PT Modalities • ROM wk 3—forward elevation to 90° • ROM wk 3—external rotation to 10–30° • TBS/TAS/TLS activities as recommended & tolerated • Scapular exercises • Wk 4—AAROM exercises • Wk 4—submaximal isometrics for GH joint muscles	• DC sling • PT Modalities as needed • ROM wk 6—forward elevation to 135° • ROM wk 6—external rotation to 35°–50° • ROM wk 9—forward elevation to 155° • ROM wk 9—external rotation to 35°–50° • Mobilizations as needed • TBS/TAS/TLS activities as recommended & tolerated • Scapular exercises—PREs • TAS—Biceps/Triceps PREs • Glenohumeral exercises—PREs • Rotator cuff exercises—PREs • PNF exercises • OKC Rhythmic stabilization exercises • CKC Exercises • CKC manual perturbation exercises

Table 1-2 Staged Range of Motion Goals for Arthroscopic Anterior Capsulolabral Repair

	PFE	PER at 20° abd	PER at 90° abd	AFE
POW 3	90°	10°–30°	Contraindicated	NA
POW 6	135°	35°–50°	45°	115°
POW 9	155°	50°–65°	75°	145°
POW 12	WNL	WNL	WNL	WNL
POW 12	WNL	WNL	WNL	WNL

AFE, Active forward elevation in the scapular plane; *NA*, not appropriate; *PER*, passive external rotation; *PFE*, passive forward elevation; *POW*, postoperative week; *WNL*, within normal limits.

because of the need to protect the repair. Cervicothoracic, elbow, hand, and wrist.

Other Therapeutic Exercises

- Although lower extremity and cardiovascular exercises may begin during the first 2 weeks while in the sling, in our experience patients do not tolerate these activities until after 14 days.

Activation of Primary Muscles Involved in Injury Area or Surgical Structures

- Submaximal isometric exercises may begin POW 1 as tolerated. We recommend performing these exercises in the "safe zone" of 20° to 30° abduction in the plane of the scapula in neutral rotation first with the elbow supported then gradually removing support.

Milestones for Progression to the Next Phase

Minimal to moderate pain (NPRS: 2 to 4/10) with minimal pain at rest (2/10)

- Staged ROM goals achieved but not significantly exceeded

Phase II: Weeks 2 to 6 Postoperatively

Goals

- Minimize shoulder pain (<2/10)
- Achieve staged ROM goals to normalize passive ROM and active ROM. **DO NOT** significantly exceed
- Normalize rotator cuff guarding and neuromuscular control
- Normalize scapular position and control

Clinical Pearls

- Avoid scapular protraction during the first 6 weeks as this position has been shown to have high levels of subscapularis activity and increases stress on the anterior capsulolabral structures.[13,14]
- Restoration of ER first then FE will allow for optimal ROM recovery.

TIMELINE 1-2: **Postoperative Rehabilitation after Arthroscopic Anterior Shoulder Stabilization** (Continued)

PHASE IV (weeks 10 to 14)	PHASE V (weeks 14 to 24)	PHASE V (weeks 24 to 52)
• PT Modalities as needed • PROM-full • Mobilizations as needed • ROM wk 12—forward elevation progress to full ROM • ROM wk 12—external rotation progress to full ROM at 90°/90° • Wk 12- begin terminal shoulder girdle stretches as needed • TBS/TAS/TLS activities as recommended & tolerated • Scapular exercises—PREs • Glenohumeral exercises—PREs • Rotator cuff exercises—PREs • PNF exercises • OKC Rhythmic stabilization exercises • CKC Exercises • CKC manual perturbation exercises	• PROM-maintain full motion • Mobilizations as needed • TBS/TAS/TLS activities as recommended & tolerated • Scapular exercises—PREs • TAS—Biceps/Triceps PREs • Glenohumeral exercises—PREs • Rotator cuff exercises—PREs • PNF exercises • OKC Rhythmic stabilization exercises • CKC Exercises • CKC manual perturbation exercises • Plyometrics—2 arm progressing to 1 arm • Overhead strengthening exercises • Sport specific exercises begin • Overhead throwing athletes can begin tossing at 30ft per the • interval throwing program	• PROM-maintain full motion • Mobilizations as needed • TBS/TAS/TLS activities as recommended & tolerated • Scapular exercises—PREs • Biceps/Triceps PREs • Glenohumeral exercises—PREs • Rotator cuff exercises—PREs • IR/ER exercises at 90° • Thrower's 10 progress intensity • PNF exercises • OKC Rhythmic stabilization exercises • Exercises • CKC manual perturbation exercises • Plyometrics—2 arm chest passes progressing to 90°/90° • Single arm plyometrics • Overhead strengthening exercises • Sport-specific exercises progressed • Overhead throwing athletes progress through an interval throwing program

Patient-Oriented Outcomes

- Best clinical practice uses patient-rated measures of function and disability to comprehensively assess patient response to treatment.
- There are many available scales for measuring functional loss and disability in patients with instability and one measure is likely not superior to another.[15,16]
- We recommend two measures, a general measure of shoulder function that includes pain, function, and patient satisfaction similar to the ASES, the Pennsylvania Shoulder Score (PSS) and a measure specifically for instability, such as the Western Ontario Instability Index (WOSI).[17-21]

Protection

- Treatment for pain/analgesia oral pain medications
- Electrical stimulation (TENS) is recommended to manage pain and muscle guarding. TENS units at home are often helpful to control pain especially early following surgery.
- Intermittent cryotherapy for pain and inflammation reduction.[8] We recommend 20 minutes on/hour for the first week following surgery.

Techniques for Progressive Increase in Range of Motion

Manual Therapy Techniques

- Gentle joint distraction and grade I-III joint oscillations may be helpful before performing supervised PROM by the rehabilitation professional to decrease muscle guarding, restore capsular balance, and prepare the joint for ROM exercise. Anterior-inferior or inferior glides should not be performed. We recommend these positions to be performed in the scapular plane in approximately 30° of elevation, and neutral rotation to limit the stress on the capsulolabral repair.[12]

Soft Tissue Techniques

- Shortening, parallel techniques such as (positional release/strain-counterstrain) may be helpful to reduce protective guarding especially for the subscapularis, posterior rotator cuff, teres major, latissimus dorsi, and pectoralis major/minor.
- Passive ROM and active assist ROM exercises may be initiated after POW 2 for ER and FE (see Table 1-2)
- Stretching/flexibility techniques for the musculotendinous unit should not be performed as these are end ROM exercises.

Other Therapeutic Exercises

- Gradual introduction of TBS, TLS, core stability, and uninvolved TAS beginning POW 2.
- Additionally, cardiovascular conditioning can be initiated with attention to the safety of the activity.
- All exercises should be performed with the patient in the sling until POW 5 to 6 to decrease the use of index shoulder during these exercises.

Activation of Primary Muscles Involved in Injury Area or Surgical Structures

- Scapular retraction and PNF patterns may begin POW 3 based on patient tolerance (Figure 1-25). We recommend avoiding scapular protraction as this position has been shown to have high levels of subscapularis activity and increase stress on the anterior capsulolabral structures.[13,14] Although scapular elevation and retraction are safe we suggested limited resistance due to the load placed through the glenohumeral joint for most exercises.
- Active ROM and rotator cuff strengthening are purposefully de-emphasized until POW 6 because of the potentially detrimental effect to the healing tissues.[22,23] Although these exercises within the staged ROM goals would not likely result in excessive loading, in our opinion aggressive strengthening is not consistent with the achieving optimal healing of the repaired tissues. Therefore, we recommend beginning with sub-maximal isometric strengthening of the shoulder and elbow with the arm adducted to the side in neutral rotation. As the patient demonstrates improved rotator cuff endurance and absence of pain or other symptoms we recommend progressing to dynamic isometrics then AROM exercises within the ROM restrictions.

Sensorimotor Exercises

- Angular reposition, rhythmic stabilization, and repeated contractions within staged ROM limits may be implemented beginning POW 2.

Open and Closed Kinetic Chain Exercises

- CKC exercises may be implemented below 90° of elevation beginning POW 2. These exercises should begin in a modified weight-bearing position and progressed to full weight-bearing by POW 6.

Techniques to Increase Muscle Strength, Power, and Endurance

- See above w/AROM

Milestones for Progression to the Next Phase

- Appropriate healing of the surgical repair by adhering to the precautions and immobilization guidelines.
- Staged ROM goals achieved but not significantly exceeded
- Minimal to no pain (NPRS: 0 to 2/10) with ROM
- PSS greater than 60% and WOSI less than 50%. These are estimates based on reported normative data and our experience. This combined with other objective criteria provides clear communication between the patient and medical professionals on how the patient perceives their shoulder function and potential insight as to how care can be improved upon.

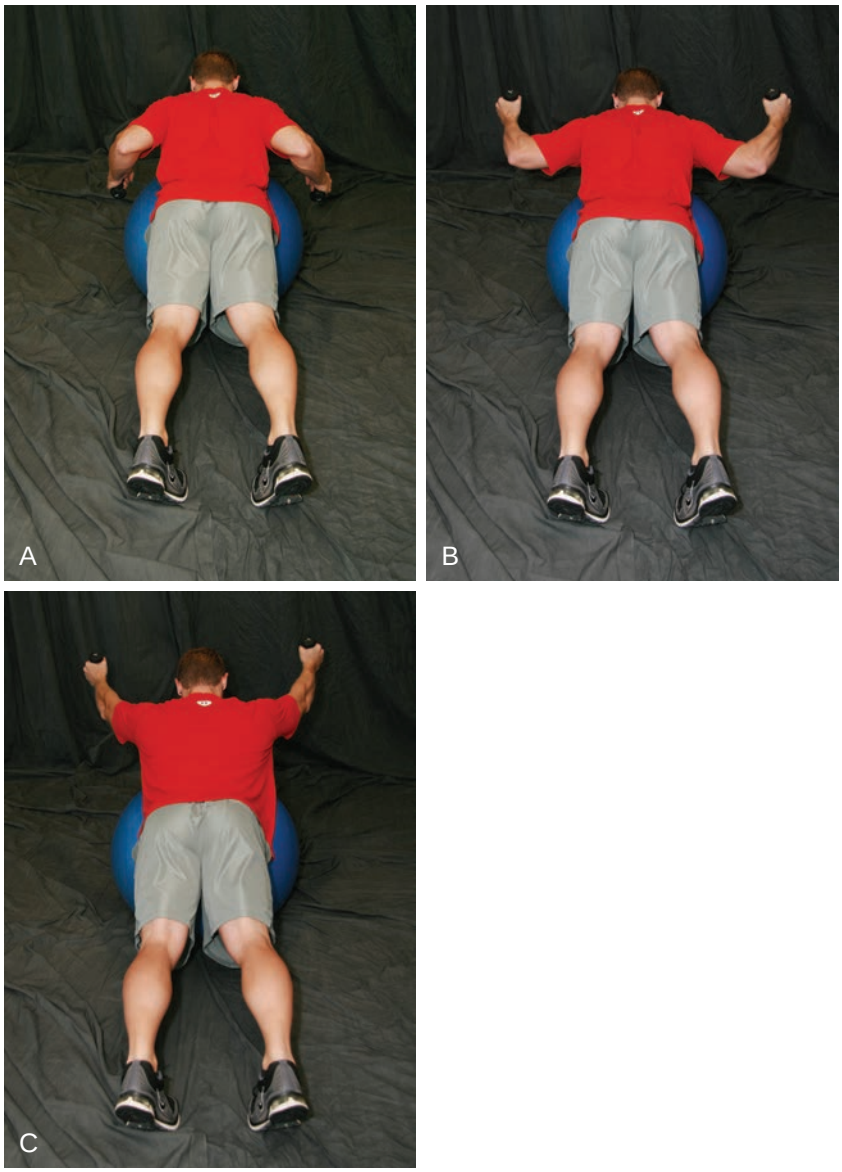

FIGURE 1-25. A–C, Ws to Ys: Patient performs scapular retraction, then glenohumeral external rotation, then elevates to the "Y" position while maintaining scapular stability.

Phase III: Weeks 7 to 12 Postoperatively

Goals

- Achieve staged ROM goals to normalize passive ROM and active ROM. DO NOT significantly exceed especially for ER at 90° of abduction.
- Minimize shoulder pain (0/10 at rest and <2/10 following exercises or activity).
- Begin to increase strength and endurance.
- Increase functional activities as evidenced by PSS > 80% and WOSI < 30%.

Clinical Pearls

- Nearly full active forward elevation should be achieved before progressing to elevation in other planes or initiating resistive elevation exercises.
- Ensuring posterior rotator cuff performance and scapular stability below 90° of abduction before progressing to higher elevation and difficulty of exercises.
- Anterior-inferior glides are often helpful to gain full ER and FE. Addition of posterior shoulder flexibility exercises in conjunction with these mobs before and after exercise is helpful in the stiff shoulder.
- In our opinion, rapid gain of ER towards 90° of abduction should be avoided (before 8 weeks). If the athlete must return to overhead, throwing sports and the involved shoulder is their throwing arm, then more aggressive stretching of ER towards 90° of abduction may begin at 8 weeks.
- Functional exercises may begin toward the end of this phase. Simple patient instruction of *"keeping their hands where they can see them"* will allow the patient to resume desired activities without risking reinjury.

Protection

- No sling use.
- Avoid positions of max ER towards 90° of abduction, especially with a posteriorly directed load. (e.g., NO push-ups, bench press, pectoral flys).

Management of Pain and Swelling

- Pain should not be a limiting factor at this point. If pain is limiting progression of activities rest and reevaluation of all aspects of the shoulder should be performed in consultation with the referring surgeon.
- Cryotherapy as needed.
- NSAIDS as needed.

Patient Education

- Counsel about using the upper extremity for appropriate ADLs in the pain-free and nonprovocative ROM (starting with waist level activities and progressing to shoulder level and finally to overhead activities over time).
- Continue education regarding avoidance of heavy lifting or quick sudden motions.
- Education to avoid positions which place stress on the anterior inferior capsule during ADLs.

Techniques for Progressive Increase in Range of Motion

- Forward elevation should be progressed from active-assistive exercises (e.g., rope and pulley, wall walks), to active, to resistive upright exercises, then finally to prone exercises as per reported EMG activity of the shoulder.[10,11] Although protection of the rotator cuff is not needed we feel the EMG activity reflects overall stress to the shoulder and good guide to exercise progression.

Manual Therapy Techniques

- Grade I-III joint mobilizations (up to tissue resistance) are most often all that is required especially for anterior/inferior directions. If ROM is greater than 50% less than staged ROM goals as compared with the uninvolved extremity then gentle joint mobilizations may be performed. However, they should be done only into the limited directions and only until staged ROM goals are achieved. It is crucial in the patients that appear "tight" to discern if there is capsuloligamentous tightness/stiffness, musculotendinous, pain limited or some combination.

Soft Tissue Techniques

- Deeper soft tissue techniques may be initiated during this phase. More aggressive techniques such as Active Release® or other instrumented soft tissue mobilizations to normalize muscle tone and extensibility. Particular attention should be paid to the subscapularis, latissimus, pectorals, teres major, and posterior rotator cuff. In our experience these techniques often allow for gradual return consistent with the staged goals without aggressive joint mobilizations or excessive end range stretching.
- Stretching/flexibility techniques for the musculotendinous unit.
- Total upper quarter mobility should be evaluated with restoration of cervical, thoracic, and scapulothoracic mobility to facilitate optimal return upper extremity ROM.
- End range flexibility exercises may begin in particular for posterior shoulder (horizontal adduction and sleeper stretch beginning at 60° to 70° of elevation on side (Figure 1-14*A*,*B*).[24,25] Pectoralis minor flexibility can begin with attention not to increase stress on anterior shoulder as these have been shown to be effective at increasing pectoralis minor length.[26,27] Gradual introduction of latissimus, posterior shoulder, and FE stretches as needed.

Other Therapeutic Exercises

- Address core stability deficits PRN beginning in the sagittal plane and progressing to frontal and transverse plane exercises.
- Total leg strengthening exercises may be progressed as tolerated but high loads should be avoided on the shoulder in activities such as power clean, dead lifts, and back squats should be avoided. We recommend front squats during this phase to allow for safe positioning of the shoulder with large loads.
- We also recommend using this phase of rehabilitation to address kinetic chain deficits using basic functional screens such as the overhead squat, single leg squat, or more in-depth approaches such as the Functional Movement Screen. These approaches will provide areas for improvement for the athlete allowing for total body movement evaluation of the entire kinematic chain.

Activation of Primary Muscles Involved in Injury Area or Surgical Structures

- Elbow flexion/extension strengthening with elbow by the side can begin in this phase
- Exercises and functional activities should be pain free and performed without substitutions or aberrant movement patterns (shrugging, thoracic extension)
- Balanced rotator cuff strengthening to maintain the humeral head centered within the glenoid fossa during progressively more challenging activities
- Should be initially performed in a position of comfort with low stress to the glenohumeral joint such as less than 45° elevation in the plane of the scapula (e.g., elastic band or dumbbell external rotation, internal rotation, forward elevation).
- Exercises should be progressive in terms of shoulder elevation (e.g., start w/exercises performed at waist level progressing to shoulder level and finally overhead activities).
- Depending upon the goals of the exercise (control vs. strengthening), rehabilitation activities may also be progressive in terms of speed once the patient demonstrates proficiency at slower speeds.

Sensorimotor Exercises

- Activities to improve neuromuscular control of the rotator cuff and shoulder girdle such as use of unstable surfaces, body blade, and manual resistance exercises in conjunction with auditory, visual, or tactile cues or biofeedback.
- Proprioceptive Neuromuscular Facilitation (PNF) patterns are particularly effective for restoring muscle balance and proper coordination patterns. We prefer this manual feedback especially early during this phase as the clinician controls the load to the extremity and is able to best match the patient's level of performance.

Open and Closed Kinetic Chain Exercises

- Strengthen scapular retractors and upward rotators
- Weight-bearing exercises with a fixed distal segment. Examples: quadruped position while working to maintain proper position of the scapula, quadruped with scapula protraction, progressing from quadruped to tripod position, *no push-ups*.[28]

Techniques to Increase Muscle Strength, Power, and Endurance

- Exercises should be progressive in terms of muscle demand. It is suggested to use activities that have muscle activity levels documented with EMG.[9,28-44] In general, increasing elevation increases deltoid and supraspinatus activity while increasing ER at lower levels of elevation increases posterior rotator cuff EMG.[9,28-44] The subscapularis is most active during forward punches (combined scapular protraction and glenohumeral IR) and should be performed at lower and higher levels of elevation (Figure 1-26).[40]
- Exercises should be progressive in terms of adding stress to the anterior capsule, gradually working towards a position of 90° of ER and 90° of abduction by 12 weeks.
- Rehabilitation should include isolated and complex movement patterns progressing form isolated to complex movement patterns.
- The rotator cuff and scapula stabilizer strengthening program should emphasize high repetitions (typically 30 to 50 reps) and relatively low resistance (typically 1 to 2 kg) during this phase.
- General shoulder strengthening exercises (front/side raises, shoulder presses) may be initiated as full AROM is achieved and rotator cuff and scapular stabilizer strength is adequate for normal movement patterns. This is usually a late Phase III exercise and should begin with 3 to 5 kg and similar repetitions (15 to 20 for 3 to 4 sets).

Neuromuscular Dynamic Stability Exercises

- Development of dynamic stability is crucial during this phase of rehabilitation following stabilization

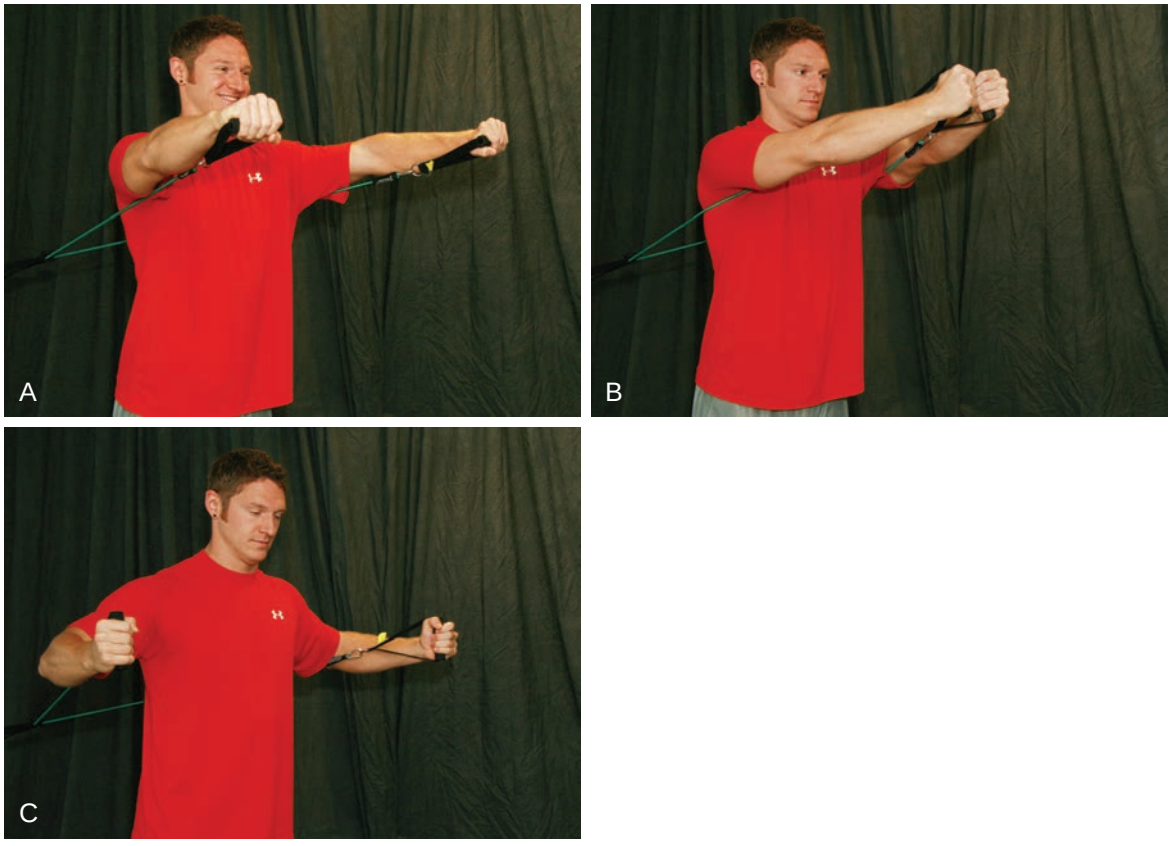

FIGURE 1-26. A–C, Forward punches with internal rotation: The patient steps and punches forward emphasizing scapular protraction without scapular elevation at varying levels of forward elevation then internally rotating the humerus at the end of the motion.

procedure. Rhythmic stabilization starting at 45° of abduction in the scapular pane in neutral rotation and gradually increasing in elevation and ER as performance increases. Four to five bouts for 30 seconds is recommended before progressing difficulty of exercises.
- CKC pushup plus progression are important exercises as it promotes rotator cuff and scapular stabilizer co-contraction needed for dynamic stability.[38,45]

Plyometrics

- No heavy lifting or plyometrics should be performed during this stage.

Functional Exercises

- Functional exercises may be initiated toward the end of Phase III (weeks 9 to 12) however we strongly recommend avoiding undue stress on the anterior shoulder.
- Multiplanar exercises should be progressed in a similar fashion as previously described emphasizing rotational control across each plane of elevation.

Milestones for Progression to the Next Phase

- Staged active ROM goals achieved with minimal to no pain (NPRS 0 to 2/10) and without substitution patterns
- Appropriate scapular posture at rest and dynamic scapular control during ROM and strengthening exercises
- Strengthening activities completed with minimal to no pain (NPRS 0 to 2/10).
- <20% deficit using isokinetic or hand held dynamometer for ER, IR, abduction, and elevation.
- Able to complete 20 hand-taps during modified Davies CKC UE test.[46] We recommend modifying the Davies test by using biacromial width as in our experience a standard 36″ is too wide for many patients.
- Able to complete 30 reps of ER at <20° of abduction in 30 seconds (1 rep/sec).

Phase IV: Weeks 13 to 24 Postoperatively

The length of Phase IV will vary dependent upon sport participation. For noncontact sports with less stress on the anterior shoulder and therefore reinjury risk return to sport progression may begin at 16 weeks. For contact sports with high dislocation rates (football, wrestling) or high stress on the anterior shoulder (throwing sports) return to sport progression will begin between POW 20 to 24. Phase IV will overlap with Phase V return to sport progression depending on injury, sport, and timing of season and return to play goals.

Goals

- No complaints of pain at rest and minimal to no pain (NPRS 0 to 2/10) following activities.
- No or minimal sensation of instability with activities.
- Normalize strength, endurance, neuromuscular control, and power as evidenced by:
  - <10% deficit using isokinetic or hand held dynameter for ER, IR, abduction, and elevation.
  - 30 repetitions in 30 seconds with blue Thera-Band at 0° and 90° abduction.
  - Able to complete 90 hand-taps during modified Davies CKC UE test in 60 seconds.[46]
  - Gradual demonstration of confidence and performance in sports specific positions.
  - Functional improvement in ADLs and sport as evidenced by PSS > 90% and WOSI < 20%.

Clinical Pearls

- Athletes should perform a structured, reproducible dynamic warm up including rotator cuff exercises before pre sport and sport activities.
- Progression of presport training activities should be monitored reevaluating the athlete's pain & strength (no >10% advancement as compared to presport).
- We recommend a balance of posterior and anterior rotator cuff strength (ER:IR ratio) of 66% before beginning return to sport training.[47,48]

Management of Pain and Swelling

- Pain should not be a limiting factor at this point. If pain is limiting progression of activities rest and reevaluation of all aspects of the shoulder should be performed in consultation with the referring surgeon.
- Cryotherapy as needed.
- NSAIDS as needed.

Patient Education

- Counsel about using the upper extremity for appropriate ADLs in the pain-free ROM (starting with waist level activities and progressing to shoulder level and finally to overhead activities over time).
- Continue education regarding avoidance of heavy lifting or quick sudden motions.
- Education to avoid positions which place stress on the anterior inferior capsule during ADLs.

Other Therapeutic Exercises

- Progressing from Phase III there are no limitations to TBS/TLS or TAS. However, unless end range of motion is required for the athlete's sport then we strongly recommend avoiding training that stresses the shoulder the ABER position as the risk of developing recurrent instability outweighs the benefits of training.

Open and Closed Kinetic Chain Exercises

- Progression of OKC and CKC consistent with principles previously outlined.

Techniques to Increase Muscle Strength, Power, and Endurance

- During this phase the focus of exercises should progress from endurance to strength and power. This will require increasing loads, speed of movements, and type of contraction.
- Loads—loads now may be increased appropriate to sport and body weight beginning with 3 to 5 sets of 10 and progressing to 3 to 5 sets of 4 to 6 reps over the next 8 to 10 weeks consistent with a traditional strength training program.
- Speed of movement—concentric movements are challenged first beginning with IR, then ER, then punches and complex movements. Punches are last as this as scapular protraction places increased stress on the capsulolabral complex and is a common mode of dislocation.
- Type of contraction—eccentric loads can now be initiated beginning with ER (towards IR) and abduction (towards adduction) first then progressing to IR and abduction in preparation for plyometric exercises.
- We recommend gradually progressing to positions of high stress during this phase as needed. For example, in order to progress back to bench press begin with the athlete performing dumbbell bench press on the floor, then barbell on the floor, then dumbbell.

Neuromuscular Dynamic Stability Exercises

Integration of higher loads and greater perturbations are important in particular for athletes returning to sport.

Examples include:

- For football players clap pushups on foam or DynaDisc.
- For throwers repeated ER yo-yos (with 1-kg weight on band) (Figure 1-27).

Plyometrics

- Because of the explosive nature of this type of exercise, emphasis of plyometric exercises should be on quality not quantity. Additionally, we recommend 2 to 3 weeks of tolerance to high speed multiplanar activities which progressively mimic functional demands before initiating plyometric exercises.
- Perform two to three times/week and utilize moderate repetitions (e.g., 3 to 5 sets of 15 to 20 repetitions)
- Begin with unweighted balls and progress to lightly weighted balls (Plyoballs)

Functional Exercises

- Continue per Phase III.

Sport-Specific Exercises

- Med ball throws against a wall, for distance for OKC sports.
- UE fitter/stepper in prone position for CKC sports.
- Dribbling on wall or rebounding with one hand.

Milestones for Progression to the Next Phase

- Clearance from physician.
- PSS > 90% and WOSI < 10%.
- No complaints of pain at rest and minimal to no pain (NPRS 0 to 2/10) following activities.
- No or minimal sensation of instability with activities.
- Restoration of sufficient ROM to perform desired activities.
- Maintenance of strength and endurance as evidence by:
  - < 10% deficit using isokinetic or hand held dynameter for ER, IR, abduction, and elevation.
  - 30 repetitions in 30 seconds with blue Thera-Band at 0° and 90° abduction.
  - Able to complete 90 hand-taps during modified Davies CKC UE test in 60 seconds.[46]

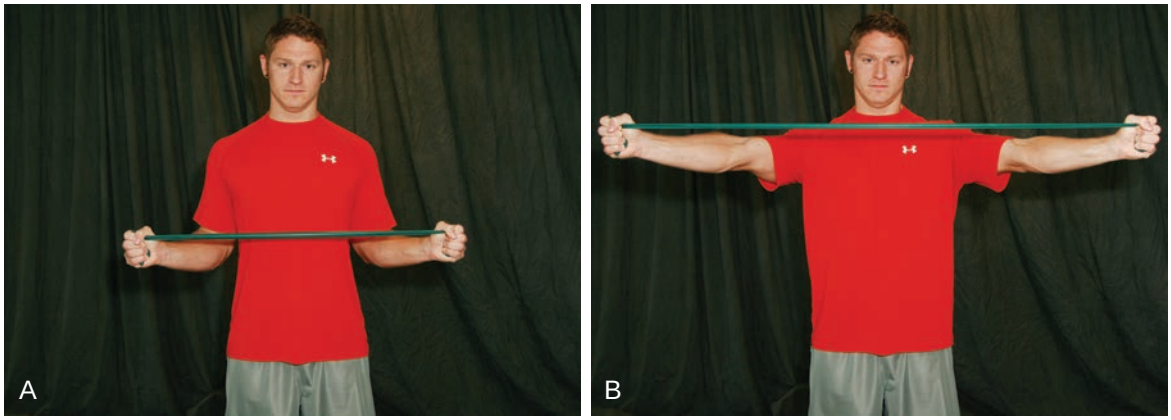

FIGURE 1-27. A,B, External rotation to scaption. Patient holds a 1-kg weight tied into a Thera-Band at 0° of ER, then externally rotates and elevates to 90°.

Phase V: >Weeks 16 to 24 Postoperatively—Return to Sport Progression

Similar to Phase IV the length will vary dependent upon sport participation. The timing of this phase will be greatly impacted by risk of reinjury and timing relative to competition requirements. As risk of reinjury increases we recommend more conservative approach in return to competition. As maturity of the athlete and level of competition increase athlete education becomes imperative allowing the sports medicine team (athlete, PT, ATC, and MD) to reach the best decision for that athlete.

Goals

- No complaints of pain at rest and minimal to no pain (NPRS 0 to 2/10) following activities.
- No or minimal sensation of instability with activities.
- Maintenance of sufficient ROM to perform desired activities.
- Maintenance of shoulder strength and endurance as previously described with minimal to no pain (NPRS 0 to 2/10) or difficulty.

Clinical Pearls

- 1 to 2 times/week of soft tissue and joint mobilizations will prevent loss in ROM during the return to sport progression. Careful attention to maintenance of ROM and flexibility will allow for long-term successful return to sport.
- Begin sessions with a complete dynamic warm-up including rotator cuff before complex, functional, and plyometric exercises.
- Continued strengthening of the rotator cuff and scapular stabilization exercises to fatigue should be performed 1 to 2 times/week.
- Instruct patients to: *"Perform all exercises so that you can see the backs of your hands"* to protect their surgical repair.

Protection

- Use of either a Sully or Donjoy (formerly SaWa) brace is recommended during initial return to sport, in particular for contact athletes. We prefer the SaWa brace (lace up/strap brace) for contact athletes as it is the only brace demonstrated to limit ER and abduction ROM.[49] We recommend the Sully (neoprene) for all others as it has been shown to increase proprioception and kinesthetic awareness which are altered in shoulders with anterior instability.[50,51]

Techniques for Progressive Increase in Range of Motion

Manual Therapy Techniques

- As previously described PRN.

Soft Tissue Techniques

- As previously described PRN.

Stretching/Flexibility Techniques for the Musculo-Tendinous Unit

- Regular assessment of ROM/flexibility during the return to sport progression and after return to sport is important for long term shoulder function.

Other Therapeutic Exercises

- As previously described.

Open and Closed Kinetic Chain Exercises

- As previously described.

Techniques to Increase Muscle Strength, Power, and Endurance

- Care should be taken to ensure that the athlete maintains shoulder-strengthening and dynamic strengthening exercises. We recommend 3 days for 20 to 30 minutes of focused rotator cuff and scapular stabilizing exercises in addition to TBS and TAS that may be apart from normal athletic activities.

Plyometrics

- PRN as previously described.

Sport-Specific Exercises

- PRN as previously described.

Criteria for Return to Sport

General

- PSS > 95% and WOSI < 10%.
- No complaints of pain at rest and minimal to no pain (NPRS 0 to 2/10) following activities.
- No or minimal sensation of instability with activities.
- Maintenance of sufficient ROM to perform desired activities.
- A balance of posterior and anterior rotator cuff strength (ER:IR ratio) of 66% before beginning return to sport training.[47,48]
- Maintenance of strength and endurance as evidence by <10% change in strength measures post activity using isokinetic or hand held dynameter for ER, IR, abduction, and elevation.
- 30 repetitions in 30 seconds with blue Thera-Band at 0° and 90° abduction.
- Able to complete 90 hand-taps during modified Davies CKC UE test in 60 seconds.[46]

Sport-Specific

Overhead athlete—The return to sport of an overhead athlete requires consideration for all position specific

factors before return to full participation. Before and during of progression of throwing, batting, and hitting activities the following criteria should be obtained and maintained throughout the interval throwing program:

- PSS > 95% and WOSI < 10%.
- No sensation of instability with activities.
- No complaints of pain at rest or during activity. Minimal discomfort postactivity with minimal discomfort (NPRS 0 to 2/10) following activities.
- Before throwing/hitting, the throwing arm rotational ROM must measure within 15° of the non-throwing arm. Total rotation must be >150°. External rotation must measure ≥100°. Additionally, horizontal adduction (HA) ROM must be within 15° of the non-throwing arm.
- Postthrowing/hitting the rotational and HA ROM should be within 10% of the prethrowing/hitting ROM within 24 to 48 hours and return to preactivity baseline ROM before subsequent participation.
- The athlete should recover from soreness for 24 to 48 hours before returning to full participation.
- Before competition or practice, throwing arm ER strength should be similar to the nonthrowing arm ER strength[52] and the athlete should demonstrate a balance of posterior and anterior throwing arm rotator cuff strength (ER:IR ratio) of 66%.[47,48]
- The athlete must demonstrate sufficient core and scapula control for participation. This is measured by completion 90 hand taps during the modified Davies CKC UE test in 60 seconds before throwing/hitting.[46]
- Post throwing/hitting the rotational strength and stability (hand taps during modified Davies CKC UE test in 60 seconds) should be within 10% of the prethrowing/hitting levels within 24 to 48 hours and return to preactivity baseline before subsequent participation.
- Athletes should be monitored for performance and fatigue levels during their progression to full competition as athletes pitching while fatigued have 36 times greater risk of injury.[53]

After Return to Sport

Continuing Fitness or Rehabilitation Exercises

- Maintain ROM with regular flexibility routine in particular for latissimus, pectoralis and posterior shoulder flexibility.
- Maintain rotator cuff and scapular stabilization force couples with 2 to 3 times/week of core exercises integrated into regular fitness/training routine.

Exercises and Other Techniques for Prevention of Recurrent Injury

- We recommend postoperative bracing for at least the first season returning to competition.
- Unless the sport requires motion in extremes of abduction and ER limit training in these ranges.
  - For all training patients are instructed to: "*Perform all exercises so that you can see the backs of your hands*"

Evidence

Boileau P, Villalba M: Risk factors for recurrence of shoulder instability after arthroscopic Bankart repair. *J Bone Joint Surg* 88A(8):1755–1763, 2006.

This is a retrospective study conducted to look at outcomes and determine risk factors related to the recurrence of shoulder instability following arthroscopic Bankart repair. Ninety-one patients who underwent arthroscopic stabilization were included in the study and followed up at a mean of 36 weeks. Absorbable suture anchors were used for capsulolabral reattaching and capsule retensioning. Fourteen patients experienced recurrent instability, six experienced dislocation, and eight had an episode of subluxation. The study results suggest that bone loss or defect on the glenoid or humeral side along with anterior or inferior hyperlaxity was significantly related to postoperative recurrent instability. The presence of either condition led to a 75% recurrence rate in the study. In addition, less than three sutures used during surgery led to an increased risk of recurrence. The study suggests that arthroscopic treatment for shoulder instability should be used only after patient selection and rigorous technique.

Ellenbecker TS, Mattalino AJ: Glenohumeral joint range of motion and rotator cuff strength following arthroscopic anterior stabilization with thermal capsulorraphy. *J Orthop Sports Phys Ther* 29:160–167, 1999.

This descriptive study of 20 patients diagnosed with anterior shoulder instability described their postoperative rehabilitation program following arthroscopic shoulder stabilization. The involved patients experienced return of ROM and scapular/ rotator cuff strength at 12 weeks when compared with the uninjured extremity.

Hiemstra LA, Sasyniuk TM, Mohtadi NG, et al: Shoulder strength after open versus arthroscopic stabilization. *Am J Sports Med* 36:861–867, 2008.

Arthroscopic or open shoulder stabilization surgeries are currently the standard of treatment for recurrent anterior shoulder dislocations. The difference between the surgical techniques is the violation of the subscapularis tendon during the open stabilization. This study looks at the strength differences in internal and external rotation of the two surgical groups. The study included 48 patients with an average age of 30.6 who were randomized into either the open or arthroscopic group. Each group underwent standardized rehabilitation and was followed up with isokinetic strength testing (concentric and eccentric peaks at 60 and 180 degrees) between 12 and 36 weeks postop. The results showed no significant difference between groups in the area of age, gender, and operative limb. When comparing the arthroscopic versus open surgical shoulder stabilization, no significant isokinetic strength deficits were observed. Both groups showed strength deficits when compared to the non-involved limb.

Kim SH, Ha KI, Kim HS, et al: Electromyographic activity of the biceps brachii muscle in shoulders with anterior instability. *Arthroscopy* 17:864–868, 2001.

The study evaluated the activity of the biceps muscle in 38 patients with traumatic anterior shoulder instability. The abduction and external rotation positions were evaluated. Electromyographic (EMG) data was used to determine activity levels of the biceps muscles. The unstable side was compared with the opposite non-involved shoulder of each patient. EMG data was obtained for the following positions:

0°, 45°, 90°, and 120°. The root mean squared voltage of the bicep muscle was significantly greater in the unstable shoulder in all positions. The maximum voltage was greatest in the unstable arm at 90° and 120° of external rotation. No difference was seen in the RMS voltage of the supraspinatus muscle. In conclusion, the results show that in an unstable shoulder, in the abducted and externally rotated positions, the bicep muscles play a compensatory role.

Matias R, Pascoal AG: The unstable shoulder in arm elevation: a three-dimensional and electromyographic study in subjects with glenohumeral instability. *Clin Biomech (Bristol, Avon)* 21(Suppl 1):S52–S58, 2006.

An altered scapula-humeral rhythm is said to be related to some shoulder dysfunction, but little is known about the shoulder muscle activation patterns in patients with glenohumeral instability. The study included 6 subjects with glenohumeral instability who were all performed arm elevations in 8 positions. A 6 DOF electromagnetic device was used to record the kinematics. The scapulohumeral rhythms were compared among subjects. The most significant differences were seen in the scapular protraction and spinal tilt and no differences were seen in the scapular lateral rotation. The kinematic changes during certain angles of arm elevation may be due to changes in alignment of the humeral head and glenoid and as results contributing to shoulder instability. The study emphasizes the importance of assessing scapulohumeral rhythms in the rehabilitations process of individuals with shoulder instability.

Myers JB, Ju YY, Hwang JH, et al: Reflexive muscle activation alterations in shoulders with anterior glenohumeral instability. *Am J Sports Med* 32:1013–1021, 2004.

The study looks at the relationship between anterior shoulder instability and muscle activation alterations. Eleven patients with anterior shoulder instability where matched with 11 control subjects. Each subjected underwent external humeral rotation apprehension perturbation while muscle activation characteristics were recorded using electromyographic analysis. Patients with instability showed decreased pectoralis major and biceps brachii mean activation along with increases peak activation in the subscapularis, supraspinatus, and infraspinatus when compared with the control subjects. A much slower bicep brachii mean reflex latency as well as suppressed supraspinatus-subscapularis coactivation was seen in the patients with instability. These results may explain recurring episodes of instability in patients with glenohumeral instability.

McMahon PJ, Jobe FW, Pink MM, et al: Comparative electromyographic analysis of shoulder muscles during planar motions: anterior glenohumeral instability versus normal. *J Shoulder Elbow Surg* 5:118–123, 1996.

The electromyographic activity of the rotator cuff and scapular muscles were compared between normal subjects and those with anterior instability. 23 subjects had instability, 15 were normal. Fine wire electrodes were placed in the scapular muscles. Abduction, scaption, and forward flexion were performed over the range of motion. In patients with instability, the supraspinatus showed significantly less electromyographic activity from 30° to 60° during abduction and scaption compared with normal shoulders. During all three motions, shoulder with instability showed significantly less activity in the serratus muscle compared with the normal shoulders at 30° to 120° of abduction and 0° to 120° of scaption and forward flexion. These results show that the supraspinatus and serratus muscles may be under challenged in daily activities and add to the complexity of shoulder instability.

Nelson BJ, Aciero RA: Arthroscopic management of glenohumeral instability. *Am J Sports Med* 28:602–614, 2000.

Over the last 20 years there have been new developments in arthroscopic shoulder techniques, especially in the area of shoulder instability. The article discusses the various arthroscopic surgical techniques used to treat the unstable glenohumeral joint. The article looks at arthroscopic stabilization techniques for primary anterior glenohumeral instability, recurrent anterior instability, and multidirectional instability. The wide ranges of results are also discussed.

Uhorchak JM, Arciero RA, Huggard D, et al: Recurrent shoulder instability after open reconstruction in collision and contact sports. *Am J Sports Med* 28:794–799, 2000.

This study evaluated the recurrence of instability in a group of 66 young athletes who had previously undergone open shoulder stabilization using a modified Bankart repair and anterior capsulorrhaphy. In order for the incidence to be considered a recurrent dislocation, it had to be a complete dislocation with manual reduction. "Slipping or popping" was considered a recurrent subluxation. The results showed that two patients experienced recurrent shoulder instability, eight patients had fewer than three episodes of subluxation, and five patients had multiple episodes of recurrent subluxation. The studied concluded that a 3% to 5% recurrent dislocation rate is reasonable to expect after undergoing open Bankart repair/capsulorrhaphy for young athletes involved in collision sports. This same patient group experiences a 20% frequency in recurrent postsurgical subluxations. This incidence is higher than most literature and is attributed the athletes being involved in collision sports. Factors such as age, activity level and type of instability may influence postoperative recurrence rates.

Warner JJ, Micheli LJ, Arslanian LE, et al: Patterns of flexibility, laxity, and strength in normal shoulders and shoulders with instability and impingement. *Am J Sports Med* 18:366–375, 1990.

This is a prospective study looking at factors of flexibility, laxity, strength and their causality to the conditions of shoulder impingement and instability. Fifty-three subjects were included in the study: 15 asymptomatic volunteers, 28 patients with glenohumeral instability, and 10 patients with impingement. Range of motion was performed using a goniometer and Biodex testing was used to measure strength. Normal subjects showed significant differences in IR/ER ratios for peak torque between the dominant and nondominant shoulder and greater IR strength in the dominant side. Impingement was linked to posterior capsular tightness and weakness of the external rotators. Anterior instability was associated with excessive external rotation and weakness of the internal rotators. Rehabilitation should include an emphasis on shoulder strengthening and capsular stretching for treatment of impingement. Performing isokinetic strength testing in the modified abducted position can help determine if either impingement or instability is the problem.

Multiple-Choice Questions

QUESTION 1. Clear communication from the surgeon to the rehabilitation team concerning tissues to be considered following anterior instability surgery includes:

A. Capsule, labrum, biceps, humerus, and subscapularis.
B. Capsule, labrum, glenoid, humerus and subscapularis.
C. Labrum, biceps, glenoid, humerus, and subscapularis.
D. Capsule, labrum, biceps, glenoid, and subscapularis.

QUESTION 2. Which of the following is not included in the guiding principles of postoperative rehabilitation?

A. Understanding of the surgical procedure and anatomic structures, which require protection.
B. When patients are very painful and guarded reviewing sleeping habits, sling use, and HEP are often helpful in managing pain allowing for gentle restoration of ROM.
C. Correct application of manual techniques and therapeutic exercises to promote static balance in glenohumeral joint mobility and optimum dynamic stabilization from the rotator cuff and associated shoulder girdle muscles.
D. Gradual restoration of PROM while protecting the anterior-inferior aspect of the glenohumeral joint through initial immobilization and the rate of ROM gain.

QUESTION 3. The following goals: minimize shoulder pain, achieve staged ROM goals to normalize passive ROM and active ROM, normalize rotator cuff guarding and neuromuscular control, normalize scapular position and control, are expected by:

A. First 14 days postoperatively.
B. 2 to 6 weeks postoperatively.
C. 7 to 12 weeks postoperatively.
D. 13 to 24 weeks postoperatively.

QUESTION 4. The primary rationale for limiting ROM during Phase I is:

A. Glenoid bone loss occurs in all instability and requires protection.
B. Labral repairs require significant protection.
C. Loading from resistance exercises may "stretch out" the capsulolabral repair.
D. Cyclical loading may "stretch out" the capsulolabral repair.

QUESTION 5. A 23-year-old wrestler presents 3 months status after R anterior arthroscopic Bankart repair and capsular plication. His ROM is as follows: 145 degrees of FE, 20 degrees of IR at 90, and 75 degrees of ER at 90. Based on this you recommend:

A. Anterior stretching of the shoulder including pectorals.
B. Posterior stretching of the shoulder including sleeper stretch.
C. Anterior stretching of the shoulder for ER with hands behind the head.
D. No stretching needed his ROM is within the guidelines.

Answer Key

QUESTION 1. Correct answer: **C** (see Surgical Summary)

QUESTION 2. Correct answer: **B** (see After Surgery PostOp Rehab)

QUESTION 3. Correct answer: **B** (see Phase I)

QUESTION 4. Correct answer: **D** (see Phase I)

QUESTION 5. Correct answer: **C** (see Phase II-III criteria)

POSTOPERATIVE REHABILITATION AFTER OPEN ANTERIOR STABILIZATION OF THE SHOULDER WITH OR WITHOUT BONE GRAFTING (ILIAC CREST GRAFT, LATARJET PROCEDURE)

Amy Resler, DPT, CSCS, CMP, Matthew T. Provencher, MD, CDR, MC USN,
Emilie Schmidt, DPT, SCS, ATC, CSCS, and Courtney A. Shinost, M.S, CSCS, NSCA-CPT

Indications for Surgical Treatment

- Recurrent anterior instability of the glenohumeral joint.
- Chronic instability with recurrent subluxation or dislocation.
- First-time instability event in a young, athletic, or high-demand patient.
- Known osseous deficiency of the glenoid and/or humeral head.
- Failure of conservative treatment.
- Failure of prior anterior instability surgical procedures to address soft tissue and/or bony insufficiency.

Brief Summary of Surgical Technique

Clinical Pearls

- There are two main variations of surgical techniques for open anterior stabilization of the shoulder: with and without bone grafting. In the procedure that does not involve bone grafting, there are two options for treatment of the subscapularis which will serve as a key distinction in both the surgical procedure as well as the course of rehabilitation as reflected below.
- It remains difficult to determine which type of bone graft is chosen as there is no clear evidence of which one is superior, however, for those with very large loss, an iliac crest (or allograft) is likely the best option, versus those that have minimal loss to moderate amount of loss (usually up to 25% to 30%), a Latarjet procedure is preferred.

Major Surgical Steps

Open Shoulder Stabilization/Open Capsulolabral Repair without Bone Grafting

- Patient in "beach chair" position.
- General anesthetic, may be supplemented with regional (i.e., interscalene) block.
- Deltopectoral incision in an open Bankart incision, approximately 6 cm in length starting inferiorly just above the axillary crease and extending superiorly lateral to the coracoid.
- Identify the deltopectoral interval through axillary vein location. Keep the vein lateral (more vascular penetrators to the deltoid) (Figure 1-28).

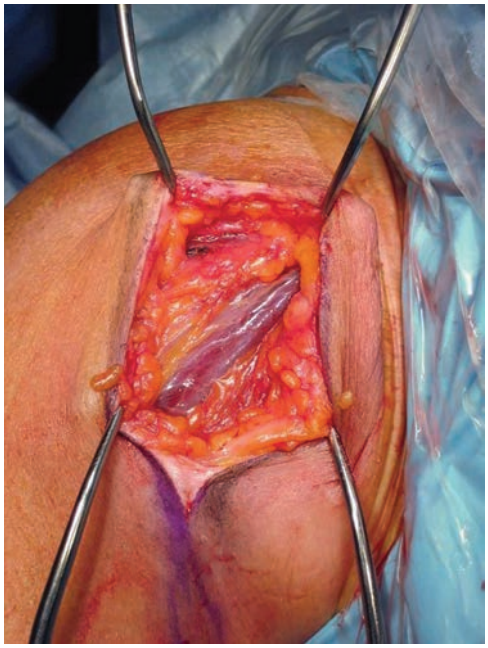

FIGURE 1-28. Identification of the deltopectoral interval and cephalic vein. *(Copyright by Michael J. Pagnani, MD. From Provencher MT, Romeo AA, editors: Shoulder instability: a comprehensive approach. Philadelphia, 2011, Elsevier (Saunders), p. 151.)*

- Develop the deltopectoral interval with gentle blunt dissection down to the bursa over the subscapularis and intertubercular groove.
- Once the biceps (long head) groove is identified, slightly externally rotate the humerus to observe the subscapularis tendon insertion, which attaches onto the lesser tuberosity just medial to the bicipital groove at an angle of about 150 degrees to the groove.
- Two options on how to handle the subscapularis tendon are outlined below:
  - Superior aspect of subscapularis takedown and repair (Figure 1-29)
    - The superior rolled edge of the subscapularis is taken laterally off the lesser tuberosity with either a knife or needle-tip bovie. A small cuff of subscapularis tissue (2 to 3 mm) is maintained in order to perform a repair at the end of the case
    - The superior two thirds of the subscapularis is taken off the lesser tuberosity and tagged with a No. 2 suture

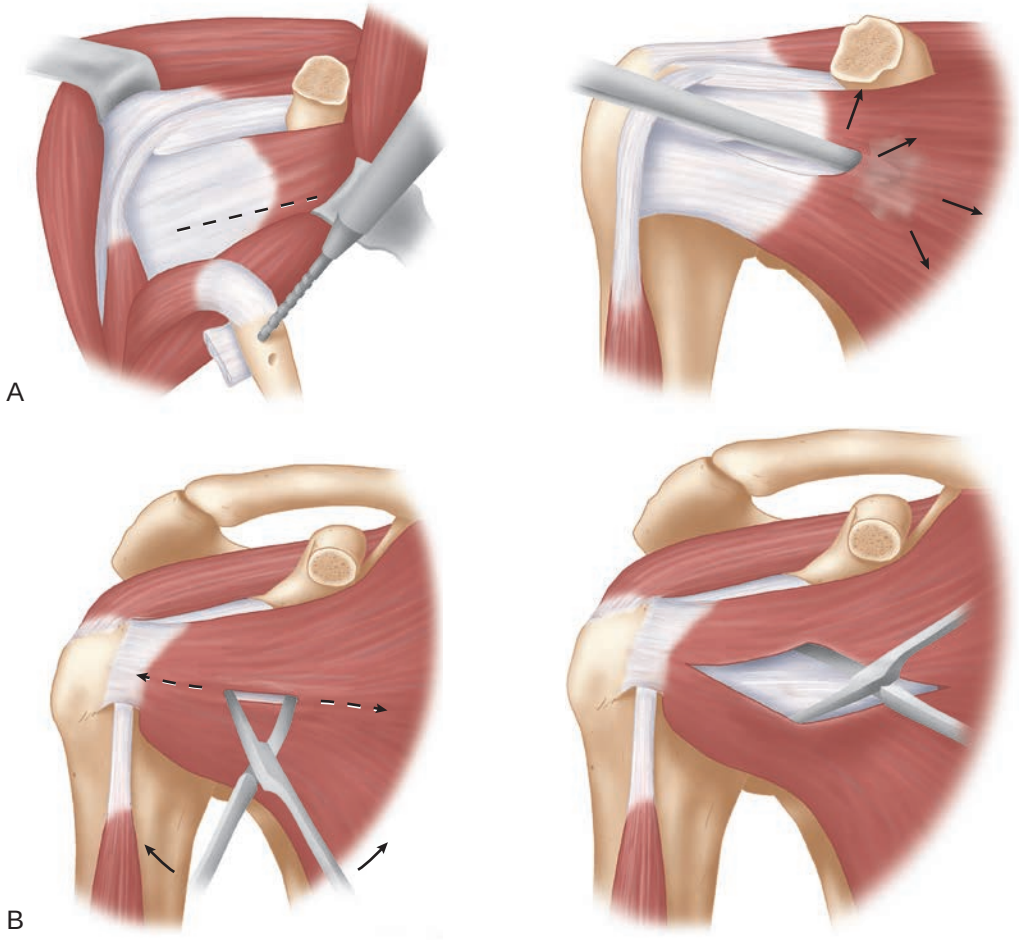

FIGURE 1-29. A, Division of the subscapularis at the junction of the upper two thirds and inferior one third. **B,** The subscapularis is split in line with its fibers, the scissors are opened vertically to expose the underlying capsule. *(From Provencher MT, Romeo AA, editors: Shoulder instability: a comprehensive approach. Philadelphia, 2011, Elsevier (Saunders))*

- Care is taken to preserve the vasculature at the inferior edge of the subscapularis (the "three sisters")
- The subscapularis is dissected off the capsule medially staying on the posterior surface of the subscapularis
- The capsule is identified and is taken sharply off the glenoid with the torn labrum (due to dislocation). The labrum may also be healed on the glenoid in an anterior labral periosteal sleeve avulsion (ALPSA) configuration and will need to be sharply elevated.
- Three to four suture anchors are then drilled into the inferior two thirds of the glenoid and then the capsular-labral complex is repaired to the suture on the suture anchors and affixed anatomically back into position. The knots are then extracapsular (anterior to the capsule) and tied securely.
- The subscapularis is then repaired using high strength No. 2 or No. 5 suture to the native remaining lateral cuff of subscapularis anatomically. Suture anchors may also be utilized.
- The deltopectoral interval is closed with absorbable suture, followed by a standard skin closure.

- Subscapularis split (preferred method) (Figure 1-29)
  - This procedure is similar to the subscapularis takedown, except that the subscapularis insertion on the lesser tuberosity is preserved.
  - This is preferred since the subscapularis insertion is preserved.
  - A longitudinal (in-line with the fibers) incision of the subscapularis starting just medial to the biceps groove and extending to the muscle-tendon junction is carried out at about the halfway position (superior to inferior) on the subscapularis (see Figure 1-30).
  - The capsule of the shoulder is identified medially and then the procedure is carried out as above with capsular and labrum takedown and anatomic repair with suture anchors.
  - The subscapularis split is closed anatomically with No. 2 *figure of eight* sutures.
  - The remainder of the closure is identical to that noted above for the subscapularis takedown.

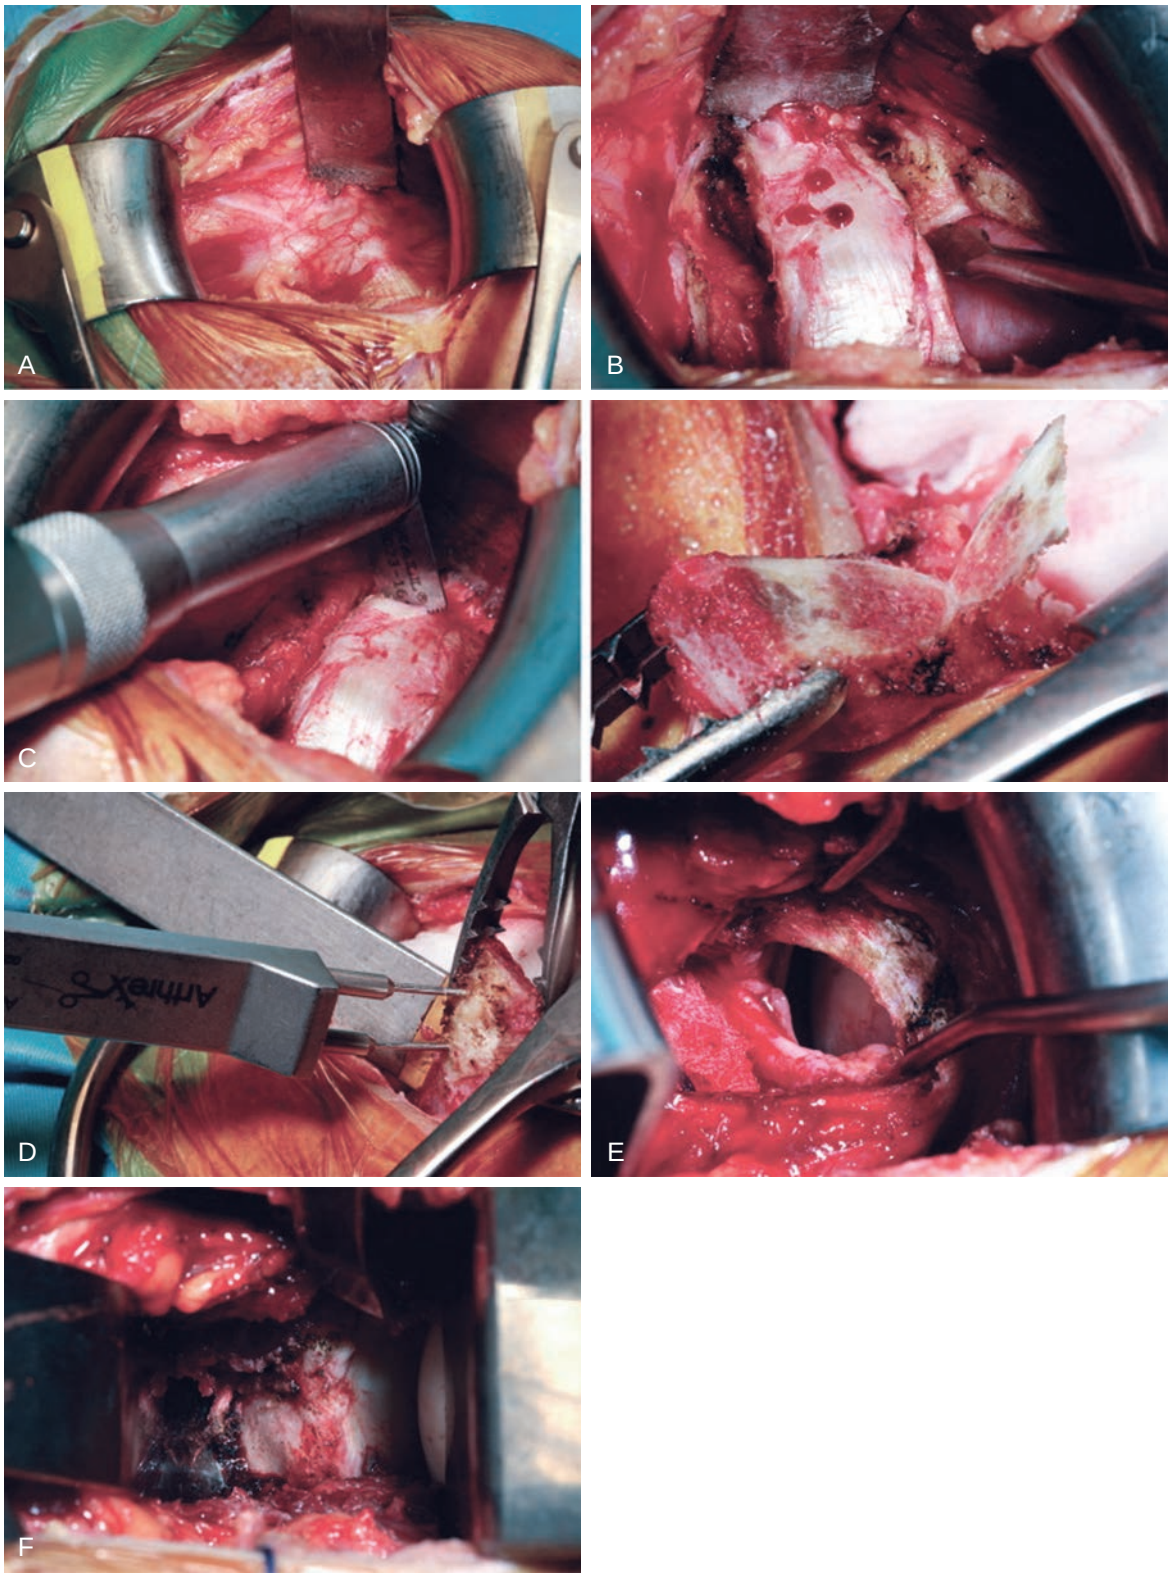

FIGURE 1-30. **A,** Exposing the coracoid process in the left shoulder with the aid of self-retaining retractor. **B,** The coracoacromial ligament and the pectoralis minor tendon insertion released from the coracoid process. **C,** Left: Osteotomy of the coracoid process with the microsagittal 90-degree angled blade. Right: Decortication of the deep surface of the coracoid bone graft. **D,** The guide wire jig allows the surgeon to insert two guide wires into the coracoid graft. **E,** Left glenohumeral joint exposure through a subscapularis split. **F,** Retractor placed on the anterior scapular neck as medial as possible to improve the visualization of the site of coracoid graft insertion.

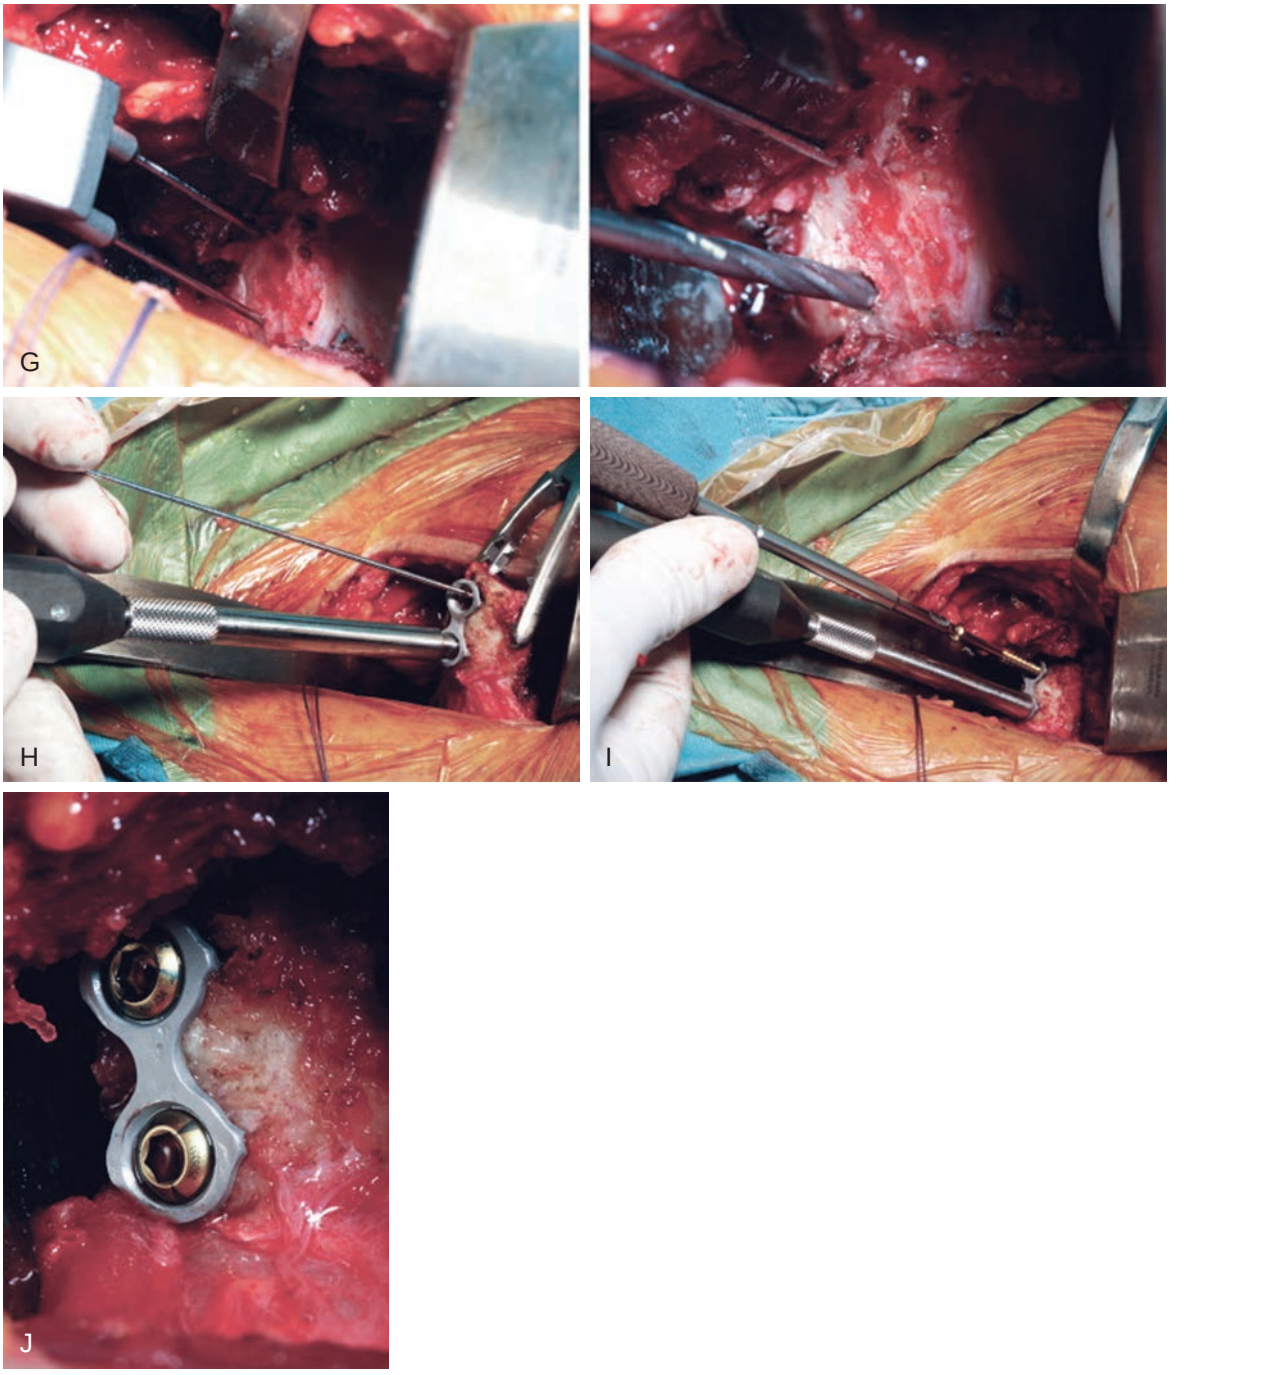

FIGURE 1-30, cont'd G, Left: Anterior glenoid neck prepared for the placement of the coracoid bone graft and insertion of two K-wires. Right: Anterior glenoid neck drilled with the 2.7-mm cannulated drill. **H,** Using the cannulated temporary compression device (TCD), we stabilize the plate over the coracoid bone graft through the inferior drilled hole. **I,** Insertion of the cannulated screw through the superior guide wire. **J,** The Mini-plate (wedge profile plate) in final fixed position. *(From Provencher MT, Romeo AA, editors: Shoulder instability: a comprehensive approach. Philadelphia, 2011, Elsevier (Saunders)).*

Open Shoulder Stabilization: With Bone Grafting

Clinical Pearl

The principle of placing the conjoint tendon through a split in the subscapularis is based on the stability of the shoulder joint that is obtained from several coordinated biomechanical factors:

- The bone of the coracoid that is transferred to the glenoid (larger glenoid surface for which the humerus to articulate or restoration of normal glenoid bone surface if the glenoid is deficient).
- The conjoint tendon which is used as a soft tissue "sling effect" through a split in the subscapularis tendon which becomes more taut with abduction and external rotation and will help decrease subluxation of the joint (Figure 1-30)
- Capsular repair.

- Latarjet procedure: coracoid transfer (Figure 1-31). The procedure is the same as for an open shoulder instability repair with subscapularis split with the following additions and modifications

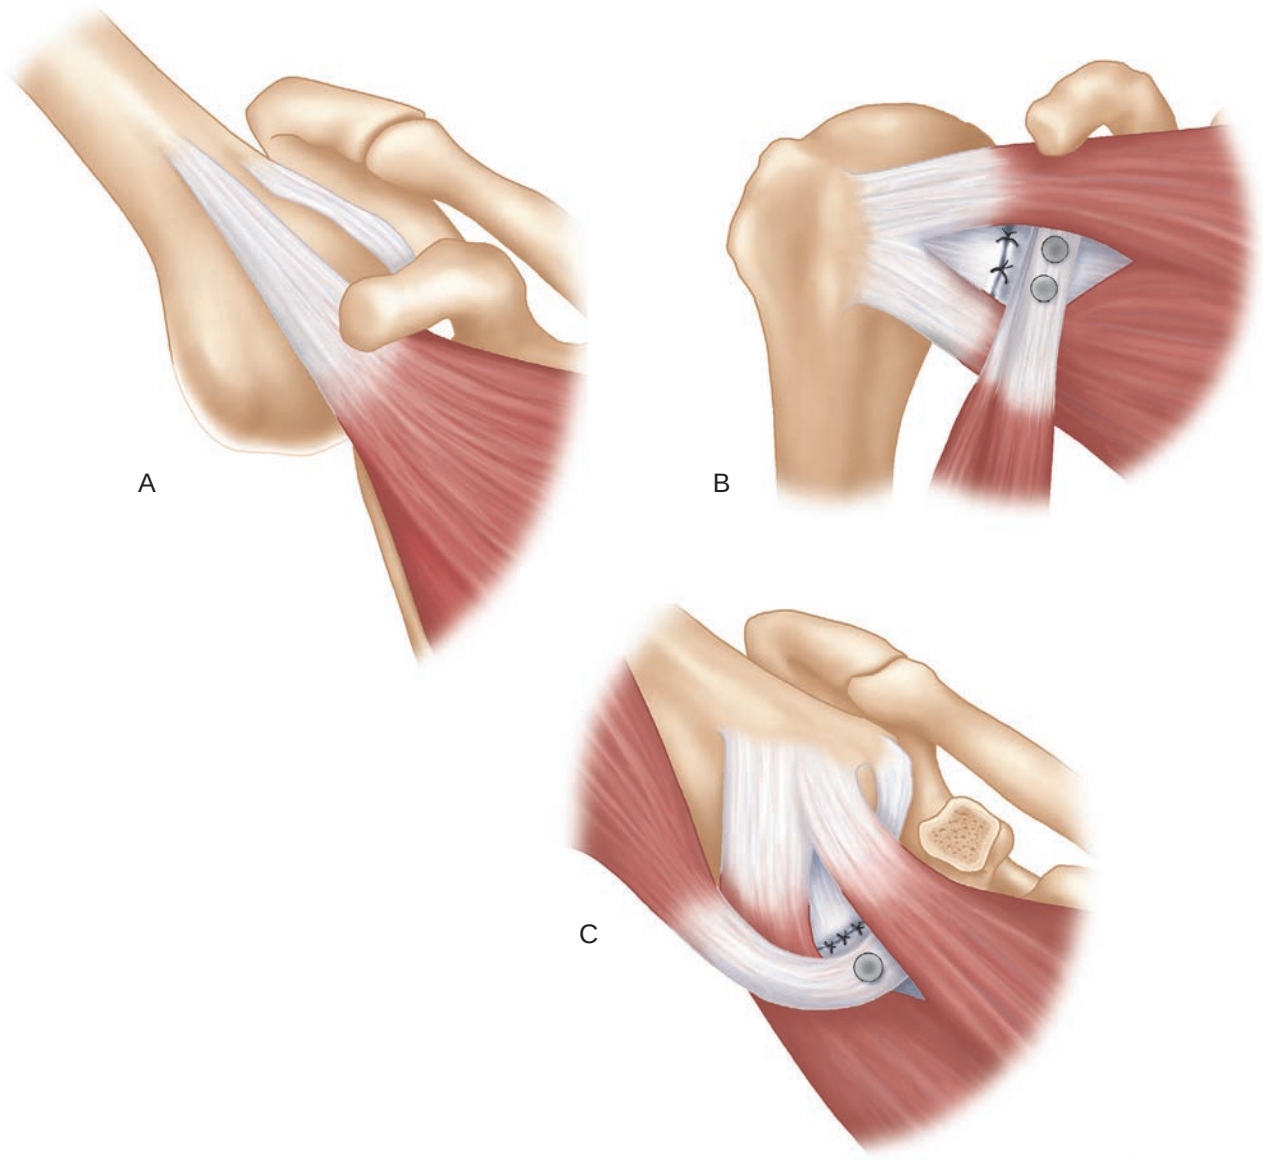

FIGURE 1-31. "Sling effect." **A,** Normal position of the subscapularis. **B,** Completed Latarjet with the arm in neutral, anterior bone block, and capsule repaired to coracoacromial ligament (CAL). **C,** The inferior displacement of the subscapularis by the conjoint tendon creates a "sling" beneath the anteriorinferior capsule, especially in the abducted, externally rotated position of the upper extremity. *(From Provencher MT, Romeo AA, editors: Shoulder instability: a comprehensive approach. Philadelphia, 2011, Elsevier (Saunders)).*

- After the deltopectoral interval is identified, the coracoid is isolated superiorly and dissected free of soft tissue.
- Pectoralis minor is attached medially (it is not reattached).
- The coracoacromial (CA) ligament is left of the coracoid and left about 1 cm in length.
- The CA ligament is then sutured to the capsule of the shoulder that was taken down the medial neck of the glenoid. Thus, some lengthening of the capsule is obtained and the capsule may be repaired by a CA ligament to capsular repair, preserving external rotation of the arm at the side (Figures 1-32 to 1-34).
- The conjoint tendon remains intact.
  - Alternative ways to handle the capsule:
    - Not to repair capsule at all.
    - Suture anchors to native glenoid and repair capsule to the native glenoid via suture anchors.
    - Suture the capsule to the anterior aspect of the coracoid underneath the washers and suture the capsule to sutures attached to the washers.
  - Approximately a 20 to 25 mm length of coracoid is harvested with either a sharp 10-mm sagittal saw or curved osteotomes just as the coracoid starts to curve. This preserves the coracoclavicular (CC) ligaments.
  - The coracoid is harvested and tucked in the inferior part of the wound
  - A subscapularis split and capsular takedown off the glenoid is performed

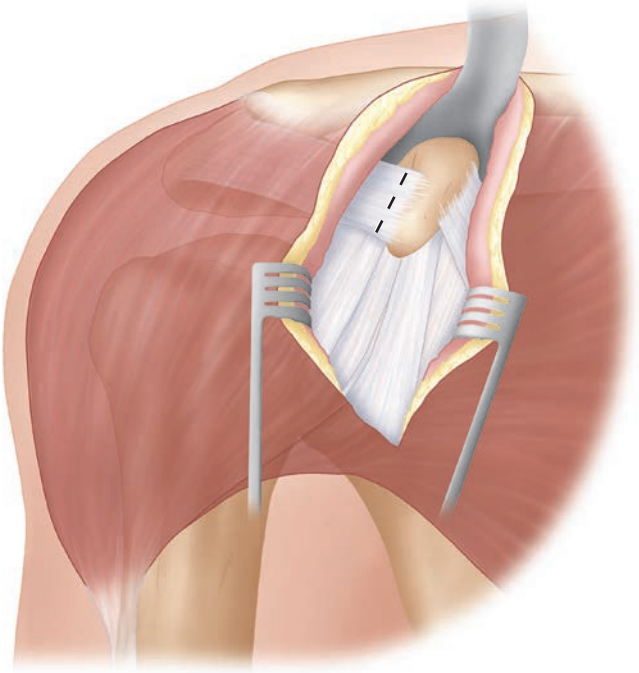

FIGURE 1-32. The CAL incised 1 cm from the coracoid insertion (arm in external rotation). *(From Provencher MT, Romeo AA, editors: Shoulder instability: a comprehensive approach. Philadelphia, 2011, Elsevier (Saunders)).*

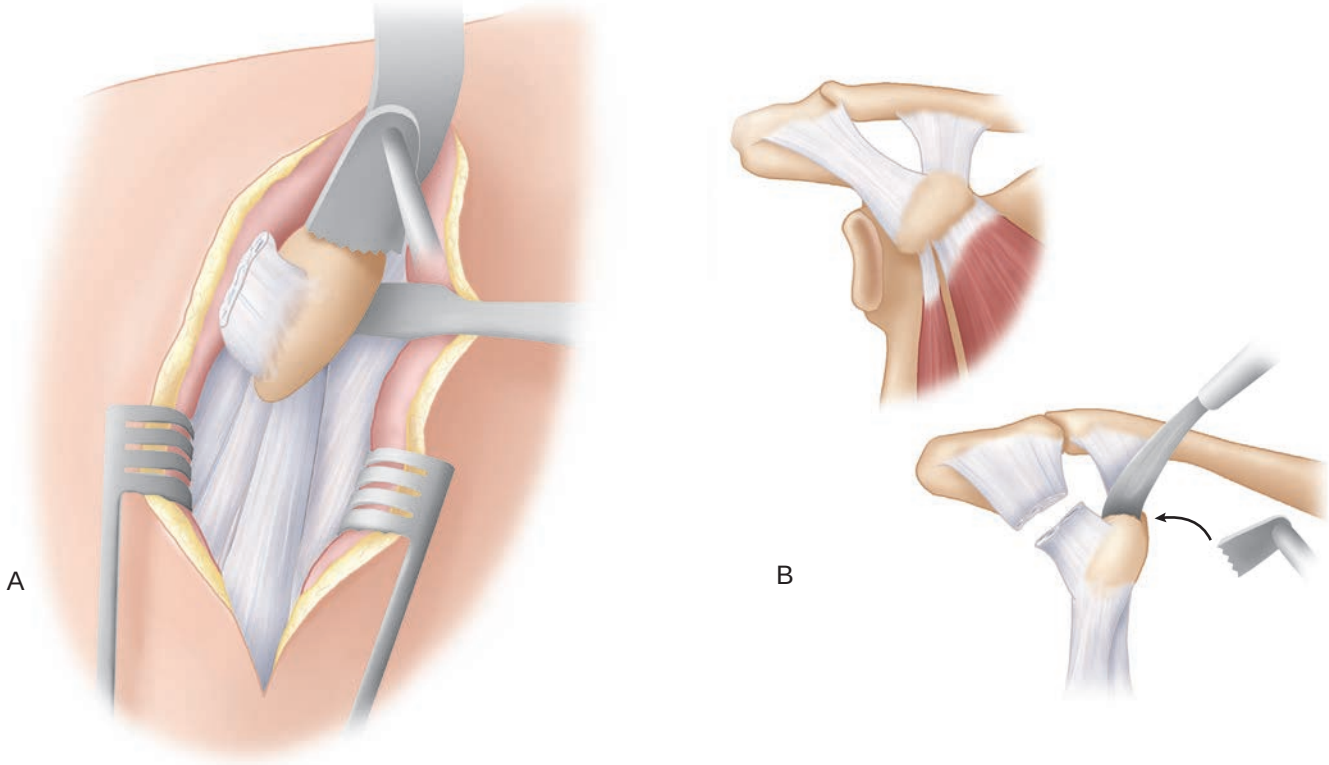

FIGURE 1-33. The pectoralis minor is released and the osteotomy is performed at the inferior coracoid. *(From Provencher MT, Romeo AA, editors: Shoulder instability: a comprehensive approach. Philadelphia, 2011, Elsevier (Saunders))*

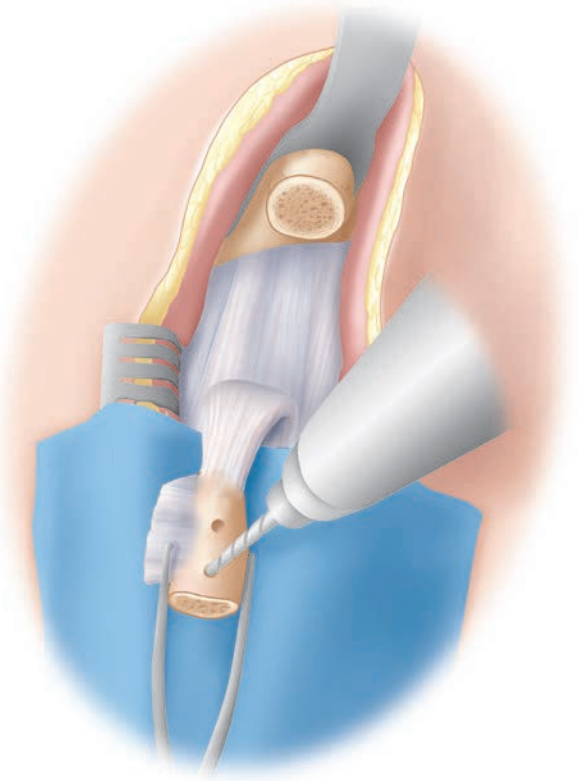

FIGURE 1-34. Preparation of the coracoid process. *(From Provencher MT, Romeo AA, editors: Shoulder instability: a comprehensive approach. Philadelphia, 2011, Elsevier (Saunders)).*

- The bony glenoid is then rasped and burred to allow for the coracoid to be transferred (bottom two thirds of the glenoid).
- The coracoid is also prepared and soft tissue dissected off (except for CA ligament).
- The bone is oriented so that the CA ligament is lateral for capsular repair (Figures 1-35 to 1-37).
- Two 35- to 38-mm bicortical screws (3.5 mm diameter) are utilized to fix the coracoid in place on the glenoid utilizing a compression technique.
- The capsule of the shoulder is repaired to the CA ligament that remains attached to the coracoid.
- The conjoint tendon drapes naturally over the subscapularis split and the lateral half of the split is closed with nonabsorbable suture.
- The remainder of the closure is the same as described above.

- Bone augmentation: iliac crest, distal tibia, or other allograft.
  - This is similar to the Latarjet procedure through either a subscapularis split or subscapularis takedown, except that the coracoid is not harvested.
  - The bone is affixed similar to the Latarjet (two screws), and the capsule may be repaired to sutures that are attached to the screws (Figure 1-38).
  - The subscapularis split is closed with *figure of eight* sutures, or if done with a subscapularis takedown, is repaired back to the native subscapularis remnant and remainder of the closure is the same.

Factors that May Affect Rehabilitation

- **Key Principle:** The treatment of the subscapularis will dictate the progression of the early stages of rehabilitation.
  - Subscapularis takedown will dictate a slower course of rehabilitation, especially in Internal Rotation (IR) strengthening and External Rotation (ER) limitations.

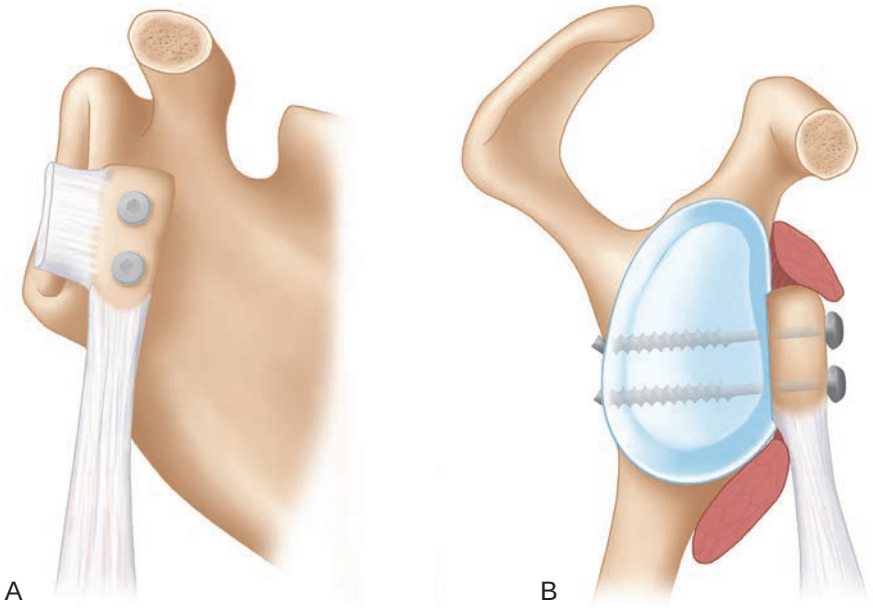

FIGURE 1-35. A, Coracoid graft securely fixed to glenoid with two screws with no lateral overhang. **B,** Lateral view of the reconstruction. *(From Provencher MT, Romeo AA, editors: Shoulder instability: a comprehensive approach. Philadelphia, 2011, Elsevier (Saunders)).*

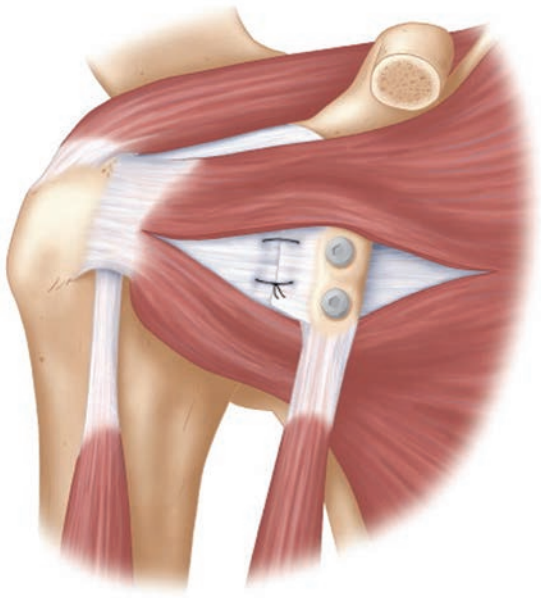

FIGURE 1-36. Anterior view of final reconstruction following repair of capsule to CAL remnant (arm in full external rotation with elbow by the side). *(From Provencher MT, Romeo AA, editors: Shoulder instability: a comprehensive approach. Philadelphia, 2011, Elsevier (Saunders)).*

- Subscapularis split will allow for more aggressive progression with the IR strengthening, but may also need ER limitations.
- Latarjet procedure (conjoint tendon transfer with coracoid fixation).
  - The sling of the conjoint may add some slight motion limitations.
  - The capsular repair may add motion limitations, especially in external rotation and abduction. This is traditionally done via a subscapularis split.

Other Surgical Techniques and Options

- Provencher et al.[1] suggests there is the potential added benefit of restoration of the articular surface of the glenoid, with the ability to provide for an anatomic fit by customizing the graft size for the defect. The distal tibia allograft provides several advantages over a glenoid allograft.
- A case series by Warner et al.[2] concluded glenoid with autogenous iliac crest bone graft for recurrent glenohumeral instability due to setting of bone deficiency is an effective form of treatment for this problem.
  - Autograft: Iliac crest (Figure 1-39).

FIGURE 1-37. X-rays from Gilles Walch—Postoperative radiographs (**A**, True AP; **B**, Lateral; and **C**, Bernageau views) demonstrating correct placement of the graft with no lateral overhang and bicortical screw fixation. *(From Provencher MT, Romeo AA, editors: Shoulder instability: a comprehensive approach. Philadelphia, 2011, Elsevier (Saunders)).*

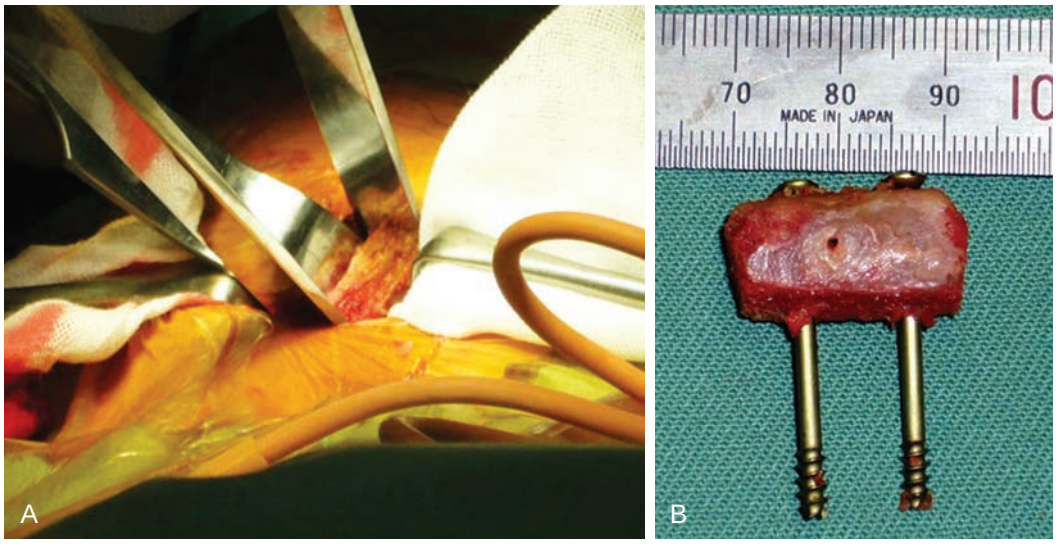

FIGURE 1-38. Iliac tricortical bone is harvested from the iliac crest and prepared using two screws. *(A, From Sugaya H: Instability with bone loss. In Angelo R, et al:, AANA advanced shoulder arthroscopy, Philadelphia, 2010, Elsevier; B, From Provencher MT, Romeo AA, editors: Shoulder instability: a comprehensive approach. Philadelphia, 2011, Elsevier (Saunders)).*

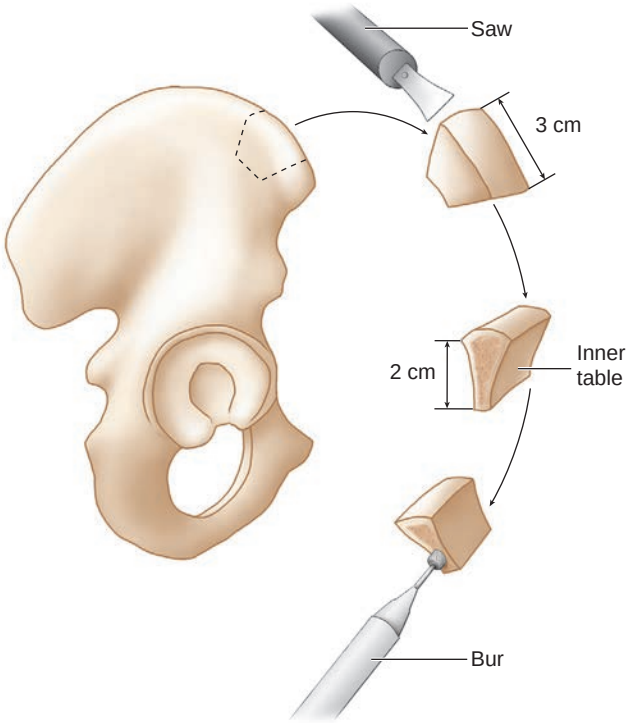

FIGURE 1-39. Harvesting and preparing iliac crest autograft. *(From Provencher MT, Romeo AA, editors: Shoulder instability: a comprehensive approach. Philadelphia, 2011, Elsevier (Saunders)).*

- Allograft: distal tibial allograft, femoral head, glenoid and others have been described.[1,2]
- These differences in type of repair may affect rehabilitation guidelines especially in consideration of the limitations in ER after the procedure for a varied period of time. Clarification from the surgeon is necessary (Figures 1-40 to 1-42).

Before Surgery: Overview of Goals, Milestones, and Guidelines[1]

GUIDING PRINCIPLES OF POSTOPERATIVE REHABILITATION

- Rehabilitation protocols must be tailored to specific surgical technique performed.
- Bone to bone healing occurs at approximately 6 to 8 weeks
- Subscapularis takedown will require attention to the healing rotator cuff as well as integrating bone graft. Active internal rotation should be limited for 6 weeks as well as passive external rotation should be gained in a protected manner.

Phase I: Weeks 0 to 3 Postoperatively (Subscapularis Takedown)

Goals

- Minimize postoperative pain and inflammation.
- Patient education regarding the stressors to the graft and soft tissues.
- Emphasize importance of sling compliance to include proper positioning to allow incision healing and minimize stress to healing soft tissues and protect bone graft.
- Surgeon-therapist communication regarding type of soft tissue and osseous structures repaired.

[1]*Prehabilitation, if appropriate, is described in the Nonoperative Rehabilitation section of this chapter.*

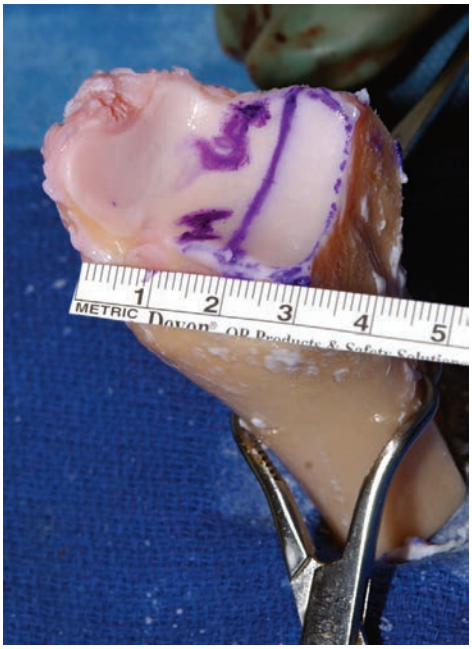

FIGURE 1-40. The lateral portion of the tibial plafond for use as an allograft. *(From Provencher MT, Romeo AA, editors: Shoulder instability: a comprehensive approach. Philadelphia, 2011, Elsevier (Saunders)).*

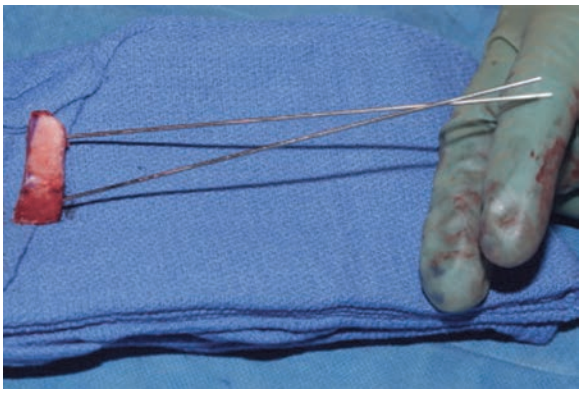

FIGURE 1-41. Two 1.6-mm K-wires are used for provisional fixation. These should be placed at a 45-degree angle to the articular surface in order to avoid penetration of the joint and achieve optimal purchase. The K-wires should be placed in a location that will allow for eventual placement of two 3.5-mm fully threaded cortical screws around them. *(From Provencher MT, Romeo AA, editors: Shoulder instability: a comprehensive approach. Philadelphia, 2011, Elsevier (Saunders)).*

- Protect both graft and soft tissue healing structures (subscapularis repair).
- Maintain elbow, wrist, and hand motion as well as postural/scapular stabilizer tone.

Clinical Pearl

- Understand what happened to the subscapularis. This is the number one item to communicate between the surgeon-rehabilitation team, as external rotation is limited due to the bone graft. The normal postoperative emphasis on internal rotation must be altered, as manual IR techniques would compromise the healing subscapularis. It is important to have patient understanding of limiting active internal rotation for the initial 6 weeks postoperatively.
- Also, clinically we have observed that pectoralis major and minor muscular restrictions and swelling at the anterior chest/shoulder region near the incision can be a pain generator. Often, soft tissue mobilization to the restricted pectoralis group will mobilize swelling and decrease muscle guarding. In addition, emphasis on patient relaxation of the pectoralis muscles has been observed to reduce pain.

TIMELINE 1-3: **Postoperative Rehabilitation After Open Anterior Stabilization of the Shoulder With or Without Bone Graft (Iliac Crest, Latarjet, etc.)**

PHASE I (weeks 1 to 2)	PHASE II (weeks 3 to 6)	PHASE III (weeks 6 to 10)
• Sling • PT modalities: e-stim, CP • PROM-scapular plane elevation and flexion to 100° • Active assistive Codman's exercises • TBS/TAS/TLS activities as recommended & tolerated	• Sling (may d/c at wk 5–6) • PT Modalities: e-stim, CP, MHP • PROM-wk-4 scaption and flexion to full • PROM-wk-6 ER to 45° • PROM-wk-6 IR to 0° • TBS/TAS/TLS activities as recommended & tolerated • Scapular exercises • Wk 4-AAROM exercises • Wk 4-submax isometrics for GH joint muscles • Wk 6-submax isometrics for ER	• DC sling • PT Modalities as needed • PROM-full • Mobilizations as needed • TBS/TAS/TLS activities as recommended & tolerated • Scapular exercises—PREs • TAS—Biceps/Triceps PREs • Glenohumeral exercises—PREs • Rotator cuff exercises—PREs • Limit IR exercises to minimize strain to posterior capsule and subscapularis • PNF exercises • OKC Rhythmic stabilization exercises • CKC Exercises • Wk 10-Seated press-ups and increased weight-bearing through joint • CKC manual perturbation exercises

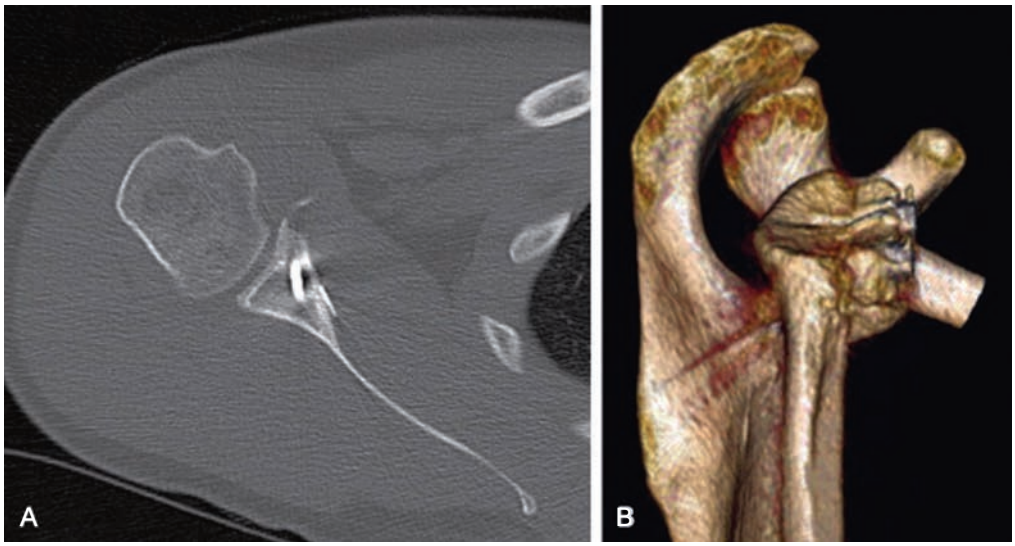

FIGURE 1-42. (**A**) Two- and (**B**) three-dimensional CT images that illustrate the excellent match of the radius of curvature of the native glenoid and distal tibia allograft. *(From Provencher MT, Romeo AA, editors: Shoulder instability: a comprehensive approach. Philadelphia, 2011, Elsevier (Saunders)).*

Protection

- Sling immobilization for at least 4 weeks is recommended by most; others recommend 5 to 6 weeks. This is based on the surgeon's discretion.

Management of Pain and Swelling

- Position of comfort, adjust sling as required for comfort and also to protect and minimize stresses to healing structures and tissues.
- Interferential current has been documented and observed to reduce postoperative pain and swelling.
- Cold therapy for pain and swelling (Figure 1-43).
- Sleeping and resting with the upper extremity supported and slightly elevated.

Techniques for Progressive Increase in Range of Motion

Manual Therapy Techniques

- May begin active and passive range of motion (PROM) of the wrist and hand immediately.
- Active and passive elbow flexion and extension is allowed.
- *For subscapularis takedown*: PROM glenohumeral joint (GHJ) to 100 degrees flexion, 0 degrees ER.
- *For subscapularis split*: PROM GHJ to 100 degrees flex, 15 degrees ER at 30 degrees abduction at week 2 and 30 degrees ER at 45 degrees abduction at week 3.
- No active range of motion (ROM) of the GHJ.

TIMELINE 1-3: **Postoperative Rehabilitation After Open Anterior Stabilization of the Shoulder With or Without Bone Graft (Iliac Crest, Latarjet, etc.)** (Continued)

PHASE IV (weeks 10 to 14)	PHASE V (weeks 14 to 24)	PHASE V (weeks 24 to 52)
• PT Modalities as needed • PROM-full • Mobilizations as needed • Wk 12-IR sleeper stretch • TBS/TAS/TLS activities as recommended & tolerated • Scapular exercises—PREs • TAS—Biceps/Triceps PREs • Glenohumeral exercises—PREs • Rotator cuff exercises—PREs • Thrower's 10 • Limit IR exercises to minimize strain to posterior capsule and subscapularis • Begin running at 12 wks • PNF exercises • OKC rhythmic stabilization exercises • CKC exercises • CKC manual perturbation exercises	• PROM-maintain full motion • Mobilizations as needed • TBS/TAS/TLS activities as recommended & tolerated • Scapular exercises—PREs • TAS—Biceps/Triceps PREs • Glenohumeral exercises—PREs • Rotator cuff exercises—PREs • Thrower's 10 progress intensity • PNF exercises • OKC rhythmic stabilization exercises • CKC exercises • CKC manual perturbation exercises • Plyometrics—2 arm progressing to 1 arm • Overhead strengthening exercises • Sport specific exercises begin • Overhead throwing athletes can begin an easy interval throwing program • 20 wks-begin full windup throwing	• PROM-maintain full motion • Mobilizations as needed • TBS/TAS/TLS activities as recommended & tolerated • Scapular exercises—PREs • TAS—Biceps/Triceps PREs • Glenohumeral exercises—PREs • Rotator cuff exercises—PREs • IR/ER exercises at 90° • Thrower's 10 progress intensity • PNF exercises • OKC Rhythmic stabilization exercises • CKC Exercises • CKC manual perturbation exercises • Plyometrics—2 arm chest passes progressing to 90°/90° 1 arm plyos • Overhead strengthening exercises • Sport-specific exercises progressed • Overhead throwing athletes progress through an interval throwing program

FIGURE 1-43. Cold therapy. *(From Provencher MT, Romeo AA, editors: Shoulder instability: a comprehensive approach. Philadelphia, 2011, Elsevier (Saunders)).*

Soft Tissue Techniques

- Soft tissue techniques to cervical musculature (levator scapulae and upper trapezius), anterior shoulder and chest wall/pectoralis major, periincisional.

Stretching and Flexibility Techniques for the Musculotendinous Unit

- Stretching/flexibility techniques for the levator scapular and upper trapezius during this phase as needed to relieve pain, shoulder girdle elevation, and the effects of immobilization and guarding.

Other Therapeutic Exercises

- For the elite athlete, lower body strengthening can continue safely in the early postoperative period. Core strengthening can be performed with the arm in the sling. Stationary bicycle can be used for cardiovascular maintenance, conditioning and circulation.

Activation of Primary Muscles Involved in Injury Area or Surgical Structures

- No active shoulder movements for 4 to 5 weeks.
- Maybe isometrics on *subscapularis split* into IR at 2 weeks' postop.
- For half *subscapularis split/takedown*, refrain from active IR for 3 to 4 weeks.
- No strengthening of internal rotation for 6 weeks if subscapularis was taken down during surgery.

Sensorimotor Exercises

- Again, for the elite athlete these can begin immediately following surgery in a supervised setting with the arm in a sling. For most patients this would be restricted until at least 6 to 8 weeks to avoid falling or loss of balance that may produce sudden movements of the protected upper extremity.

Open and Closed Kinetic Chain Exercises

- No active range of motion (AROM) of the glenohumeral joint.
- Supported or short lever Codman's exercises (Figure 1-44) during this phase, three times/day.
- Ball Squeeze for hand.
- Wrist and gripping exercises.

Techniques to Increase Muscle Strength, Power, and Endurance

- Strengthening should be avoided until full passive and active motion have returned.

Neuromuscular Dynamic Stability Exercises

- Elite athletes may begin this during Phase II.

Plyometrics

- Lower extremity plyometrics can begin at 8 weeks following surgery.

Milestones for Progression to the Next Phase

- Minimal to no pain.
- 100% sling/immobilizer compliance.
- No signs or symptoms of compromise or failure of the repair.

FIGURE 1-44. Short lever or supported Codman's exercises. *(From Provencher MT, Romeo AA, editors: Shoulder instability: a comprehensive approach. Philadelphia, 2011, Elsevier (Saunders)).*

Phase II: Weeks 4 to 6 Postoperatively

Goals

- Prevent loss of motion of hand, wrist, and elbow
- Protect graft and continue to prevent stresses soft tissue repair.
- Pain-free GHJ PROM within postoperative restrictions to prevent stiffness.
- Eliminate postoperative pain and swelling.

Clinical Pearl

Pain during this phase is often at the supraspinatus or subacromial space. This may occur upon initiating PROM of the GHJ. Clinically we have had success eliminating this pain during this phase with soft tissue mobilization to the supraspinatus tendon while the GHJ is in the loose packed position. In addition, gentle grade 1 to 2 joint mobilizations to the GHJ (posterior glides in general due to ROM limitations) may be applied to improve arthrokinematics that may be contributing to subtle rotator cuff (RC) impingement caused by stiffness and faulty mechanics.

Protection

- The sling may be weaned at week 4 to 5 unless indicated by the surgeon.

Management of Pain and Swelling

- Cold therapy and electric stimulation modalities may be continued as needed during this phase.
- Moist heat may be applied to the pectoralis group if patient has difficulty relaxing or guarding continues during this phase.

Techniques for Progressive Increase in Range of Motion

Manual Therapy Techniques

- No active GHJ ROM.
- PROM GHJ flexion and scaption to pain-free tolerance. ER 0 to 45 degrees in 45 degrees abduction until week 6. IR PROM to 45 degrees in 30 degrees abduction.
- Continue PROM to the wrist and elbow. Grade 1 to 2 posterior joint mobilization to the GHJ (no anterior or inferior mobilization) to facilitate PROM (Figure 1-45).

Soft Tissue Techniques

- Continue soft tissue mobilization to muscles discussed in Phase I.

FIGURE 1-45. Therapist performs PROM of GHJ within postoperative external rotation restrictions. *(From Provencher MT, Romeo AA, editors: Shoulder instability: a comprehensive approach. Philadelphia, 2011, Elsevier (Saunders)).*

- Begin scar mobilization when incisions are sufficiently closed.

Stretching and Flexibility Techniques for the Musculotendinous Unit

- Stretching/flexibility techniques for the cervical and shoulder girdle musculature as discussed in Phase I.

Other Therapeutic Exercises

- Stationary bike at week 4 while wearing sling.

Sensorimotor Exercises

- Elite athletes may begin lower extremity (LE) unilateral balance and proprioceptive exercises, single limb LE balance with head movements.

Open and Closed Kinetic Chain Exercises

- May begin trunk or thoracic rotation while wearing sling.

Functional Exercises

- Functional one third squats (wearing sling).
- Stationary lunges.

Milestones for Progression to the Next Phase

- No postoperative swelling or pain.
- Elbow, wrist, and hand ROM within normal limits
- Full PROM except ER by week 6.
- No signs or symptoms of compromise or failure of the repair.

Phase III: Weeks 6 to 10 Postoperatively

Goals

- Full pain-free end range AROM without sensation of instability.
- Gradual, pain-free steady return of end range abduction external rotation (ABER).
- Restore arthrokinematics.
- Maximize scapular stabilizer strength and restore rotator cuff strength.

Clinical Pearl

As a patient begins AROM, clinically we have observed the patient exhibiting signs and symptoms consistent with impingement. Continue soft tissue mobilization to the supraspinatus or posterior rotator cuff if tender and painful during this phase. Cautiously and gently apply GHJ mobilization inferiorly and anteriorly toward the later stage of this phase as appropriate to address stiffness. Restore scapulohumeral rhythm with manual cueing to further improve faulty arthrokinematics. Initiation of serratus anterior and lower trapezius strengthening is key to facilitate proper mechanics.

Protection

- Discontinue sling completely prior to initiation of this phase.

Management of Pain and Swelling

- NSAIDs as needed.
- Moist heat may be applied to the GHJ for stiffness.
- Continue ice for any residual pain or swelling apply to rotator cuff if indicated.

Techniques for Progressive Increase in Range of Motion

Manual Therapy Techniques

- Continue joint mobilizations, manually facilitate scapulohumeral rhythm. Continue PROM and AAROM to full AROM by week 10.

Soft Tissue Techniques

- Continue stretching and flexibility for the restricted shoulder girdle and parascapular muscle groups (i.e., pectoralis major, minor, levator scapula, upper trapezius).

Stretching and Flexibility Techniques for the Musculotendinous Unit

- Stretching/flexibility techniques restricted muscles (i.e. pectoralis major, minor).

Other Therapeutic Exercises

- LE gym weights and machines, light resistance.
- Elliptical (week 8), StairMaster (week 6).
- UBE minimal resistance week 6, progress resistance (week 8).
- Stationary bike with increased resistance.

Activation of Primary Muscles Involved in Injury Area or Surgical Structures

- Begin isometrics of IR after week 6. Begin gentle PREs of biceps, triceps, deltoids, middle, and lower trapezius and ER at week 6.

Sensorimotor Exercises

- Hand on baps board in partial UE weight-bearing (WBing) at 6 weeks.
- Progress to body blade at side in neutral at week 8.

Open and Closed Kinetic Chain Exercises

- AAROM using towel for end range IR.
- AAROM using with wand or dowel for flexion, abduction, ER.
- Closed chain scapular exercises and kinetic chain exercises begin at 8 weeks, allowing the patient to improve scapular kinetics
- Scapular clocks.
- Wall protraction at weeks 8 to 10 with B UEs, progressing to unilateral UE.

Techniques to Increase Muscle Strength, Power, and Endurance

- Seated small arc scapular depression at week 6.
- Seated scapular retraction at week 6.
- Prone "I" scapular three-step exercise at weeks 8 to 10.
- Isometric ER, IR, flexion, extension and abduction at week 6.
- Progress to light resistance band for RC strength, in neutral at week 8.
- Progress to scapular depression and rows with light resistance band at week 8.
- Sidelying ER with no resistance.

Neuromuscular Dynamic Stability Exercises

- Scapular PNF in sidelying; repeated isometric progressing to slow reversals.
- IR and ER PNF repeated contractions after week 6 beginning in neutral.
- GHJ PNF in supine; rhythmic stabilization progressing to slow reversals.
- Elbow PNF.

Plyometrics

- LE low impact plyometrics at week 8 for elite athletes.

Functional Exercises

- Lawnmowers (Figure 1-46).
- Romanian dead lifts (RDLs).
- Thoracic spine ROM and mobility, functional trunk movements and activities.

Sport-Specific Exercises

- LE sport specific agility drills for elite athletes.

Milestones for Progression to the Next Phase

- Full AROM GHJ without compensatory movement strategies.
- No pain or sensation of instability.
- Strength UE and scapular stabilizers 4+/5.
- Restored joint mobility.

Phase IV: Weeks 10 to 14 Postoperatively

Goals

- Restore scapulohumeral rhythm and normalize arthrokinematics.
- Maximize strength of UE and parascapular musculature.
- Initiate overhead (ABER) functional movement patterns.

Clinical Pearl

To attain end range ABER, careful anterior, inferior or combined anterior-inferior joint mobilization may be helpful. In addition, scapular tilting is often observed. Pectoralis minor stretching may assist in restoring the normal resting position of the scapula during the later stages of this phase into the next phase.

Protection

- May apply postural tape, kinesiotape to cue or facilitate parascapular muscles.

Techniques for Progressive Increase in Range of Motion

Manual Therapy Techniques

- Continue joint mobilization.
- Manually facilitate scapulohumeral rhythm.
- Low-load long-duration capsular stretch if lacking end range combined ABIR or ABER.

Soft Tissue Techniques

- Continue scar mobilization and soft tissue mobilization as described in previous phases.

Stretching/Flexibility Techniques for the Musculo-Tendinous Unit

- Hold relax stretching of pectoralis major, minor, latissumus dorsi, levator scapula as needed.

FIGURE 1-46. Lawnmowers. *(From Provencher MT, Romeo AA, editors: Shoulder instability: a comprehensive approach. Philadelphia, 2011, Elsevier (Saunders))*

Other Therapeutic Exercises

- Upper body ergometer (UBE).
- LE gym weights and machines, increase resistance.
- Add bent over low row with light weight.
- Progress to low- and mid-row machine, low resistance.

Activation of Primary Muscles Involved in Injury Area or Surgical Structures

- Full Can to 90 degrees only for nonthrowers with light weights.
- Shoulder raises (flexion, abduction) to 90 degrees with light weights.
- Biceps curls, begin with supported preacher curl.

Sensorimotor Exercises

- Increase UE WBing on unstable surface (i.e., half-kneeling UE balance on BOSU ball).
- Progress UE resistance band exercises with decrease base of support (unilateral balance or on unstable surface).

Techniques to Increase Muscle Strength, Power, and Endurance

- Add PNF patterns with resistance bands.
- Prone T and Y.
- Isometric ER, IR, flexion, extension, and abduction at week 6.
- Begin isokinetics.
- Wall pushup progression.

Neuromuscular Dynamic Stability Exercises

- Seated GHJ PNF.
- Body blade at varying flexion, abduction and scaption angles.

Plyometrics

- Progress LE plyometrics.

Functional Exercises

- Begin jogging at week 12

Sport-Specific Exercises

- LE sport specific agility drills for elite athletes.

Milestones for Progression to the Next Phase

- Strength of RC and parascapular stabilizers all 5/5.
- No pain or instability.
- Optimized scapulohumeral rhythm and arthrokinematics.

Phase V: Weeks 14 to 24 Postoperatively

Goals

- Continue strengthening, focusing on scapular stabilizing muscles and core strengthening.
- Initiate sports specific exercises.
- Maximize muscular strength, flexibility, and endurance.

Clinical Pearl

Observation of trunk and torso ROM (i.e. combined thoracic extension and rotation) while the patient begins overhead GHJ movements is important. Any asymmetries should be addressed with thoracic spine AROM, joint mobilization and strengthening to prevent return to sport, in particular throwing, without faulty mechanics.

Techniques for Progressive Increase in Range of Motion

Manual Therapy Techniques

- Continue Gr 3 to 4 GHJ mobilization, scapulothoracic joint mobilization as needed.

Soft Tissue Techniques

- PRN as described previously.

Stretching/Flexibility Techniques for the Musculo-Tendinous Unit

- PRN as described previously.

Other Therapeutic Exercises

- Sit ups.
- Begin plank progression (start with half planks or pillars).

Activation of Primary Muscles Involved in Injury Area or Surgical Structures

- Progress to cables for RC strengthening (see below).
- Lat pulls.
- Seated row machine.
- Gentle seated chest press from midrange.

Sensorimotor Exercises

- Hand-eye coordination drills for racquet or overhead athletes.

Open and Closed Kinetic Chain Exercises

- Increase resistance to rotator cuff, middle and lower trapezius, and serratus anterior strength.

- Protraction progression: unilateral at wall, bilateral at table, bilateral ½ kneeling unstable surface.

Techniques to Increase Muscle Strength, Power, and Endurance

- Add "endurance" sets to all PREs.
- Transition from hypertrophic to strength load.

Neuromuscular Dynamic Stability Exercises

- Progress UE weight on unstable surface (i.e., unilateral wall ball perturbations)

Plyometrics

- Begin UE plyometrics (i.e., dribble on floor, progress to wall dribble).

Functional Exercises

- Begin swimming at week 16.

Sport-Specific Exercises

- Overhead athletes begin throwing program (Table 1-3).
- Thrower's Ten (Figure 1-47).

Milestones for Progression to the Next Phase

- Strength 5/5 including RC, middle and lower trapezius and serratus anterior.
- Minimal torso/thoracic ROM deficiencies or asymmetries.

Phase VI: Weeks 24 to 52 Postoperatively

Goals

- Return to sport when full ROM and strength at 90% of contralateral extremity.
- Maintenance of scapular stabilizing strength.
- Maximize core strength and endurance.
- Optimize throwing mechanics and UE agility.
- Prevent future injury.

Clinical Pearl

The authors emphasize ongoing targeted and specific scapular muscular strengthening and optimal scapulohumeral rhythm for successful return to sport. Progress the athlete through a linear periodization consisting of hypertrophy, strength, strength-power, power, and de-load phases. This allows the athlete to build a foundation of strength as the musculoskeletal system responds better to volume rather than intensity after a long period of inactivity. When considering functional exercises, utilize the Olympic lifts and complex training to restore power. As the exercises get more sport specific, choose a dumbbell snatch as an overhead exercise to elicit power. The use of a single arm dumbbell snatch will reinforce the importance of unilateral movement especially in throwing athletes.

Techniques for Progressive Increase in Range of Motion

Stretching/Flexibility Techniques for the Musculo-Tendinous Unit

- Ongoing static stretching for muscle groups used throughout workout to emphasize continued mobility

Techniques to Increase Muscle Strength, Power, and Endurance

- Linear periodization for return to sport.
- Body responds to volume before intensity.
- Weeks 24 to 29: Hypertrophy phase.
  - Higher repetition scheme with longer rest times.
  - 3 days per week of lifting and 2 days per week of conditioning.
- Weeks 30 to 36: Strength phase.
  - Upper/lower body split, multijoint exercises.
  - 4 days per week lifting and 3 days per week of conditioning.
- Week 37: De-load
  - 3 days per week of full body lifting at approximately 65% to 70% max.
  - 2 days per week of conditioning with an increase of mobility exercises.
- Weeks 38 to 44: Strength/Power phase.
  - Reintroduce Olympic lifting.
  - Reintroduce more complex plyometric exercises.
  - 3 days per week of lifting and 3 days per week of conditioning.
- Weeks 38 to 41: 3 days of lifting consisting of total body.
- Weeks 42 to 44: 1 day consisting of upper body lifting, 1 day consisting of lower body lifting, and 1 day consisting of total body lifting.
- Week 45: De-load
  - 3 days per week of lifting and 3 days per week of conditioning.
- Weeks 46 to 52: Power phase.
  - Olympic lifting and complex training.
  - 3 days per week of lifting (2 days per week if in preseason phase).
  - 4 days per week of conditioning (3 days per week if in preseason phase).

Neuromuscular Dynamic Stability Exercises

- Olympic lifting.
  - Clean and Jerk (modifications and variations).
  - Snatch (modifications and variations).

Table 1-3 High School, College, and Professional Baseball Pitchers Interval Throwing Program

Phase I	Return to Throwing Throws at 50% Effort	Phase II	Return to Pitching Throws at Effort Level Given	Phase III	Intensified Pitching
Step 1	Warmup toss to 60′ 15 throws at 30′* 15 throws at 30′* 15 throws at 30′* 20 long tosses to 60′	Step 7	15 throws at 60′6″ (75%)* 20 throws at 60′6″ (75%)* 20 throws at 60′6″ (75%)* 15 throws at 60′6″ (75%)* 20 throws at 60′6″ (75%)*	Step 12	25 fastballs (75%)* 20 fastballs (100%)* 10 fastballs (75%)* 15 fastballs (100%)* 25 fastballs (75%)*

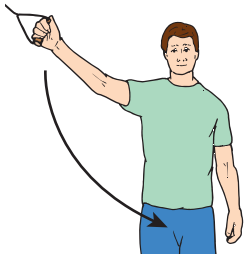
- Power lifts.
  - Deadlift.
  - Squat.
  - Bench press.
- Rotation and antirotation.
  - Cable and banded rotation.
  - Cable and banded antirotation.

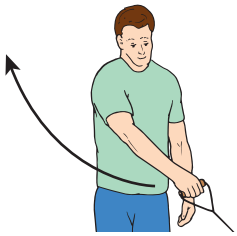
Plyometrics

- Lower body plyometrics.
  - Hurdle hops (double and single leg).
  - Double leg jump.
  - Single leg jump.
  - Single leg bound.
  - Box step-up/step-down.



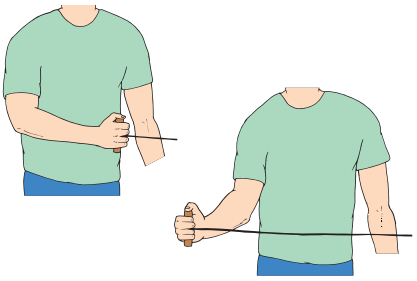
Diagonal pattern D2 extension:
Involved hand will grip tubing handle overhead and out to the side. Pull tubing down and across your body to the opposite side of leg. During the motion, lead with your thumb.

Perform ___ sets of ___ repetitions ___ daily.



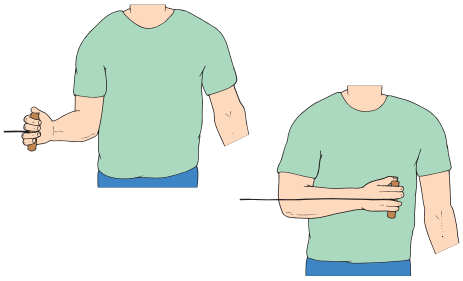
Diagonal pattern D2 flexion:
Gripping tubing handle in hand of involved arm, begin with arm out from side 45° and palm facing backward. After turning palm forward, proceed to flex elbow and bring arm up and over involved shoulder. Turn palm down and reverse to take arm to starting position.

Perform ___ sets of ___ repetitions ___ daily.



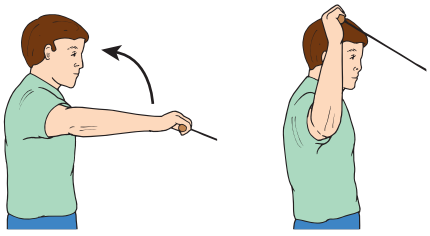
External rotation at 0° abduction:
Stand with involved elbow fixed at side, elbow at 90° and involved arm across front of body. Grip tubing handle while the other end of tubing is fixed. Pull out arm, keeping elbow at side. Return tubing slowly and controlled.

Perform ___ sets of ___ repetitions ___ daily.



Internal rotation at 0° abduction:
Standing with elbow at side fixed at 90° and shoulder rotated out. Grip tubing handle while other end of tubing is fixed. Pull arm across body keeping elbow at side. Return tubing slowly and controlled.

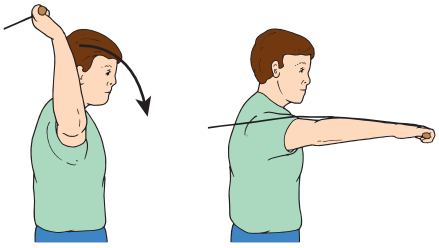
Perform ___ sets of ___ repetitions ___ daily.



(Optional) **External rotation at 90° abduction:**
Stand with shoulder abducted 90°. Grip tubing handle while the other end is fixed straight ahead, slightly lower than the shoulder. Keeping elbow at 90°. Return tubing and hand to start position.

I. Slow speed sets: (Slow and controlled)
Perform ___ sets of ___ repetitions ___ daily.

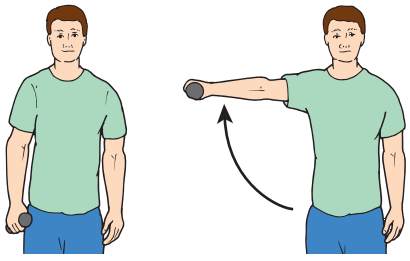
II. Fast speed sets:
Perform ___ sets of ___ repetitions ___ daily.



(Optional) **Internal rotation at 90° abduction:**
Stand with shoulder abducted to 90°, externally rotated 90° and elbow bent to 90°. Keeping shoulder abducted, rotate shoulder forward, keeping elbow bent at 90°. Return tubing and hand to start position.

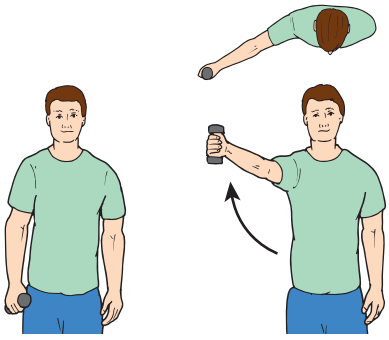
I. Slow speed sets: (Slow and controlled)
Perform ___ sets of ___ repetitions ___ daily.

II. Fast speed sets:
Perform ___ sets of ___ repetitions ___ daily.



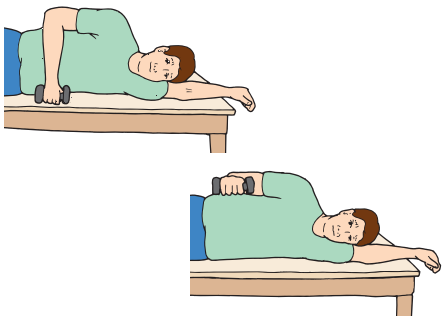
Shoulder abduction to 90°:
Stand with arm at side, elbow straight, and palm against side. Raise arm to the side, palm down, until arm reaches 90° (shoulder level).

Perform ___ sets of ___ repetitions ___ daily.



Scaption, external rotation:
Stand with elbow straight and thumb up. Raise arm to shoulder level at 30° angle in front of body. Do not go above shoulder height. Hold 2 seconds and lower slowly.

Perform ___ sets of ___ repetitions ___ daily.

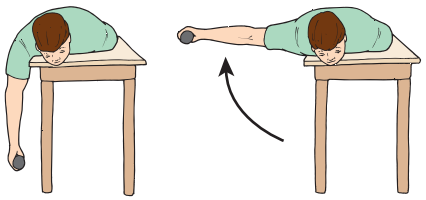


Sidelying external rotation:
Lie on uninvolved side, with involved arm at side of body and elbow bent to 90°. Keeping the elbow of involved arm fixed to side, raise arm. Holds 2 seconds and lower slowly.

Perform ___ sets of ___ repetitions ___ daily.

FIGURE 1-47. The "Thrower's Ten Program" is designed to exercise the major muscles necessary for throwing. The program's goal is to be an organized and concise exercise program. In addition, all exercises included are specific to the thrower and are designed to improve strength, power and endurance of the shoulder complex musculature. *(Modified from Wilk KE, et al: Preventative and rehabilitative exercises for the shoulder and elbow, Birmingham, AL, 2001, American Sports Medicine Institute, pp. 34–37.)*

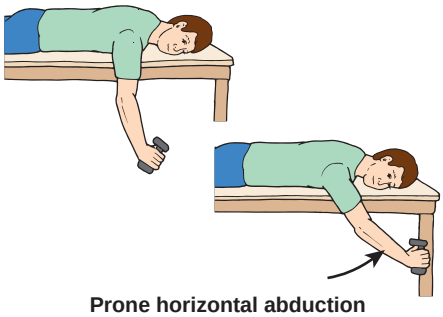
Continued



Prone horizontal abduction (Neutral):

Lie on table, face down, with involved arm hanging straight to the floor, and palm facing down. Raise arm out to the side, parallel to the floor. Hold 2 seconds and lower slowly.

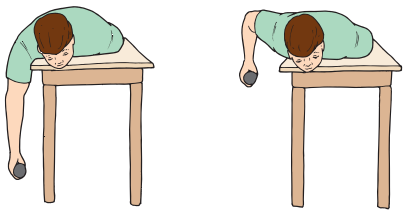
Perform ___ sets of ___ repetitions ___ daily.



Prone horizontal abduction (Full ER, 100° ABD):

Lie on table face down, with involved arm hanging straight to the floor, and thumb rotated up (hitchhiker). Raise arm out to the side with arm slightly in front of shoulder, parallel to the floor. Hold 2 seconds and lower slowly.

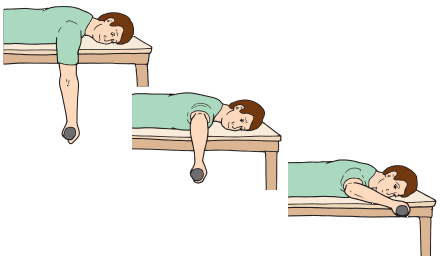
Perform ___ sets of ___ repetitions ___ daily.



Prone rowing:

Lying on your stomach with your involved arm hanging over the side of the table. dumbbell in hand and elbow straight. Slowly raise arm, bending elbow, and bring dumbbell as high as possible. Hold at top for 2 seconds, then slowly lower.

Perform ___ sets of ___ repetitions ___ daily.



Prone rowing into external rotation:

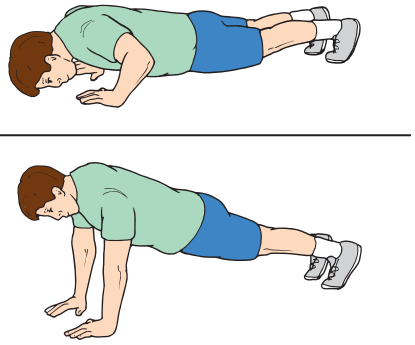
Lying on your stomach with your involved arm hanging over the side of the table, dumbbell in hand and elbow straight. Slowly raise arm, bending elbow, up to the level of the table. Pause one second. The rotate shoulder upward until dumbbell is even with the table, keeping elbow at 90°. Hold at top for 2 seconds, then then slowly lower taking 2-3 seconds.

Perform ___ sets of ___ repetitions ___ daily.

Press ups:

Seated on a chair or table, place both hands firmly on the sides of the chair or table, palm down and fingers pointed outward. Hands should be placed equal with shoulders. Slowly push downward through the hands to elevate your body. Hold the elevated position for 2 seconds and lower body slowly.

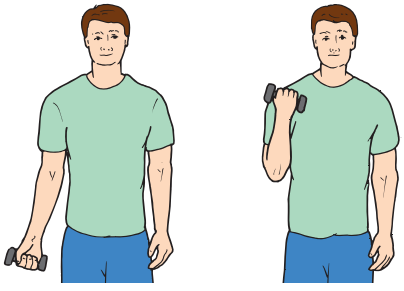
Perform ___ sets of ___ repetitions ___ daily.



Push-ups:

Start in the bottom position with arms in a comfortable position. Place hands no more than shoulder width apart. Push up as high as possible, rolling shoulders forward after elbows are straight. Start with a push-up into wall. Gradually progress to table top and eventually to floor as tolerable.

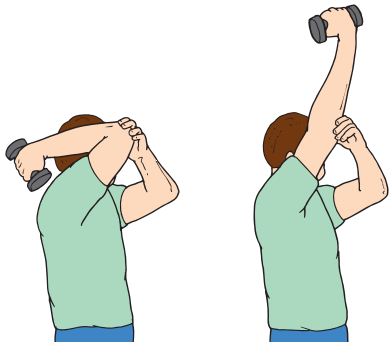
Perform ___ sets of ___ repetitions ___ daily.



Elbow flexion:

Standing with arm against side and palm facing inward, bend elbow upward turning palm up as you progress. Hold 2 seconds and lower slowly.

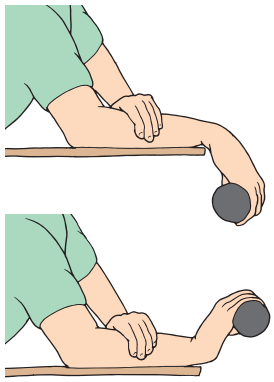
Perform ___ sets of ___ repetitions ___ daily.



Elbow extension (Abduction):

Raise involved arm overhead. Provide support at elbow from uninvolved hand. Straighten arm overhead. Hold 2 seconds and lower slowly.

Perform ___ sets of ___ repetitions ___ daily.

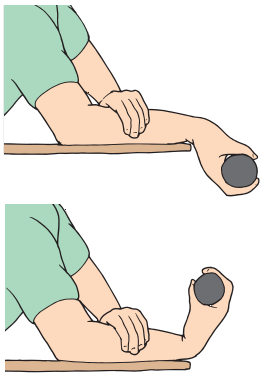


Wrist extension:

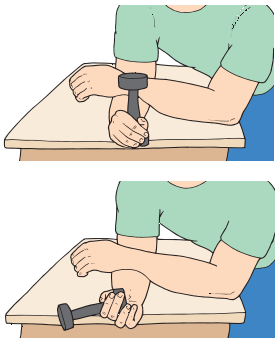
Supporting the forearm and with palm facing downward, raise weight in hand as far as possible. Hold 2 seconds and lower slowly.

Perform ___ sets of ___ repetitions ___ daily.

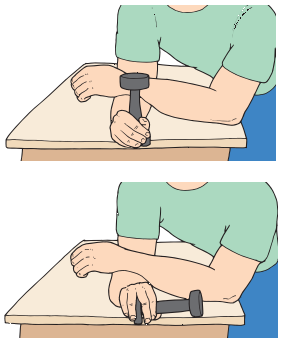
FIGURE 1-47, cont'd



Wrist flexion:
Supporting the forearm ans with palm facing upward, lower a weight in hand as far as possible and then curl it up as high as possible. Hold 2 seconds and lower slowly.
Perform ___ sets of ___ repetitions ___ daily.



Supination:
Forearm supported on table with wrist in neutral position. Using a weight or hammer, roll wrist taking palm up. Hold for a 2 count and return to starting position.
Perform ___ sets of ___ repetitions ___ daily.



Pronation:
Forearm should be supported on a table with wrist in neutral position. Using a weight or hammer, roll wrist taking palm down. Hold for a 2 count and return to starting position.
Perform ___ sets of ___ repetitions ___ daily.

FIGURE 1-47, cont'd

- Box jump/step-down
- Lateral box jump
- Seated box jump
- Depth jump
- Upper body plyometrics
  - Pushup plus
  - Pushup plus beyond ROM
  - Medicine ball pushups
  - Medicine ball standing chest pass
  - Medicine ball seated chest pass
  - Medicine ball lying chest pass
  - Clapping pushups

Functional Exercises

- Olympic lift modifications.
  - Primarily dumbbell snatch as athlete progresses closer to return to sport.
- Power lifts.
- Single arm exercises with dumbbell and neutral grip.
- Single leg exercises.

Sport-Specific Exercises

- Throwing deceleration progression.
- Anti-rotation push/pull exercises.
- Posterior deltoid exercises.

Milestones for Progression to the Next Phase

- Ability to correctly execute sport specific exercises.
- Ability to progress with throwing exercises.

Criteria for Return to Sport

General

- No pain with sport specific movements.
- Full active and passive shoulder ROM without pain.
- Strength greater than or equal to 90% of the contralateral extremity.
- No instability or subluxations/dislocations.

Evidence

Escamilla RF, Fleisig GS, Yamashiro K, et al: Effects of a 4-week youth baseball conditioning program on throwing velocity. *J Strength Cond Res* 24:3247–3254, 2010.

This randomized controlled trial demonstrated the effectiveness of a 4-week baseball conditioning program on increasing maximum throwing velocity of youth baseball players. This authors concluded that a conditioning program including a sport-specific warmup, resistance training, throwing program, and stretching increased throwing velocity. (Level I evidence).

Lauder MA, Lake JP: Biomechanical comparison of unilateral and bilateral power snatch lifts. *J Strength Cond Res* 22:653–660, 2008.

In this study, the authors quantify unilateral and bilateral weightlifting movement data. The findings suggest how unilateral weightlifting variations may provide an alternative training approach for athletes. (Level III evidence).

Owens BD, Dickens JF, Kilcoyne KG, et al: Management of mid-season traumatic anterior shoulder instability in athletes. *J Am Acad Orthop Surg* 20:518–526, 2012.

This article reviews the controversial management of mid-season traumatic shoulder instability. Rehabilitation, bracing and surgical management are discussed. (Level III evidence).

Provencher MT, Ghodadra N, LeClere L, et al: Technical note: anatomic osteochondral glenoid reconstruction for recurrent glenohumeral instability with glenoid deficiency using a distal tibia allograft. *Arthroscopy: J Arthrosc Rel Surg* 25:446–452, 2009.

This article describes a novel surgical treatment of shoulder instability with glenoid bone loss by using a distal tibia allograft. It describes the surgical technique and discusses the, initial results in a series of three patient cases. (Level IV evidence).

Terzis G, Stratakos G, Manta P, et al: Throwing performance after resistance training and detraining. *J Strength Cond Res* 22:1198–1204, 2008.

This study examined the effect of short -term resistance training and a detraining on shot put throwing performance. The authors investigated muscular strength, fat-free mass, muscle fiber type composition and cross-sectional area. Their results suggest that 4 weeks of detraining did not affect performance in moderately resistance-trained subjects. (Level II evidence).

Warner JJ, Gill TJ, O'Hollerhan JD, et al: Anatomical glenoid reconstruction for recurrent anterior glenohumeral instability with glenoid deficiency using an autogenous tricortical iliac crest bone graft. *Am J Sports Med* 34:205–212, 2006.

In this article, the authors review 11 cases of traumatic recurrent anterior shoulder instability that underwent boney reconstruction using an iliac crest bone graft. It was concluded that this is an effective form of treatment for this condition and all patients were able to return to sport without complaint of recurrent instability. (Level IV evidence).

Multiple-Choice Questions

QUESTION 1. What is the minimum time for immobilization following this surgical procedure?

A. 0 weeks.
B. 2 weeks.
C. 4 weeks.
D. 8 weeks.

QUESTION 2. What muscle must be protected for 6 weeks if taken down and reattached during this procedure?

A. Supraspinatus.
B. Subscapularis.
C. Long head biceps.
D. Pectoralis minor.

QUESTION 3. How many days per week should the athlete be lifting during a pre-season power phase?

A. 2 days.
B. 3 days.
C. 4 days.
D. No lifting at all.

QUESTION 4. During which weeks should Olympic lifting be reintroduced to the athlete?

A. Weeks 24 to 29.
B. Weeks 31 to 36.
C. Weeks 38 to 44.
D. Weeks 46 to 52.

Answer Key

QUESTION 1. Correct answer: **C**. (see Phase II, weeks 4 to 6)

QUESTION 2. Correct answer: **B** (see Open Shoulder Stabilization: With Bone Grafting, Clinical Pearl)

QUESTION 3. Correct answer: **B** (see weeks 26 to 52)

QUESTION 4. Correct answer: **C** (see weeks 38 to 44)

Chapter 2

Posterior Shoulder Instability

INTRODUCTION

Demetris Delos, MD, Travis G. Maak, MD, and Russell F. Warren, MD

Epidemiology

- Posterior shoulder instability is less frequently encountered than anterior instability, accounting for only 2% to 10% of all instability cases.[1,2]
- Treatment of this condition can be challenging, and a high index of suspicion is often required for an accurate diagnosis.
- The literature is primarily limited to small case series and retrospective studies; however, from this, an epidemiological pattern emerges.

Age

- Most series describing outcomes after surgical treatment for symptomatic posterior instability report a median patient age between 20 and 30 years.[3,4]
- In a recent report that included the largest series of patients with posterior glenohumeral dislocation to date, the median age at time of diagnosis of posterior *dislocation* was 43 years.[5]

Sex

- Males constitute the majority of patients in most operative series of patients with posterior instability (51% to 100%).[1,3]

Sport

- Sports commonly associated with posterior shoulder instability include
  - American football
  - Overhead weight lifting
  - Rowing
  - Racket sports
  - Swimming
  - Golf

Position

- Lineman in American football
- Bench press, overhead press in weight lifting

Pathophysiology

Intrinsic Factors

Intrinsic factors that may contribute to posterior glenohumeral joint (GHJ) instability may be classified as biological or anatomical in nature.

- Biological
  - Collagen disorders such as Ehlers-Danlos syndrome
  - Generalized ligamentous laxity
- Anatomical
  - Glenohumeral bony abnormalities:
    - Glenoid hypoplasia/dysplasia
    - Glenoid retroversion
    - Humeral retroversion
- Activities such as the following place the shoulder in the provocative position
  - Heavy bench pressing
  - Blocking during American football (such as demonstrated by football linemen)
  - The backswing in golf
- Provocative positions include
  - Flexion
  - Adduction
  - Internal rotation (IR)
- Provocative positions increase the risk of posterior instability (both microinstability and frank dislocation).
- These repetitive activities can lead to microtrauma and attenuation of the posterior inferior glenohumeral ligament (PIGHL) and posterior capsulolabral structures over time.[6–8]

- Pathological attenuation of the posterior structures of the shoulder that can manifest in clinically significant instability can be caused by
  - Overhead weight lifting
  - Rowing
  - Racket sports
  - Swimming

In most cases subluxation events may be painless because of capsular redundancy, which may initiate labral breakdown and injury with subsequent pain. However, acute traumatic dislocation events typically produce frank labral tears.

Classic Pathological Findings

- Pain and/or sense of glenohumeral instability with the shoulder placed in the provocative position (flexion, adduction, IR)
- Attenuation of the posterior inferior glenohumeral ligament and posterior capsulolabral structures
- For frank posterior glenohumeral dislocations, patients often demonstrate a prominent coracoid anteriorly and humeral head posteriorly on examination.
- The shoulder is typically maintained in the adducted, internally rotated position.
- This is why posterior dislocations may be missed in that the patient is most comfortable in a traditional sling.
- Shoulder external rotation (ER) and abduction are limited because of mechanical block.

Clinical Presentation

History

- The patient history is a crucial component of diagnosis and management in posterior shoulder instability.
- Complaints of generalized posterior shoulder discomfort, pain, and weakness are commonly associated with this pathology. Nevertheless, patients may also complain of anterior shoulder pain during shoulder adduction.
- Difficulty with or reduced performance during athletic activities may also be described, including poor performance during bench press or push-ups.[9]
- Although these complaints are less common, the patient may also report mechanical symptoms, including
  - Catching
  - Clicking
  - Popping
- Background regarding the inciting event, including
  - History of trauma
  - Position of the shoulder and arm
- Specifics regarding associated external forces should also be elicited.
- Underlying laxity should be evaluated in the absence of trauma, including
  - Patient history of shoulder or other joint instability
  - Family history of instability or other diagnosed collagen disorders
- Any history of prior surgical procedures, including anterior stabilizations, especially those performed on the injured shoulder, should be ascertained and reviewed.
- Although it is frequently difficult to discriminate between purely voluntary and traumatic instability, any history regarding previous instability including chronic voluntary dislocation may be useful in this regard.

Physical Examination

- Aids to supplement the information acquired during the patient history may be focused based on this information.
- In addition to a detailed shoulder examination, previous history suspicious for laxity should prompt a general examination for hypermobility. Use of the Beighton criteria for hyperlaxity is most helpful in this regard.
- Physical exam tests include
  - Approximating the thumb to the volar surface of the forearm
  - Hyperextension of the second metacarpophalangeal (MCP) greater than 90°
  - Hyperextension of the elbow
  - Recurvatum/hyperextension of the knee
  - The ability to lay the palm of the hand flat on the floor with the knees straight
- If at least three of these five test results are positive, then laxity is likely present.
- The sulcus test is an important test that can be used to assess for inferior glenohumeral laxity/instability of the shoulder.
- To perform this test
  - Apply downward traction to the patient's elbow or wrist.
  - Observe the shoulder for dimple (sulcus) lateral or inferior to the acromion.
- If the size of the sulcus does not reduce with ER, a defect in the rotator interval may be present.[10]
- Side-to-side comparisons should always be performed for accurate diagnosis.
- A thorough shoulder examination should begin with observation.
  - Contour should first be inspected.
  - Any prior incisions should be thoroughly reviewed.
- Muscle atrophy is not typically present except in chronic cases of rotator cuff tear or nerve palsy.
- Tenderness to palpation may be elicited along the posterior GHJ line.
- Evaluate
  - Range of motion (ROM; both active and passive)
  - Motor strength
- Compare with the contralateral side.
- Useful provocative tests for suspected posterior instability include
  - The posterior stress test
  - The jerk test
  - The load and shift
  - The modified load and shift
  - The Kim test (Figure 2-1)[11]

FIGURE 2-1. The load and shift test should be performed with the patient in a supine position to stabilize the scapula. The arm should then be placed in the plane of the scapula with an axial load placed on the elbow while the humerus is shifted on the glenoid as demonstrated here.

- The current authors suggest performing these provocative tests with the patient in the supine position to stabilize the scapula and isolate the GHJ.
- The posterior stress test is performed with the examiner applying a posterior force to the humerus with the arm flexed and internally rotated in an attempt to subluxate or dislocate the joint.
- The jerk test is performed with the patient seated or standing; the shoulder is flexed to 90° and internally rotated. With the elbow flexed the examiner applies a load posteriorly—the test result is positive if a sudden "jerk" occurs when the subluxated humeral head relocates into the glenoid fossa.
- The load and shift (patient seated) and modified load and shift (patient supine) are also useful to gauge the degree of posterior humeral head translation across the glenoid.
- Finally, the Kim test was recently described and has been shown, in conjunction with the jerk test, to have sensitivity for detecting posterior instability as high as 97%.[12] To perform the Kim test, the examiner should abduct the affected arm 90°, forward flex 45°, and then apply a posteroinferior load to the humerus. The exam is positive if pain is elicited with this maneuver.

Any prior history of cervical pathology or neuropathic symptoms should prompt a more focused examination of dermatomal sensation and motor strength.

Imaging

- Plain radiographs should be obtained in all patients, such as
  - An anteroposterior view of the GHJ (Grashey view)[13]
  - Scapular-Y view
  - Axillary view
- Specific views including the West Point or Stryker-Notch views may be included if clinical concern exists for a glenoid rim or a reverse Hill-Sachs lesions, respectively.
- These images should be critically evaluated for
  - Evidence of posterior glenoid rim fractures (reverse bony Bankart lesions)
  - Anterior humeral head impaction fractures (reverse Hill-Sachs lesions)
  - Bennett lesions
  - Early osteoarthrosis
  - Increased humeral or glenoid retroversion
  - Dynamic radiographs may also be indicated in patients with voluntary instability.[10]
- A computed tomography (CT) scan may be used to more clearly delineate the osseous morphology and identify previously unrecognized humeral and glenoid fractures (Figure 2-2).
- Calculation of the glenoid and humeral version and the degree of glenoid bone loss can be performed on axial cross-sectional images at the level of the mid-glenoid.[14]

Some authors have also used CT arthrography to evaluate the posterior and superior labrum and the capsule.[15] However, the intracapsular injection that is required to perform CT arthrography may artificially distend the glenohumeral capsule and hinder identification of a patulous capsule. Although the current authors routinely used CT to evaluate the glenohumeral osseous morphology, magnetic resonance imaging (MRI) with cartilage sensitive sequences is preferred for evaluation of soft tissue structures.

- MRI and MR arthrography (MRA) is used to evaluate the associated soft tissues, including
  - Labrum and capsule
  - Rotator cuff
  - Biceps complex
  - Rotator interval
- Care should be placed on complete evaluation of the images, including humeral-based injuries such as a posterior humeral avulsion of the glenohumeral ligament (PHAGL), especially when no glenoid-based pathology is identified (Figure 2-3).

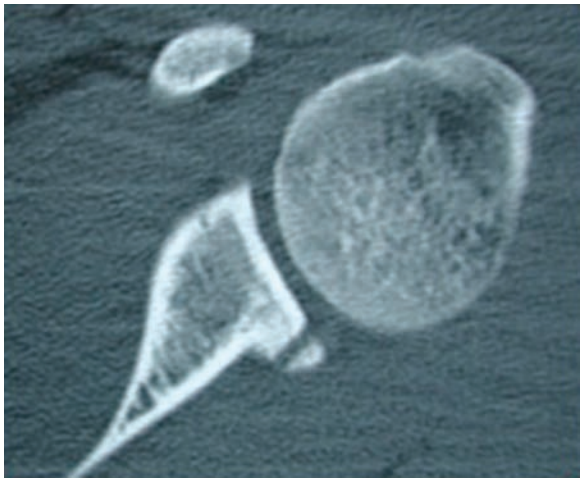

FIGURE 2-2. Axial CT image demonstrating a reverse bony Bankart injury. Care should be placed on complete evaluation of these injuries to ensure adequate preservation of bone stock before surgical stabilization.

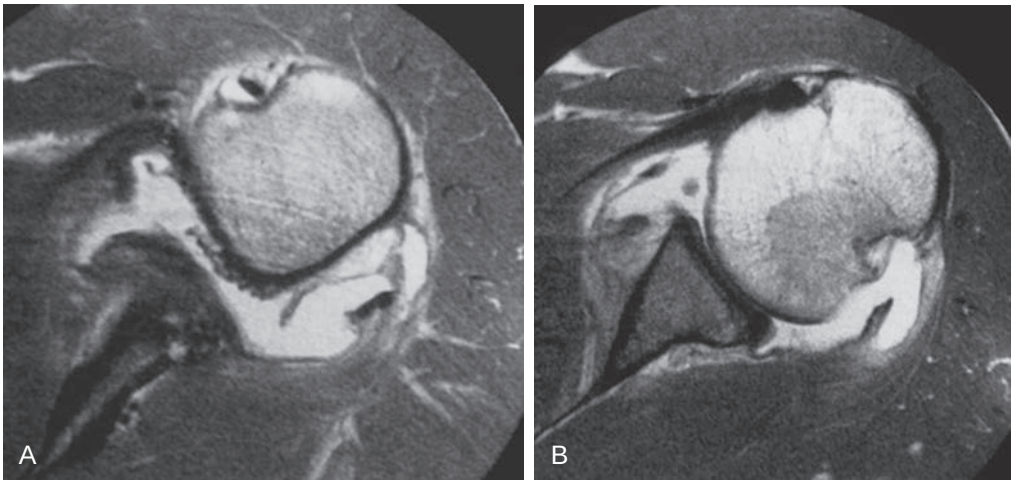

FIGURE 2-3. Axial MRI images demonstrating a posterior humeral avulsion of the glenohumeral ligament. **A,** Periosteum and subchondral bone can be seen attached to the capsule and (**B**) the donor defect in the humerus can be visualized.

- The presence and extent of posterior labral injury should also be identified, including extension of injury to the anterior labrum. In this regard, Kim et al.[16] have suggested a classification scheme for posterior labral tears. Preoperative identification of all associated pathology will facilitate planning and optimize postoperative outcomes.

Differential Diagnosis

- As previously described, posterior glenohumeral instability presents with
  - Complaints of posterior shoulder pain
  - Sensation of instability with the arm in the following position
    - Forward flexed
    - Adducted
    - Internally rotated
- Pain in this position may mimic pathology with the acromioclavicular joint or superior labrum, including a SLAP lesion.
- Nevertheless, this complete constellation of symptoms may not exist, but rather, the patient may demonstrate only a subset of signs and symptoms.
- In this vein, the differential diagnosis and fundamental differences among these diagnoses should be considered.

The following pathologies must be included in the differential diagnosis of posterior shoulder pain in addition to traumatic or atraumatic posterior glenohumeral instability:

- Posterior osteoarthritis
- Tear of the superior labrum from anterior to posterior (SLAP)
- Subluxating tendon of the long head of the biceps
- Acromioclavicular pathology
- Rotator cuff tear
- Proximal humerus fracture
- Scapular fracture
- Cervical radiculopathy
- Oncological lesions

The vast majority of these etiologies may be eliminated with a

- Careful history
- Physical examination
- Plain radiographic imaging

Nevertheless, more subtle differentials exist such as posterior instability with concomitant radiculopathy. In these circumstances, both diagnoses should be completely evaluated, including

- Imaging
- Electromyography
- Nerve conduction studies, if applicable, such that management and patient outcome can be optimized

Additionally, differentiating between multidirectional instability (MDI) and atraumatic unidirectional instability with mild generalized laxity can be difficult. In this circumstance, the data obtained during the aforementioned history and physical examination can significantly aid the surgical or nonsurgical options, which are detailed in the following.

- Adding to the diagnostic difficulty of posterior instability is the fact that the patient may present with anterior shoulder pain, particularly with shoulder adduction and have no sensation of posterior pain.
- Finally, concomitant or previously unappreciated pathology may be identified at the time of the arthroscopic or open surgery and may confirm or alter the preoperative plan. For this reason, the current authors perform a diagnostic arthroscopy before any posterior stabilization procedure to augment the preoperative plan and ensure that all contributing pathology is appropriately addressed.

Treatment

- In general, an initial course of nonoperative management including the following should be attempted before surgical intervention.[6,17]
  - Physical therapy
  - Rehabilitation for posterior glenohumeral instability

Strengthening dynamic muscular stabilizers allow patients to compensate for damaged or deficient static stabilizers, resulting in improved stability and pain control in a majority of those with posterior subluxation.[6,17]

- This approach is successful in 65% to 80% of atraumatic patients with MDI.[17,18]
- However, prior data have demonstrated that this nonoperative approach is less successful in patients with a history of trauma, with 70% to 89% success rate in atraumatic patients compared with 16% success in patients with a traumatic history.[17]
- Patients with a specific identified injury or posterior labral tear can also have documented recurrent instability following nonoperative management.[19]

Nonoperative Management

Nonoperative management represents the mainstay for primary treatment of posterior shoulder instability.[6,17]
Physical therapy, including

- Improving scapular stability
- Strengthening the dynamic stabilizers surrounding the GHJ will facilitate postoperative recovery and may obviate the need for surgical management in some cases. Physical therapy and rehabilitation has been particularly effective in patients with atraumatic posterior instability and MDI.
- Prior studies have documented success rates between 65% and 80% in patients with MDI and up to 89% in those with atraumatic, unidirectional posterior instability.[17,18,20]
- Nonoperative management of patients with traumatic, unidirectional posterior instability, however, has demonstrated success in only 16% of cases.[20]
- High recurrence rates following nonoperative management have also been documented in patients with a specific identified injury or radiographic evidence of a posterior labral tear.[19]

These data are in accordance with the current authors' clinical experience; thus, the suggested nonoperative treatment algorithm is similar. Nonoperative treatment is suggested as the first management modality in patients with an atraumatic instability etiology or with clinical evidence of MDI. Athletes competing in contact sports, however, typically exist in the traumatic, unidirectional posterior instability category; thus, early operative management is often recommended for this population.

Surgical Indications

The principal indication for open or arthroscopic surgical management of posterior glenohumeral instability is pain or perceived instability that is refractory to nonoperative measures.

- Although the main etiology of both symptoms is underlying glenohumeral instability, pain represents the most common presenting symptom.
- Optimal surgical outcomes have been associated with patients who have posttraumatic, unidirectional recurrent instability.
- Nevertheless, these patients represent a subset of patients with posterior glenohumeral instability, which also includes MDI, voluntary instability, and atraumatic posterior instability, among others.
- Surgical management may include either arthroscopic or open approaches, and both approaches may be combined in some situations depending on the identified pathology.
- Open surgical stabilization has been previously recognized as the gold standard for recurrent posterior instability with excellent outcomes[21–23]; however, recent advancements in arthroscopic techniques and instrumentation have resulted in many surgeons using this approach as the primary treatment method.
- It is the current authors' opinion that at this time posterior instability can be more effectively managed with an arthroscopic approach.
- Open surgical stabilization, on the other hand, may be indicated in cases including
  - Contact athletes
  - Revision stabilization
  - Significant generalized laxity or poor tissue quality
  - Excessive capsular insufficiency
  - Bony deficiency
  - Glenohumeral retroversion
- Open posterior stabilization has many advantages over an arthroscopic approach, including a complete visualization of the posterior capsule, which provides the opportunity for the treating surgeon to address labral pathology as well as perform a full posterior capsular shift.
- In addition, bone loss that is identified at the time of surgery can be addressed with a variety of osseous procedures in combination with the posterior capsular shift.
- Pollack et al.[24] suggested the capsular shift as the workhorse procedure for addressing posterior glenohumeral instability, with good to excellent results in up to 80% to 90% of patients.[6]
- These authors also noted that concomitant procedures should be used when necessary to address all apparent pathology.
- They suggested using bone block augmentation only in the setting of revision surgery with bony deficiency or glenoid hypoplasia.[24]
- This suggestion is based on the higher incidence of recurrent instability following posterior stabilization in patients with
  - Large posterior bony Bankart lesions
  - Glenoid hypoplasia
  - Significant humeral or glenoid retroversion
- Increased failure because of recurrent instability has also been identified in contact athletes and patients with significant capsular laxity or engaging reverse Hill-Sachs lesions.[24]
- Notably, although open surgical stabilization has been suggested in these patient populations, recent data have demonstrated improved outcomes following arthroscopic posterior stabilization in contact athletes.[25]
- Contraindications to surgery include voluntary instability with a psychogenic etiology and poor patient compliance.

Following appropriate patient indication for surgical stabilization, the surgeon must decide among the various

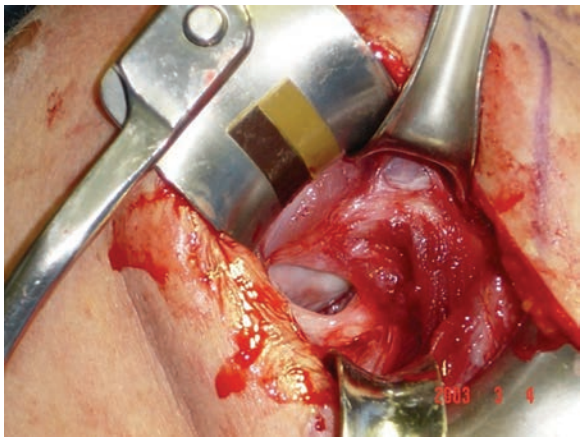

FIGURE 2-4. Open posterior stabilization may be required in the setting of significant capsular deficiency, as seen in this image.

stabilization options. As previously mentioned, the posterior capsular shift is commonly used as the principal stabilization procedure.[3,19,26–28] This capsular shift is performed through an open approach. The arthroscopic capsular plication and posterior labral repair can also be used in a similar fashion to effectively address soft tissue deficiency and laxity (Figure 2-4).[29] Other soft tissue procedures may include

- Posterior biceps tendon transfer[4,16]
- Subscapularis transfer[18,31]
- Posterior capsule reconstruction with the tensor fascia lata[30]
- Posterior Putti-Platt repair[17,22]

If the aforementioned indications for bony procedures are identified pre- or intraoperatively, then the following may be performed for bony deficiency greater than 20%, glenoid retroversion greater than 15°, or humeral retroversion greater than 60°, respectively:

- Bone block augmentation[1,11–13,15,21]
- Glenoid opening wedge osteotomy[30–34]
- A humeral rotational osteotomy[9,24]

Despite the multitude of treatment options, however, the current authors use an arthroscopic posterior capsular plication and labral repair with suture anchor fixation in the vast majority of patients, including contact athletes with recurrent posterior instability (Figure 2-5). Bony procedures are very rarely used and only in revision cases or patients with significant bony deficiency or glenoid retroversion.

Complications

Although surgical management of posterior glenohumeral instability has been associated with excellent patient outcomes, complications also have been reported, including

- Stiffness
- Neurological injury to the suprascapular and axillary nerves
- Early osteoarthritis
- Recurrent instability and subcoracoid impingement

Recurrent instability represents the most common complication, with reported rates up to 23% following open posterior capsular shift, and may require revision surgical stabilization.[21,35] Recurrence may be caused by failed index stabilization or recurrent trauma.[6,22] If revision stabilization is necessary, postoperative outcomes have been improved in posttraumatic patients compared with failure of the index stabilization.[6,22]

- Axillary and suprascapular nerve injury has also been reported, mainly following open posterior stabilization.[36,37] Fortunately, these injuries are rare and have been associated with
  - Excessive dissection
  - Retraction
  - Suture entrapment

Stiffness has been reported in up to 36% of patients with reduced ROM in IR and abduction.[3,13,33] Fortunately, the majority of these patients do not require intervention, except for athletes, who require increased ROM, including overhead-throwing athletes such as football quarterbacks. In this circumstance, stiffness may impede return to play, and intervention may be required, including

- Manipulation under anesthesia
- A capsular release at 6 months postoperatively

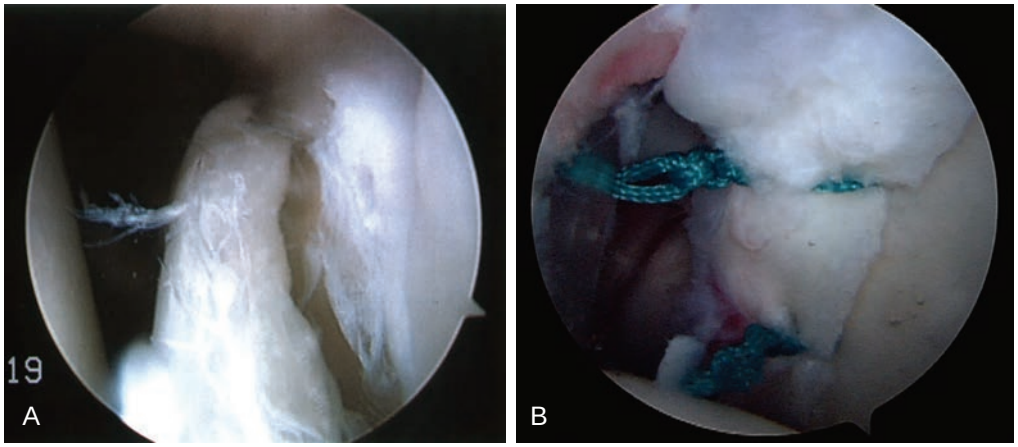

FIGURE 2-5. Arthroscopic posterior stabilization represents the current authors' preferred treatment method for posterior shoulder instability. **A,** The posterior labral tear can be easily visualized from the anterior portal and (**B**) repaired with suture anchor glenoid fixation.

Care should be taken, however, to perform a minimal release and not produce recurrent instability.

- Stiffness owing to overtightening during the posterior capsular shift or plication may not only produce decreased IR and abduction but may also lead to
  - Increased GHJ reaction forces
  - Altered mechanics
  - Scapular winging
  - Arthropathy
- Previous data have hypothesized that postcapsulorrhaphy arthropathy may be caused by increased shear forces that are concentrated at the posterior glenoid rim. These forces may lead to
  - Chondral injury
  - Early glenohumeral osteoarthritis[38]
- On the other hand, post-stabilization osteoarthritis has also been associated with iatrogenic etiologies, including
  - Bone block humeral head impingement
  - Prominent intraarticular hardware
  - Glenoid fracture

Evidence

Bigliani LU, Pollock RG, McIlveen SJ, et al: Shift of the posteroinferior aspect of the capsule for recurrent posterior glenohumeral instability. *J Bone Joint Surg Am* 77:1011–1020, 1995.

This study used open posterior capsulorrhaphy to manage patients with posterior shoulder instability and reduced the preoperative instability in 83% of patients. Subjective 5-year follow-up good to excellent results were obtained in 80% of shoulders and 71% of these patients returned to full activity. An 11% recurrence rate was documented and revision outcomes were noted to be worse than primary stabilization procedures. (Level IV evidence)

Fuchs B, Jost B, Gerber C: Posterior-inferior capsular shift for the treatment of recurrent, voluntary posterior subluxation of the shoulder. *J Bone Joint Surg Am* 82:16–25, 2000.

A unique subset of patients with recurrent, voluntary posterior shoulder instability was treated with open posterior capsulorrhaphy. Good to excellent results were reported in 93% of these patients, although a recurrent instability rate of 23% was documented. (Level IV evidence)

Kim SH, Park JS, Jeong WK, et al: The Kim test: A novel test for posteroinferior labral lesion of the shoulder—a comparison to the jerk test. *Am J Sports Med* 33:1188–1192, 2005.

A prospective cohort study of 172 painful shoulders was conducted, of which 33 had a positive Kim test result demonstrating a posteroinferior labral lesion. Twenty-four of these patients had radiographic evidence of a posteroinferior labral lesion. Among the remaining 133 shoulders with a negative Kim test, only six had radiographic evidence of a posteroinferior labral tear. Sensitivity of the Kim test was 80%, and specificity of the test was 94%.

Provencher MT, Bell SJ, Menzel KA, et al: Arthroscopic treatment of posterior shoulder instability: Results in 33 patients. *Am J Sports Med* 33:1463–1471, 2005.

Thirty-three consecutive patients with posterior instability caused by traumatic and atraumatic etiologies were treated with arthroscopic posterior stabilization with suture anchor technique. Seven failures were reported because of recurrent instability or pain. Significant improvements were noted in multiple outcome measures; however, worse outcomes occurred with patients with voluntary instability or prior shoulder surgery. (Level IV evidence)

Wolf BR, Strickland S, Williams RJ, et al: Open posterior stabilization for recurrent posterior glenohumeral instability. *J Shoulder Elbow Surg* 157–164, 2005.

Open posterior capsulorrhaphy was used to successfully treat 84% of patients with posterior shoulder instability and produce a 74% rate of return to play at the baseline level. Additionally, only 19% of patients experienced postoperative instability symptoms, and no evidence of radiographic arthrosis was identified. (Level IV evidence)

Multiple Choice Questions

QUESTION 1. Posterior glenohumeral joint instability accounts for what percent of all shoulder instability cases?

A. 90%
B. 60%
C. 30%
D. 10%

QUESTION 2. Patients with posterior glenohumeral instability often report symptoms when the shoulder is placed in

A. extension, adduction, and external rotation.
B. extension abduction, and internal rotation.
C. flexion, adduction, and external rotation.
D. flexion, adduction, and internal rotation.

QUESTION 3. Intrinsic causes of posterior glenohumeral instability include

A. glenoid hypoplasia.
B. collagen disorder (e.g., Ehlers-Danlos).
C. humeral retroversion.
D. all of the above.

QUESTION 4. What is the most common complication after surgical management of posterior shoulder instability?

A. Axillary nerve palsy
B. Axillary artery laceration
C. Recurrent instability
D. Intraoperative fracture

QUESTION 5. All of the following provocative tests can be used to help diagnose posterior instability except:

A. Jerk test
B. Kim test
C. Martin test
D. Load and shift

Answer Key

QUESTION 1. Correct answer: **D** (see Epidemiology)

QUESTION 2. Correct answer: **D** (see Pathophysiology)

QUESTION 3. Correct answer: **D** (see Pathophysiology)

QUESTION 4. Correct answer: **C** (see Treatment)

QUESTION 5. Correct answer: **C** (see Clinical Presentation)

POSTOPERATIVE REHABILITATION AFTER OPEN OR ARTHROSCOPIC POSTERIOR SHOULDER STABILIZATION

Emilie Schmidt, DPT, SCS, ATC, CSCS, Amy Resler, DPT, CMP, CSCS,
Michael D. Rosenthal, PT, DSc, SCS, ECS, ATC, CSCS, CAPT, and
Matthew T. Provencher, MD, MC, USN

Indications for Surgical Treatment

- Failure of nonoperative treatment
- Persistent activity-related pain and/or pain with instability with desire to continue in these sports/activities
- Optimized nonoperative care, especially optimization of the scapular stabilizers, pectoralis minor stretching, and subscapularis strengthening
- In the nonathletic population, conservative treatment is recommended for a minimum of 3 to 6 months and would discern their level of symptoms and activities in which they are limited before deciding on surgery.
- Surgery may be recommended earlier in an athlete.

Brief Summary of Surgical Management

Major Surgical Steps

- General anesthesia and shoulder arthroscopy
- Patient in lateral decubitus position
- Diagnostic arthroscopy to document all pathology
- Keep scope posterior and start preparation of the posterior labrum
- Preparation of the glenoid labrum at the labrum–bone junction for adequate healing after repair (Figures 2-6 and 2-7).
- Arthroscopic capsulolabral repair with suture anchors (usually 2.4 to 3.0 mm in diameter) and repair of the capsule and labral structures (Figures 2-8 and 2-9).
- Reduction of glenohumeral joint (GHJ) volume, especially in the posteroinferior quadrant (noting that posterior instability most commonly occurs at the 7 o'clock position), with capsular imbrication and repair with sutures.
- Padded abduction sling postoperatively for a total of 5 to 6 weeks. Consider use of an external rotation (ER) sling to reduce strain on repaired posterior capsular structures.

Factors That May Affect Rehabilitation

Anesthetic

- For regional anesthesia: the block may wear off 8 to 24 hours after the case. Be cognizant of rebound pain and use subsequent modalities.
- *Surgical*
- Amount of capsulolabral repair:
  - Posterior only (centered at 7 o'clock): 90° posterior quadrant repair versus more extensive repair
  - Posterior with some anterior augmentation (if tear extends anteriorly): will need to work on anterior capsule and note that an anterior repair was done for rehabilitation considerations. It is key to understand that the pathology of posterior instability is at 7 o'clock as the shoulder subluxes posteroinferiorly out of the joint.

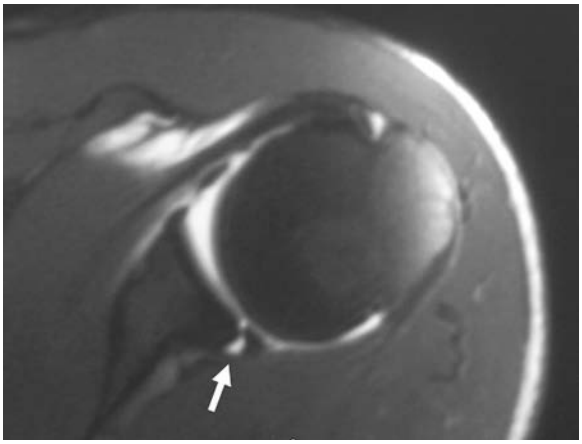

FIGURE 2-6. Magnetic resonance arthrogram of a posterior labral tear.

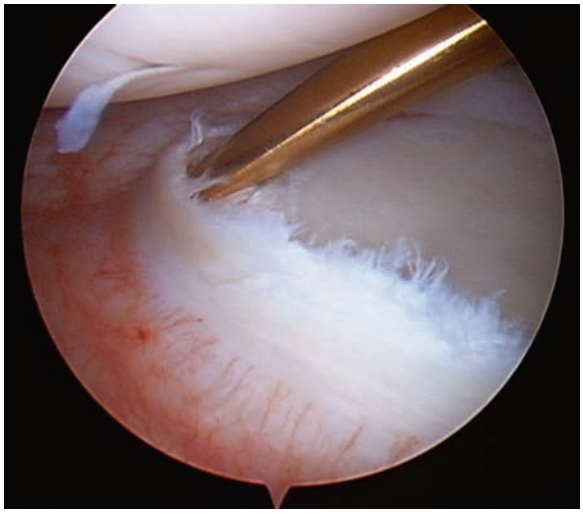

FIGURE 2-7. Posterior labral tear. Preparing the tear for surgical repair with an elevator device.

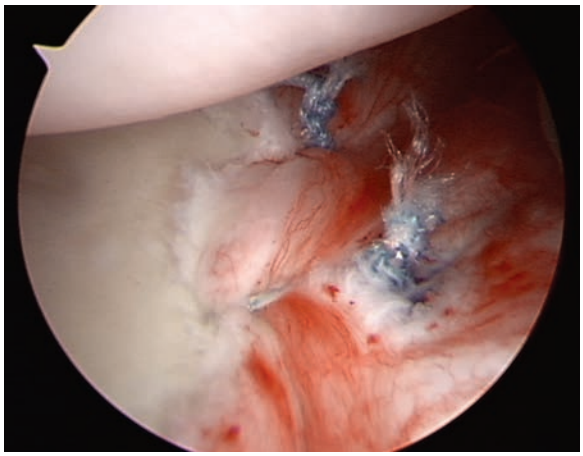

FIGURE 2-8. Posterior labral repair.

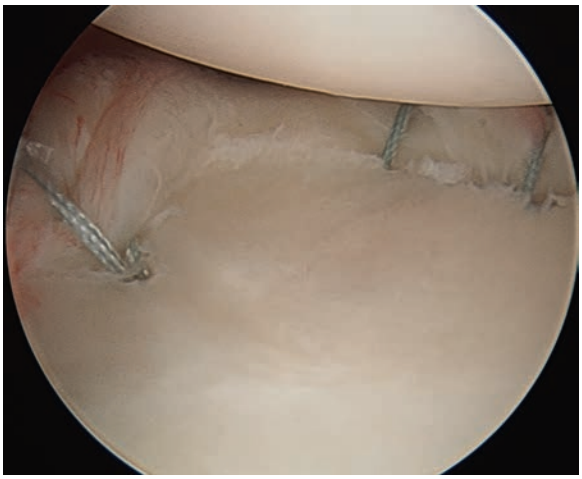

FIGURE 2-9. If the tear extends anteriorly, this is repaired posteriorly and then extended anteriorly for a balanced inferior 180° repair of the glenoid labrum.

- Additional repair construct (e.g., rotator interval closure): may lead to a tighter shoulder with ER at the side (Figure 2-10).
- If case is performed open, the posterior rotator cuff (infraspinatus and teres minor) will need to be protected for 6 weeks.

Before Surgery: Overview of Goals, Important Milestones, and Guidelines

Steps to Minimize Debilitation and Atrophy

Clinical Pearl

Pursuit of normal motor patterns, correction of scapular dyskinesis, and restoration of glenohumeral and scapulohumeral arthrokinematics preoperatively will aid in postoperative recovery. Thorough movement-pattern evaluation is a key component to preoperative posterior instability rehabilitation. Recognition of faulty motor patterns associated with pain complaints will assist the therapist in developing a treatment program that will effectively and efficiently address movement pattern dysfunctions.

Supervised Exercises

- Open and closed chain scapular stability: Scapular clocks with and without manual resistance, scapular depression (manual, resisted with tubing, Graviton).
- Rotator cuff isokinetic/progressive resistive exercises (PREs): tubing, Thera-Band, cable column IR/ER at 0, 45°, and 90° of abduction
- Serratus anterior exercises: wall slides (Figure 2-11) with and without resistance, supine punch (Figure 2-12), standing cable/band punch. (Care should be taken to avoid posterior-directed forces during traditional serratus anterior strengthening exercises such as plank-plus and pushup-plus.)
- Scapular stability: prone Y, T, W, I (Figure 2-13), closed chain Swiss ball movement patterns, standing shoulder flexion/scaption (open can position with scapular setting)
- PNF patterns and rhythmic stabilization

Modalities During Treatment

- Transcutaneous electrical nerve stimulation (TENS) to control pain as well as inhibit muscular guarding when performing both passive (PROM) and active (AROM) ROM exercises
- Interferential current (IFC) electrical stimulation to assist with pain and inflammation following treatment sessions

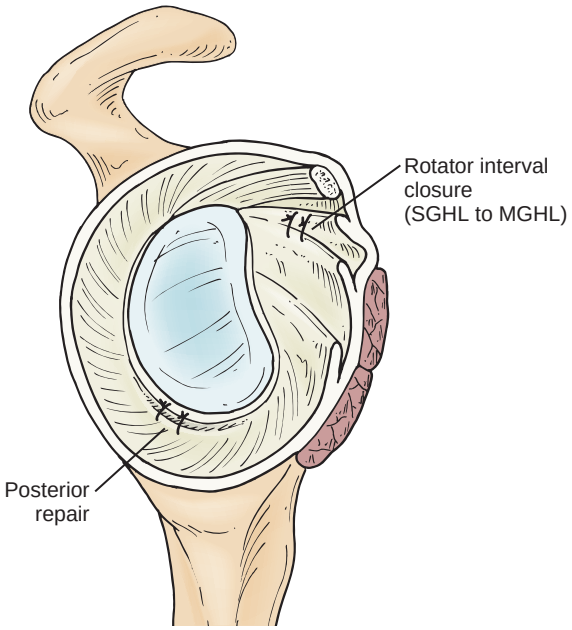

FIGURE 2-10. Typical arthroscopic rotator interval closure: Two sutures are placed to arthroscopically imbricate the superior to middle glenohumeral ligaments after the posterior instability repair is completed.

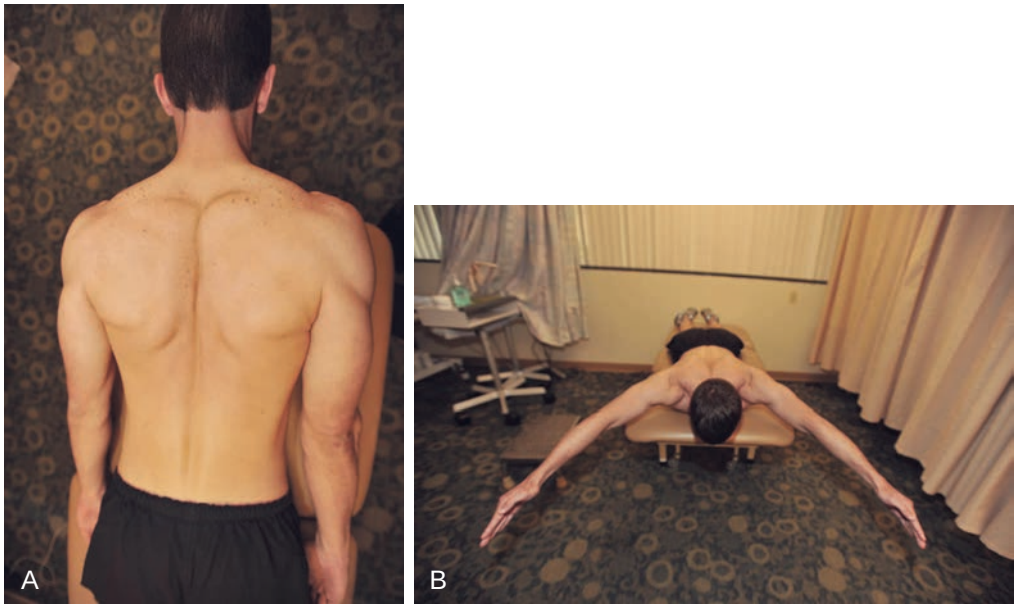

FIGURE 2-13. A,B, Prone Y, T, W, I.

- Thermal agents and/or cryotherapy for muscle guarding and inflammation[1]
- Neuromuscular electrical stimulation (NMES) in patients with a concomitant nerve injury such as suprascapular nerve neurapraxia

Steps to Relieve Disability of Acute Injury

Exercise

- Joint protection following an acute traumatic subluxation or posterior dislocation via sling for comfort
- Supported Codman's pendulum exercises for passive and active assisted ROM with the modification of elbow support of the contralateral side (Figure 2-14)
- Rest, ice, compression, and elevation (RICE) for 7 to 10 days
- Gradual return to AROM activities: pulleys, wands, wall walks, table slides
- Progressive strengthening and motor control per preceding recommendations
- Continuation of cardiovascular activities
- Pain should be respected and thereby serve as an indication of safe progression during this phase.

Modalities

- IFC electrical stimulation for pain and inflammation
- Cryotherapy for pain and spasm reduction

Steps to Relieve Disability of Chronic Injury

Exercise

- Avoid instability and pain-producing activities. Educate the patient about positions and activities likely to create episodes of instability, such as cross-chest horizontal adduction and posterior axial loading with the arm elevated greater than 90°.
- Posterior rotator cuff (infraspinatus/teres minor) exercises are essential, as is eccentric control of the subscapularis.
- Emphasis on scapulohumeral rhythm

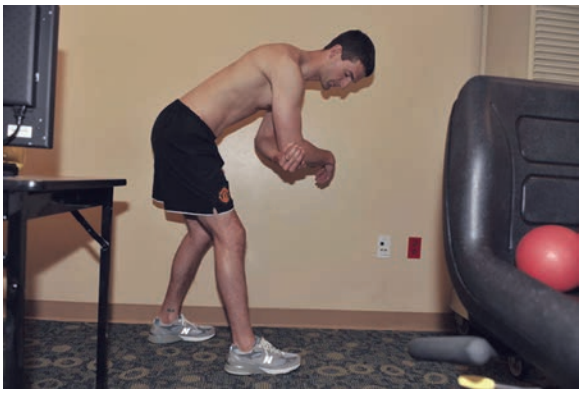

FIGURE 2-14. Supported Codman's pendulum exercises.

- Concomitant injuries of the rotator cuff must be recognized and accurately diagnosed to avoid undue stresses on other injured tissues during rehabilitation of chronic injuries
- See the preceding for supervised and home exercises for rehabilitation recommendations.

Modalities

- IFC electrical stimulation and/or TENS to reduce pain
- Biofeedback and NMES to assist in restoring motor control
- Thermal agents and cryotherapy to reduce spasm, pain, and inflammation

Phase I (days 0 to 14 postop)

Protection

- Postoperative immobilization is achieved via sling use with the arm in slight abduction and neutral rotation.
- A sling with an abduction pillow is preferred because of patient comfort and proper positioning to prevent stress to the healing posterior structures.
- Sling is to be used at all times, including sleep.

TIMELINE 2-1: **Postoperative Rehabilitation After Open or Arthroscopic Posterior Shoulder Stabilization**

PHASE I (weeks 0 to 2)	PHASE II (weeks 2 to 6)	PHASE III (weeks 6 to 10)
• Sling • PT modalities • ROM: scapular plane elevation to 90° • Active assistive Codman's exercises • TBS/TAS/TLS activities as recommended and tolerated	• Sling d/c at 4–5 weeks • PT modalities • ROM wk 4: scapular plane elevation to 120° • ROM wk 6: scapular plane elevation to 160° • ROM wk 4: start flexion to 90° • ROM wk 6: ER to 30° • ROM wk 6: IR to 0° • TBS/TAS/TLS activities as recommended and tolerated • Scapular exercises • Week 4: AROM exercises • Week 4: submax isometrics for GHJ muscles • Week 6: submax isometrics for ER	• PT modalities as needed • PROM: full • Mobilizations as needed • TBS/TAS/TLS activities as recommended and tolerated • Scapular exercises: PREs • TAS: biceps/triceps PREs • GHJ exercises: PREs • Rotator cuff exercises: PREs • Limit IR exercises to minimize strain to posterior capsule • PNF exercises • OKC rhythmic stabilization exercises • CKC exercises • Week 10: seated pressups and increased weight-bearing through joint • CKC manual perturbation exercises

Management of Pain and Swelling

- Regional anesthetic block or a regional pain pump (not intraarticular)
- Oral pain medications
- Therapeutic modalities for pain and inflammation to include TENS, Hi-Volt, and IFC electrical stimulation
- TENS to control pain as well as inhibit muscular guarding when performing PROM
- Continuous cryotherapy for pain and inflammation reduction[2]
- Patient education: using pillows or bolsters to find a "position of comfort" to reduce stress on contractile structures of the shoulder as well as repaired structures

Techniques for Progressive Increase in Range of Motion

Manual Therapy Techniques

- ROM precautions: IR 0°, humeral elevation in scapular plane 90° (precautions adjusted for other concurrent surgical repairs such as SLAP or Bankart repairs)
- PROM: manual range of humerus (per precautions) as well as affected elbow, wrist, and scapula. Muscular guarding should be considered and manual therapy adjusted as necessary to facilitate relaxation to avoid undue stresses on the posterior capsulolabral complex.

Stretching and Flexibility Techniques for the Musculotendinous Unit

- Shoulder stretching is not to be performed during this stage with the exception of the cervical musculature (i.e., levator scapula, upper trapezius) as needed.

Other Therapeutic Exercises

- Athletes are encouraged to participate in low-intensity cardiovascular conditioning activities such as stationary biking or treadmill walking. The sling must be worn during these activities, and if there is increased pain or muscle guarding, the activity should be adjusted.

Activation of Primary Muscles Involved in Injury Area or Surgical Structures

- Hand gripping and active wrist flexion-extension ROM activities initiated
- Codman's pendulum exercises to maintain passive motion at the GHJ. Because of improper technique, which is often observed clinically, the authors recommend the use of assisted Codman's with sound-side support of the affected arm (see Figure 2-14).

Milestones for Progression to the Next Phase

Goals of the immediate postoperative phase:
- Protect the repaired structures.
- Minimize the effects of immobilization.
- Decrease pain and inflammation.

Assuming the athlete is progressing without complications (signs of infection, frank signs and symptoms of instability or repair failure, or intractable pain limiting ROM tolerance), progression to the next phase is allowed.

Phase II (weeks 2 to 6 postop)

Protection

- Use of the sling is continued. If arthroscopic labral repair was performed without involvement of the rotator cuff musculature or biceps tendon, the sling may be discontinued at 4 to 5 weeks postoperatively depending on surgeon preference and patient compliance with ROM restrictions.

TIMELINE 2-1: **Postoperative Rehabilitation After Open or Arthroscopic Posterior Shoulder Stabilization** (Continued)

PHASE IV (weeks 10 to 14)	PHASE V (weeks 14 to 24)	PHASE VI (weeks 24 to 52)
• PT modalities as needed • PROM: full • Mobilizations as needed • Week 12: IR sleeper stretch • TBS/TAS/TLS activities as recommended and tolerated • Scapular exercises: PREs • TAS: biceps/triceps PREs • GHJ exercises: PREs • Rotator cuff exercises: PREs • Thrower's 10 • Limit IR exercises to minimize strain to posterior capsule • PNF exercises • OKC rhythmic stabilization exercises • CKC exercises • CKC manual perturbation exercises	• PROM: maintain full motion • Mobilizations as needed • TBS/TAS/TLS activities as recommended and tolerated • Scapular exercises: PREs • TAS: biceps/triceps PREs • GHJ exercises: PREs • Rotator cuff exercises: PREs • Thrower's 10 progress intensity • PNF exercises • OKC rhythmic stabilization exercises • CKC exercises • CKC manual perturbation exercises • Plyometrics: two-arm progressing to one-arm • Overhead strengthening exercises • Sport-specific exercises begin • Overhead throwing athletes can begin an easy interval throwing program • 20 weeks: begin full-windup throwing	• PROM: maintain full motion • Mobilizations as needed • TBS/TAS/TLS activities as recommended and tolerated • Scapular exercises: PREs • TAS: biceps/triceps PREs • GHJ exercises: PREs • Rotator cuff exercises: PREs • IR/ER exercises at 90° • Thrower's 10 progress intensity • PNF exercises • OKC rhythmic stabilization exercises • CKC exercises • CKC manual perturbation exercises • Plyometrics: two-arm chest passes progressing to 90/90 one-arm plyos • Overhead strengthening exercises • Sport-specific exercises progressed • Overhead throwing athletes progress through an interval throwing program

Table 2-1 Postoperative Range of Motion Guidelines

	Range of Motion					
Postoperative Time	*Scaption*	*Flexion*	*Adduction*	*Abduction*	*ER*	*IR*
0–14 days*	90	30	0	90	60	0
2–4 weeks*	120	90	0	100	30	0
4–6 weeks*	140	120	0	120	45	0
6–10 weeks**	160	160	20	160	90	70
10–14 weeks	***	***	***	***	***	***

*PROM only
**A/AROM no limitations
***Full AROM

Management of Pain and Swelling

- Electrotherapy (TENS and IFC electrical stimulation) is continued for pain and muscle guarding
- Oral pain medications are usually continued
- Continuous cryotherapy with compression
- Hi-Volt electrical stimulation

Techniques for Progressive Increase in Range of Motion

Manual Therapy Techniques

- ROM precautions: IR 0°, ER 30°, horizontal adduction 0°, scapular plane elevation to 120° at week 4, scapular plane elevation to 140° at week 6, sagittal plane flexion 90° at week 4, and sagittal plan flexion 120° at week 6 (Table 2-1).
- PROM: manual ROM of the humerus (per preceding precautions) while ensuring quality of glenohumeral and scapulothoracic motion and avoidance of excessive/compensatory scapular mobility to impingement. Scapular elevation, depression, and abduction.
- Grades I and III GHJ mobilizations may improve available PROM and also contribute to pain management.
- Posterior capsular stress should be avoided.

Soft Tissue Techniques

- Scar mobilization to postsurgical incisions once closed

Stretching and Flexibility Techniques for the Musculotendinous Unit

- Patients may begin table slides or physio ball rolling for passive techniques within the ROM precautions.
- AROM: Scapular clocks are continued and scapular dumps (performing thoracic rotation while protracting the scapula) are initiated to emphasize thoracic and lumbar mobility.
- Elbow and wrist ROM is encouraged and can be done as part of the home exercise program.
- Pulleys for AAROM may begin during the fourth postoperative week as long as correct technique is demonstrated. As patients gain PROM to 120° in the scapular plane without guarding or pain, AAROM techniques are begun to include flexion and abduction via wands and wall walks with cues to avoid compensatory shoulder shrugs.
- Careful observation for compensation and emphasis on restoring scapulohumeral mechanics is important while increasing ROM during this phase to avoid subacromial impingement.

Other Therapeutic Exercises

- Submaximal isometrics are begun in neutral rotation and less than 30° abduction with the elbow flexed to 90° for flexion, abduction, ER, and extension.
- Scapular squeezes/pinches without resistance may also be added during this phase.
- Lower extremity exercises during this phase may include use of the stationary cycle, stair climber, elliptical, and machine-based lower extremity strength training equipment.

Activation of Primary Muscles Involved in Injury Area or Surgical Structures

- Unsupported Codman's pendulum exercises are continued.
- AROM may be initiated as to include wall walks and standing shoulder raises (arm flexion and scaption in the open can position).
- Patients are reminded to avoid horizontal adduction or IR until postoperative week 6.
- Well-arm exercises are begun to promote the neuromuscular crossover effect.

Sensorimotor Exercises

- Begin active angular replication exercises, for motor control, in the range of 0° to 90° scaption.

Techniques to Increase Muscle Strength, Power, and Endurance

- Lower body strengthening such as wall sits or bodyweight squats and lunges

Neuromuscular Dynamic Stability Exercises

- Lower extremity balance activities such as single-leg balance, BOSU ball (Figure 2-15), star excursion
- Manual rhythmic stabilization of trunk and core

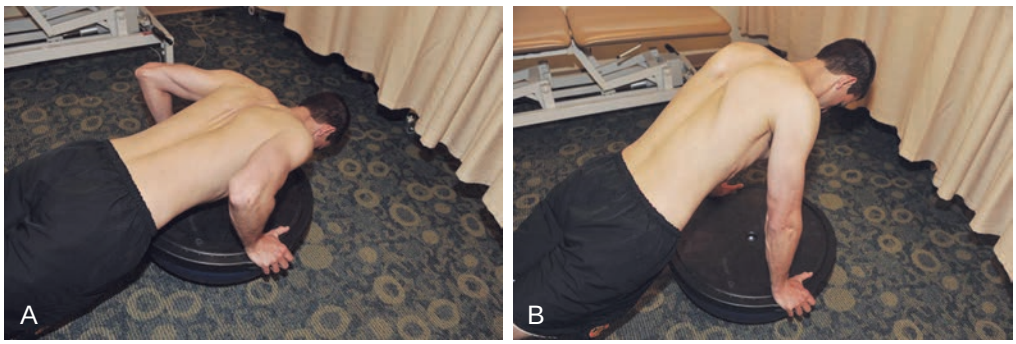

FIGURE 2-15. BOSU ball.

Functional Exercises

- Seated and standing trunk rotation combined with flexion and extension while wearing sling may be performed to maintain thoracolumbar mobility.

Milestones for Progression to the Next Phase

Goals of this phase
- Protect repaired structure.
- Minimize effect of immobilization.
- PROM glenohumeral elevation in scapular plane of 140°, ER 30°
- No marked pain at the posterior GHJ
- No signs or symptoms of instability

Phase III (weeks 6 to 10 postop)

Protection

- Sling use is discontinued.

Management of Pain and Swelling

- Oral analgesic use is continued as needed.
- NSAID therapy may be prescribed for persistent pain.
- IFC electrical stimulation for pain control as needed
- Cryotherapy is used post-therapy to mitigate postexercise inflammation and soreness.

Techniques for Progressive Increase in Range of Motion

Manual Therapy Techniques

- ROM precautions: IR 70°, ER 90°, horizontal adduction 20°, scapular plane elevation 160°, sagittal plane flexion 160°, abduction 160° (see Table 2-1)
- PROM: techniques continue in the scapular plane. Sagittal flexion and IR/ER at 45° of abduction are introduced while respecting pain complaints.
- Joint mobilizations: If adhesions are noted, capsular joint mobilizations may begin in reduced ranges, such as oscillatory techniques grade I to II for inferior and anterior capsule. Care must be taken when assessing posterior capsular structures. Scapular mobilizations continue, including scapular lifts if necessary.

Clinical Pearl

Gradual introduction of posterior and posterior-inferior capsule stretching using skilled manual therapy techniques beginning at the end of Phase III is important to assist with proper scapulohumeral rhythm and restore the glenohumeral arthrokinematics. Often, patients present with biceps tendinopathy or subacromial impingement caused by faulty movement patterns of which the tight posterior and inferior capsule play large roles because of the obligate translation.[3] Therefore, introduction of joint mobilizations grades II to III to the posterior capsule during this timeframe, as long as there is no pain with these techniques or rebound guarding, will aid in restoration of optimal scapulohumeral rhythm and glenohumeral arthrokinematics.

Soft Tissue Techniques

- Scar mobilization techniques including cross-friction are performed to assist with full tissue mobility around the shoulder region.
- Soft tissue techniques may be applied to the biceps tendon at this time as indicated.

Stretching/Flexibility Techniques for the Musculotendinous Unit

- Pulleys (with caution for correct technique to avoid impingement), table slides, wall walks, and wand exercises

Other Therapeutic Exercises

- Cardiovascular: Treadmill walking and stationary biking with increased resistance. Add upper-body ergometer (UBE) within pain-free ranges without resistance. Performing the UBE standing, if possible, provides an integrated conditioning exercise involving the trunk and hip girdle musculature.
- The potential need for upper-body support and loading during the use of stair climbers and elliptical machine activities restricts safe implementation of these conditioning options until 8 weeks postop.

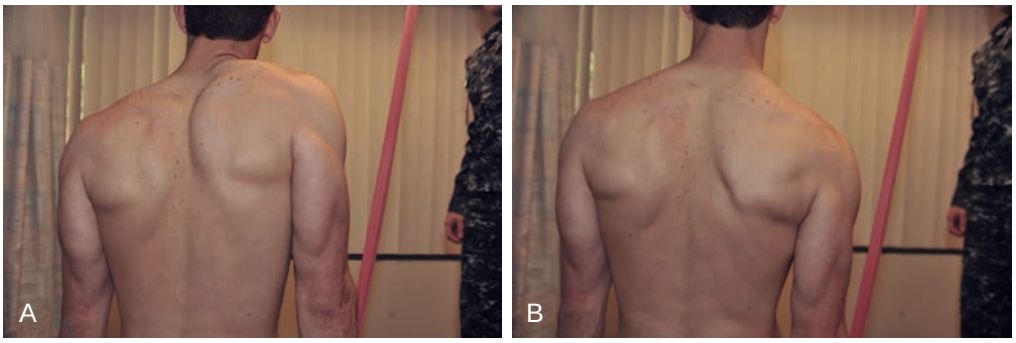

FIGURE 2-16. A,B, Scapular depression using manual cueing with light resistance bands.

- Lower-body strengthening is progressed and may include closed kinetic chain exercises (i.e., lunges, tubing resistance, hip flexion/extension/abduction, wall sits, body weight squats) and open chain resistance exercises.

Activation of Primary Muscles Involved in Injury Area or Surgical Structures

- The scapulohumeral and scapulothoracic muscles should be the primary focus during this phase. Starting to isolate middle and lower trapezius, rhomboid, serratus anterior as well as the rotator cuff musculature is imperative for successful rehabilitation following posterior stabilization.
- Begin scapular depression using manual cueing as needed with light resistance bands (Figure 2-16)
- Progressive resistance exercises (PREs) for scapulothoracic muscles: Prone W, I, Y, and Ts (see Figure 2-13), prone rows, standing forward, and lateral raises (open can position in scapular plane), supine punches (see Figure 2-12), standing facing wall shoulder flexion (wall slides) (see Figure 2-11), scapular pinches, and bilateral shoulder ER with elbow flexed to 90° at neutral abduction.
- Rotator cuff strengthening: side-lying humeral ER (Figure 2-17), standing IR/ER with light resistance tubing may begin. The humerus should not exceed 30° abduction or IR when performing resisted IR because of excessive stress on the posterior capsule.
- Biceps and triceps strengthening with light resistance may begin.

Sensorimotor Exercises

Clinical Pearl

A strategic component to successful *proprioceptive neuromuscular facilitation* (PNF) is patient education for proper positioning throughout: cueing to stabilize scapula before generating upper extremity motion or accepting resistance. In addition, PNF is used to restore movement patterns common to athletes; this includes tracking the upper extremity movement with the eyes, as well as cervical and trunk rotation. This will also prepare the patient for more functional PNF patterns to be performed with tubing or cable resistance later in the treatment progression. PNF patterns are also performed on the nonaffected arm for crossover effect. Scapular PNF patterns are continued throughout this phase progressing from side lying to seated (Figure 2-18) and standing.

- Rhythmic stabilization and manual strengthening of the upper extremity while the patient is supine, seated, or standing
- Progress manual strengthening to include the serratus anterior, rotator cuff, and scapular muscles (i.e., repeated contractions of serratus anterior in supine, side-lying D1 and D2 patterns of scapula, slow reversals)
- The Bodyblade is an effective tool to incorporate (beginning at 8 weeks postop) at 0° abduction as well as 90° scapular elevation (Figure 2-19).
- Active joint repositioning throughout the available pain-free ranges of motion

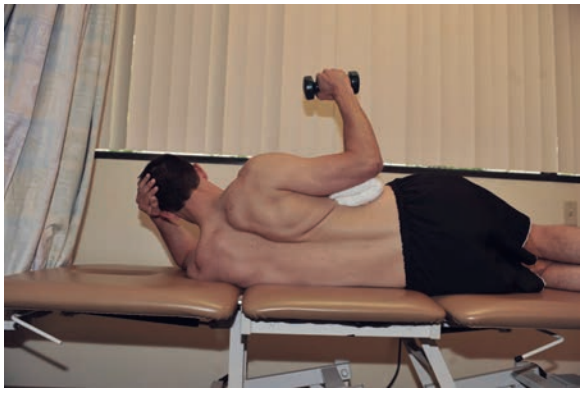

FIGURE 2-17. Side-lying humeral ER.

FIGURE 2-18. Seated proprioceptive neuromuscular facilitation.

FIGURE 2-19. Bodyblade

Open and Closed Kinetic Chain Exercises

- Closed chain proprioception activities: Lightweight medicine ball rotations at 90° scapular plane elevation progressing to 90° forward flexion against a wall and standing upper extremity weight-bearing with weight shifting on a table with the hands at least 1.5 times the bicoronial width to minimize direct posterior shear stresses through the GHJ.
- Beginning at week 10: Seated press ups for the latissimus dorsi as well as increased weight-bearing/loading through the joint is added.
- Pool-based exercises using the water for resistance may be incorporated during this phase if the incisions are well healed. Exercises should include reciprocal motions of IR/ER, flexion/extension, and abduction/adduction.

Techniques to Increase Muscle Strength, Power, and Endurance

- Progress biceps and triceps exercises in standing
- Add light weights to shoulder flexion and scapular plane elevation in the open can position at 8 to 10 weeks postop.
- Progression of lower extremity strength training exercises
- Progress to elliptical and stair stepper for cardiovascular conditioning at week 8.

Neuromuscular Dynamic Stability Exercises

- Progress manual rhythmic stabilization drills for the upper extremity in neutral and advance in varying degrees of abduction (0 to 90°) as ROM allows. Performing these exercises in sitting and standing will increase core recruitment and integrated work with the shoulder complex.

Milestones for Progression to the Next Phase

- AROM 150° scapular plane elevation
- AROM 45° degrees ER at neutral abduction
- AROM IR thumb to L1 reaching behind back
- PROM IR 70° at 90° abduction (In the overhead athlete, IR at 90° abduction is expected to be slightly less in the dominant arm, so full symmetry may not be the goal depending on specific patient demands.)
- Normal glenohumeral and scapulothoracic mechanics

Phase IV (weeks 10 to 14 postop)

Management of Pain and Swelling

- Oral NSAIDs may be continued. If pain continues to be a limiting factor to progression, the patient should return to the surgeon for reassessment.
- IFC electrical stimulation may also be used to assist with pain.
- Cryotherapy is used post-treatment sessions to mitigate muscle soreness or exercise-induced inflammation.

Techniques for Progressive Increase in Range of Motion

Manual Therapy Techniques

- PROM to full ROM (see Table 2-1)
- Graded GHJ mobilizations progressing to include grades III to IV may be incorporated to ensure full capsular mobility by the end of week 14.

Soft Tissue Techniques

- Assess the need for soft tissue mobilization to the pectoralis major/minor, subscapularis, and latissimus dorsi.

FIGURE 2-20. Sleeper stretch.

- Scar mobilizations are also included to minimize incisional adhesions.
- Monitor for development of biceps tendon and posterior rotator cuff pain and direct soft tissue mobilization to these tissues as indicated

Stretching and Flexibility Techniques for the Musculotendinous Unit

- PROM focusing on gentle end-range stretching
- Latissimus dorsi, pectoralis major/minor stretching
- IR stretching beginning 12 weeks postop via activities such as cross chest stretching and the "sleeper stretch" (Figure 2-20)
- Hot packs may be used prior to stretching and tissue flexibility to facilitate muscle relaxation

Clinical Pearl

Posterior capsule stretching should be closely monitored to ensure stabilization of the scapulothoracic joint. Without stabilization of this joint, stretching may impact the most "willing" tissue, which will equate to an increase in scapular mobility/scapulothoracic muscle stretching more so than the posterior capsule. Maintenance of posterior capsule integrity is paramount; therefore, patient education on restoration of mobility, avoidance of pain, and reporting any feelings of shoulder instability are important.

BOX 2-1 Thrower's 10 Exercises

- Diagonal pattern (D2) flexion
- Diagonal pattern (D2) extension
- Humeral ER at 0° abduction
- Humeral IR at 0° abduction
- Humeral ER at 90° abduction
- Humeral IR at 90° abduction
- Shoulder flexion to 90°
- Shoulder scaption
- Prone horizontal abduction at neutral
- Prone horizontal abduction with full ER at 100°
- Prone row
- Pressups
- Pushups
- Bicep curls/elbow flexion
- Triceps extension/elbow extension
- Wrist extension/wrist flexion
- Wrist supination/wrist pronation

Other Therapeutic Exercises

- The thrower's 10 exercises (Box 2-1) are implemented for strengthening of the shoulder complex.
- Resistance is increased within pain tolerance and the precautions of avoiding forced horizontal adduction and sagittal plane axial loading with the arm past neutral horizontal adduction.

Activation of Primary Muscles Involved in Injury Area or Surgical Structures

- Humeral IR/ER rotator cuff strengthening exercises are progressed to 90° abduction.
- Lat pulldowns in front of head are introduced.
- Bent-over rows with light dumbbell or kettle bell (Figure 2-21)

Sensorimotor Exercises (Proprioception, Kinesthesia)

- GHJ PNF D1 and D2 patterns while seated or standing (see Figure 2-18)

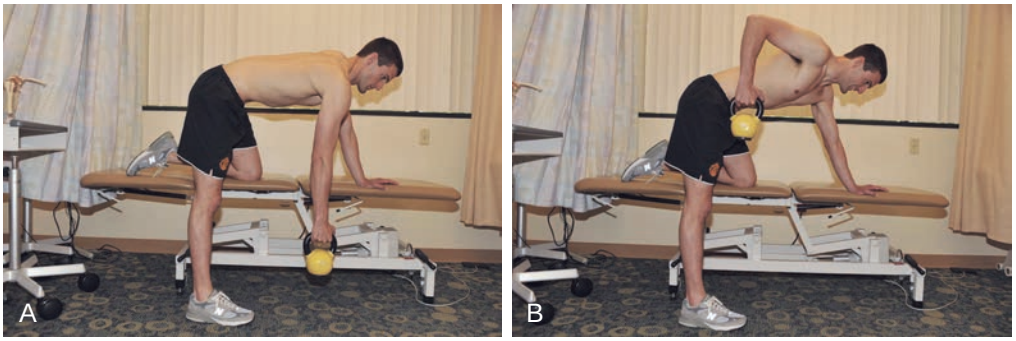

FIGURE 2-21. A,B, Bent-over rows with a light dumbbell or kettle bell.

Open and Closed Kinetic Chain Exercises

- Closed-chain activities progress to include a pushup progression beginning with wall pushups advancing to table height pushups and finally floor pushups.
- Athletes are encouraged to avoid locking out the elbows during this phase to avoid excessive loading of the posterior capsule. Hand width during closed kinetic chain (CKC) exercises should remain slightly wider than the bisacromial distance.

Techniques to Increase Muscle Strength, Power, and Endurance

- Lower extremity single-leg balance activities are progressed.
- Front squats may be introduced initially with medicine ball hugs rather than bar.
- Alternating endurance sets (perform a static hold set with resistance at mid-to-end range) to all upper extremity resistance exercises (hypertrophic load in this phase, 12 to 25 repetition sets)

Neuromuscular Dynamic Stability Exercises

- Rhythmic stabilization is progressed to standing and in positions with decreased base of support, open chain or unstable surface.
- Axial compression drills: closed chain on unstable surface (i.e., Airex pad, weighted ball, tilt boards) (Figure 2-22)
- Manual perturbation to the trunk while in dynamic closed chain loaded position

Plyometrics

- Lower extremity plyometric drills (i.e., multidirectional lunge)
- Upper extremity wall dribble
- Plyoback/rebounder exercises to include chest pass, ER/IR ball toss, and catch

Functional Exercises

- Begin a walk-jog progression at 3 months postoperatively.

FIGURE 2-22. Closed chain on unstable surface.

Sport-Specific Exercises

- Lower extremity sport-specific drills in a controlled environment at 3 months postoperatively (i.e., hopping, jumping, changes in direction/agility drills)

Outcome Measures

- Patient-reported outcome scales should be implemented by the 12-week follow-up and administered at a minimum during the 3-, 6-, 9-, and 12-month follow-up appointments. Scales that have been used in the literature for posterior instability include the Western Ontario Shoulder Instability Index (WOSI); American Shoulder and Elbow Surgeons Rating Scale; Single Assessment Numeric Evaluation (SANE); Subjective Patient Shoulder Evaluation Score; Penn Shoulder Score; Simple Shoulder Test; and Disabilities of the Arm, Shoulder and Hand (DASH) Score.[4,5]

Milestones for Progression to the Next Phase

- Normal scapulohumeral rhyth
- Full PROM all planes
- AROM within functional limits, pain-free flexion and abduction
- Strength manual muscle testing grade IV to V throughout the scapulothoracic and scapulohumeral muscles

Phase V (weeks 14 to 24 postop)

Techniques for Progressive Increase in Range of Motion

Manual Therapy Techniques

- Continue as in the preceding to achieve full capsular mobility.
- Joint mobilization grade III to IV as indicated

Soft Tissue Techniques

- Scar mobilizations as necessary

Stretching and Flexibility Techniques for the Musculotendinous Unit

- Athletes are instructed in full glenohumeral and scapulothoracic stretching techniques as well as cervical, thoracic, and lumbo-pelvic-hip mobility.

Other Therapeutic Exercises

- Progress thrower's 10 exercises with increased intensity and resistance as tolerated.
- Progress lower extremity, gluteal, and hip strength exercises.

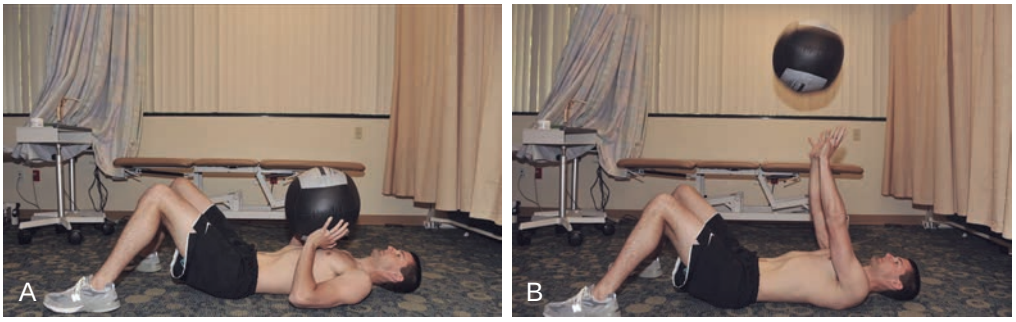

FIGURE 2-23. A,B, Overhead bilateral medicine ball slams and overhead medicine ball catching.

Activation of Primary Muscles Involved in Injury Area or Surgical Structures

- As before with progressive resistance

Open and Closed Kinetic Chain Exercises

- OKC: upright rows, seated rows, lateral raises, front raises
- OKC: ER/IR at 0° and 90° abduction, isotonic/resistance bands, PNFs, diagonal lift, and wood chop resistance exercises
- OKC: tubing fencing, step and punch, plate push
- OKC: pool resisted motions
- CKC: side planks, front planks and weight shifts on stable and progress to unstable surfaces. Figure-of-8s on a slide board in quadruped or standing with pressure against a wall.
- The BOSU ball can be used for progression of pushups to uneven surfaces for CKC activities (Figure 2-22)
- CKC may also include slide board exercises in quadruped or pushup position.

Techniques to Increase Muscle Strength, Power, and Endurance

- Advance endurance sets to strength exercises (repetitions of 6 to 10 per set)
- Implement an undulating periodization model for strength training

Neuromuscular Dynamic Stability Exercises

- The pushup progression leads to dynamic bilateral upper extremity wall pushups and then to single-arm dynamic pushups on the wall.
- The progression then leads to dynamic floor pushups.
- Rhythmic stabilization performed in quadruped

Plyometrics

- Plyometrics are initiated using bilateral arm throwing patterns beginning with chest pass motions into a rebounder and progressing to single-arm tosses.
- Overhead bilateral medicine ball slams and overhead medicine ball catches are also added (Figure 2-23).
- These activities progress to single-arm activities.
- Rebounder IR/ER at 90° abduction as well as supine IR/ER ball catch and toss with the therapist is incorporated.

Functional Exercises

- Overhead strengthening is incorporated as well as lower extremity agility drills, including ladder and hurdle drills as well as running progression (intervals, sprints).
- Resistance exercises in standing progress from double leg to single leg stance, asymmetrical resistance, and unstable surfaces.
- Initiate lower extremity agility program.

Sport-Specific Exercises

- Throwing athletes may begin light tossing at shorter distances and are instructed to avoid full wind-up throws until 20 weeks postop. Progression of throwing intensity may begin at 20 weeks as long as the patient demonstrates normal mechanics. Throwing should be closely monitored and discontinued if the athlete exhibits any compensatory movement patterns or shoulder girdle discomfort.
- Progression to formal strength and conditioning commences when athletes have full gross strength and AROM and are pain free with activity.

Outcome Measures

- Patient-reported outcome scales (see Phase IV). Recommend utilization of scales that are most consistent with the patient population being evaluated. Utilization of two or three scales is reasonable.

Milestones for Progression to the Next Phase

- Full pain-free uncompensated AROM
- No episodes of instability
- Manual muscle testing grade 5/5 strength of rotator cuff, shoulder, and scapular stabilizers
- Isokinetic testing for assessment of dynamic strength, power, and endurance may be implemented.[6] Assessment may include motions of IR, ER, flexion, extension, abduction, and adduction. Side-to-side ratios

should be within 85%, same-side ratio for ER to IR should be within 70%, and abduction to adduction 80%.
- Outcome scores at 24 weeks should be greater than 80%.

Phase VI (weeks 24 to 52 postop)

Management of Swelling

- Ice application post exercise

Techniques for Progressive Increase in Range of Motion

- Patients should have achieved full AROM by 6 months.

Manual and Soft Tissue Techniques

- Manual therapy techniques as previously stated for Phase V if full mobility is not yet achieved
- Additional joint mobilizations will be directed towards restricted joints and may include the GHJ (grade III to IV), scapulothoracic joint (usually not necessary at this late stage), and thoracic spine.
- Instructing the patient in self-management techniques with commercially available products or simply using a tennis ball or racquet ball will provide long-term self-treatment options.

Stretching and Flexibility Techniques for the Musculotendinous Unit

- Home stretching for posterior capsule progression: supine horizontal stretch, supine horizontal stretch with IR, sleeper stretch, and sleeper stretch with rollover[7]
- Continued utilization of sustained end range stretching to achieve desired symmetrical or required mobility
- Pre-performance/exercise stretching should focus on functional movement patterns that prepare the athlete for return to sport activity

Other Therapeutic Exercises

- Integrated training activities at this stage should include multijoint movements (i.e., front squats, power or hang cleans, clean and press)

Activation of Primary Muscles Involved in Injury Area or Surgical Structures

- Focus in the late stage of recovery is on establishing preinjury levels of function.

Sensorimotor Exercises

- Ball-toss exercises in standing
- D1/D2 movements with cables
- Medicine ball
- Progression to slosh ball
- Rapid repositioning drills and reaction movement drills

Open and Closed Kinetic Chain Exercises

- Advancing the previous exercises in accordance with sport-specific demands
- Examples of progression may include kettle bell swings and overhead lifts such as kettle bell snatches.
- More aggressive posterior axial loading in the sagittal place may begin in preparation for return to athletics.

Techniques to Increase Muscle Strength, Power, and Endurance

- Isokinetic training
- Refining and integrating the undulating periodization model to optimize recovery and return to athletics

Neuromuscular Dynamic Stability Exercises

- Resistance exercises in standing progress from double- to single-leg stance, asymmetrical resistance, and unstable surfaces as necessary to replicate anticipated performance demands

Clinical Pearl

Reinjury is more likely to occur when the athlete is overworked and receives posterior-directed stress on the fatigued GHJ complex. In order to optimally prepare the athlete for full return to sport, dynamic stability exercises and strength training must be taken to a sufficient level of stress to closely replicate the strength, power, and endurance demands that will be encountered.

Plyometrics

- Advanced to increasing level of difficulty (i.e., overhead tossing with a light-weight ball, dynamic pushups, hand-walking up and down over a step or ball)

Sport-Specific Exercises

- By 24 weeks postop, athletes may have begun light sport-specific training, such as short tossing for throwing athletes and limited overhead stroke work for swimmers, tennis, and volleyball players.
- A progression of throwing volume and intensity may begin at the 24th to 28th week mark in baseball and softball players.
- For athletes involved in sports with repeated anteroposterior axial stress to the GHJ, increased loading will begin during this phase
  - Weight training may now safely progress to include pressing exercises at bisacromial width at grip.
  - Wrestlers may progress to drills in the quadruped position with an increasing amount of partner drill work.
  - Football players may increase sport-specific activities, to include bag work (i.e., punches, swim techniques) for linemen and one-on-one drills.

Milestones for Progression to the Next Stage

- Less than 10% side-to-side deficit on isokinetic testing
- CKC testing may include the CKC upper extremity stability test and/or the upper extremity Y-balance test.
- Integrated power tests may include the vertical jump, standing backward overhead medicine ball throw, and standing rotational medicine ball throw. Preinjury test values would provide the best measure of functional recovery as sport-/position-specific normative data are limited.
- Patient-reported outcome scales at 36 and 52 weeks should be greater than 90%.

Criteria for Return To Sport

General

- Normal scapulothoracic and glenohumeral mechanics
- Full AROM without instability or scapular dyskinesis
- Minimum of 90% (side-to-side) symmetry on isokinetic testing of muscular strength, power, and endurance. ER to IR ratio at least 70%.
- CKC testing and integrated power tests with good quality of motion and maintenance of scapulothoracic and core stability throughout the tests with no report of shoulder pain or instability.

Sport Specific

- Implementation of return-to-sport criteria must include a demand/needs analysis of the chosen sport. The rehabilitation specialist should be able to analyze the demands on the shoulder complex and create a sufficient series of tests and exercises to ensure readiness for return to preinjury levels of activity.

After Return to Sport

Continuing Fitness or Rehabilitation Exercises

- Total-arm and total-body strengthening exercises

Exercises and Other Techniques for Prevention of Recurrent Injury

- Prevention of recurrence requires continued maintenance of dynamic neuromuscular control (strength, mobility, kinesthetic awareness, and proprioception). Degradation in any of these areas could put the athlete at risk for reinjury if a high degree of physical demands on the reconstructed posterior GHJ are continued.

Although sport-specific training is essential to ensure readiness for return to sport, a training program that does not include reactive drills and a diversity of training modalities can result in a shoulder complex unable to adapt to the ever-changing demands of athletic competition.

Multiple Choice Questions

QUESTION 1. When should stretching of the posterior capsule to promote restoration of normal mobility commence following posterior reconstruction?

A. 2 to 6 weeks
B. 6 to 10 weeks
C. 10 to 14 weeks
D. 14 to 24 weeks

QUESTION 2. When is it safe to begin posterior axial loading in the sagittal plane following posterior capsule reconstruction?

A. 6 to 10 weeks
B. 10 to 14 weeks
C. 14 to 24 weeks
D. 24 to 52 weeks

QUESTION 3. When is it safe to incorporate low amplitude joint mobilizations following posterior capsule reconstruction?

A. 0 to 2 weeks
B. 2 to 6 weeks
C. 6 to 12 weeks
D. greater than 12 weeks

QUESTION 4. When should full GHJ PROM be achieved following posterior capsule reconstruction?

A. 2 to 6 weeks
B. 6 to 10 weeks
C. 10 to 14 weeks
D. 14 to 24 weeks

Answer Key

QUESTION 1. Correct answer: **B** (see Phase III: Clinical Pearl)

QUESTION 2. Correct answer: **C** (see Phase V: Neuromuscular Dynamic Stability Exercises)

QUESTION 3. Correct answer: **B** (see Phase II: Manual Therapy Techniques)

QUESTION 4. Correct answer: **C** (see Phase IV: Techniques for Progressive Increase in Range of Motion)

BEYOND BASIC REHABILITATION: RETURN TO FOOTBALL AFTER POSTERIOR SHOULDER STABILIZATION

Travis G. Maak, MD, and Russell F. Warren, MD

Introduction

Aspects of Football that Require Special Attention in Rehabilitation

Posterior shoulder instability may result from both traumatic and atraumatic etiologies.

This injury is particularly prevalent in football and may result from an acute, traumatic subluxation or dislocation from a high-energy posteriorly directed force on an outstretched arm or, more commonly, from multiple subluxations due to recurrent posterior load on a forward flexed, adducted, internally rotated shoulder.

This posterior loading and subsequent recurrent subluxation is particularly common in football linemen. Associated posterior labral injury and capsular laxity may be treated nonoperatively; however, continued instability frequently requires surgical stabilization.

Careful postoperative consideration should be given to the football player's position, specifically linemen, in regard to rehabilitation and return to play.

Rehabilitation following posterior shoulder stabilization and return to football participation typically occurs in four distinct phases:

- Recovery phase (weeks 2 to 4)
- Range of motion (ROM) phase (weeks 4 to 8)
- Strengthening phase (weeks 8 to 12)
- Sport-specific conditioning phase (weeks 12 to 18)

This phase-specific rehabilitation program is designed to ensure that the goal of each phase is achieved before progression to the next phase. The week intervals serve as suggestions but should not be rigid as the patient should complete each phase before advancement, even if increased time is required in a given phase.

The overall goal of this program is to allow recovery, return of full ROM, and restoration of normal strength, flexibility, and proprioception.

- Notably, contact athletes, including football players, will require activity restriction until the 4- to 6-month period and return to full participation is restricted until at least 6 months.

FIGURE 2-24. Pendulum exercises should begin immediately postoperatively to minimize stiffness while protecting the stabilization repair. The arm should hang with gravity and rotate in a circular fashion about the shoulder as shown here.

- Phase I begins 2 weeks following surgery; however, careful instruction should be given to the patient during this 2-week immediate postoperative period. Sling immobilization should be maintained at all times for the first 4 weeks except during periods of rehabilitation.
- It is the authors' experience that this position is well tolerated, although others have suggested that immobilization in external rotation (ER) may reduce stress on the posterior capsule.
- The patient should also be instructed to perform passive pendulum exercises (Figure 2-24) and active elbow and wrist ROM immediately postoperatively and until the first rehabilitation session.

Return to Football After Proximal Shoulder Stabilization: Literature

- Outcomes following posterior shoulder stabilization have been promising. Initial data in 1998 documented only one case of recurrent instability with 11 of 14 patients returning to a preinjury level of function.[1] Provencher et al.[2] documented an 88% success with stabilization and 94.6 mean score on the American Shoulder and Elbow Society (ASES) scale in 33 patients.
- A study of 27 throwing and 80 nonthrowing athletes documented only one failure by ASES score with a return to preinjury sport participation in 55% of throwers and 71% of nonthrowers.[3] These results, however, are a product not only of well-performed surgery, but also of a carefully constructed and directed rehabilitation program.

Phase I (weeks 2 to 4): Recovery Phase

- This phase is a continuation of the immediate postoperative instructions. Focus should be placed on protection of the posterior stabilization repair while incrementally restoring ROM.
- This phase also attempts to reduce postoperative pain and facilitate intraarticular motion with gentle, controlled ROM in a narrow arc. Continued instruction on pendulum exercises and elbow and wrist motion is given. Gripping exercises are also performed to encourage distal motion and circulation.
- Scapular exercises are also performed during this phase, including isometrics and side-lying stabilization (Figure 2-25). This scapular-based rehabilitation serves to establish a stable base and improved posture upon which future ROM and strengthening can occur.
- Finally, careful teaching regarding protection of the surgical stabilization, pain control, and cryotherapy to

TIMELINE 2-2: **Beyond Basic Rehabilitation: Return to Football After Posterior Shoulder Stabilization**

PHASE I		PHASE II (weeks 4 to 8)
(weeks 0 to 2)	(weeks 2 to 4)	
• Sling • PT modalities • Active assistive pendulum exercises • Active elbow and wrist ROM as tolerated	• Sling • PT modalities • Gentle passive ER to 30° with arm at side • Active elbow and wrist ROM as tolerated • Scapular exercises: isometrics and side-lying stabilization • Cryotherapy	• D/C sling • PT modalities as needed • ROM: forward flexion to 120° • ROM: abduction to 90° • ROM: IR to 45° • ROM: horizontal abduction limited to neutral • Scapular strengthening • Progress ROM from passive to active when full PROM achieved • Sub-max deltoid, IR and ER isometrics • Mobilizations as needed • CKC limited to plane of scapula to maintain GH congruency • Biceps/triceps PREs • Home exercise program teaching

FIGURE 2-25. Scapular stabilization exercises including side-lying stabilization should begin at Phase II and continue throughout the rehabilitation program. A stable scapular foundation is crucial for glenohumeral stability. In this figure, the therapist or trainer can be seen manually stabilizing the scapula while the patient performs an isometric contraction.

FIGURE 2-26. Shrugging should be avoided during shoulder abduction in the plane of the scapula because this signifies detrimental weakness and scapular compensation. The shrug can be visualized on the patient's right shoulder compared with a normal abduction motion on the left.

reduce inflammation is provided. Importance should also be placed on patient counseling regarding normal pain levels, activity limitation, and immediate expectations.
- The patient should advance to Phase II upon completion of passive ER to 30 degrees with minimal pain.

Phase II (weeks 4 to 8): Range of Motion Phase

- The patient may discontinue the use of the shoulder immobilizer at the end of the 4th postoperative week.
- This marks the beginning of progression of ROM to include passive forward flexion to 120° and abduction to 90°. ER may progress as tolerated by the patient's pain limitations. Internal rotation (IR) is limited to 45° to minimize stress on the posterior structures. Horizontal adduction is limited to neutral. Elevation in the plane of the scapula is allowed during the 4- to 6-week period, after which full flexion is advanced. These limitations are particularly important during forward flexion, as the forearm may attempt to internally rotate the shoulder in this position.
- Active and active-assisted ROM should begin when the patient has achieved full passive ROM within the prescribed guidelines. Notably, hydrotherapy may be used in this stage to facilitate ROM. Care should be given to avoid shrugging during shoulder abduction, as this will promote fatigue and rotator cuff inflammation (Figure 2-26).
- Scapular strengthening may also progress at this stage to continue securing a stable foundation for shoulder motion and strengthening.

TIMELINE 2-2: Beyond Basic Rehabilitation: Return to Football After Posterior Shoulder Stabilization (Continued)

PHASE III (weeks 8 to 12)	PHASE IV (weeks 12 to 18)	PHASE V (weeks 19+)
• PT modalities as needed • PROM: full • Mobilizations as needed • Scapular exercises: PREs • Biceps/triceps: PREs • GH joint exercises: PREs • Rotator cuff exercises: PREs • Thrower's 10 • Limit IR exercises to minimize strain to posterior capsule • PNF exercises • Upper extremity ergonometrics • OKC rhythmic stabilization exercises • CKC exercises • CKC manual perturbation exercises	• PROM: maintain full motion • Mobilizations as needed • Bench press: wide grip only • Scapular exercises: PREs • Biceps/triceps: PREs • GH joint exercises: PREs • Rotator cuff exercises: PREs • Thrower's 10: progress intensity • PNF exercises • OKC rhythmic stabilization exercises • CKC exercises • CKC manual perturbation exercises • Plyometrics: two-arm progressing to one-arm • Overhead strengthening exercises • Overhead throwing athletes can begin an easy interval throwing program • 20 weeks: begin full windup throwing • Upper and lower extremity endurance and proprioception exercise • Neuromuscular fatigue drills	• Continue Phase IV program • Advance sport-specific functional activities • Increase functional repetitions and interval program • Maintain activity restrictions • Full activity at 6 months for collision play

- Deltoid and IR and ER isometrics may also be used to facilitate stress-limited muscle contraction.
- Care should be taken to avoid closed chain exercises with the shoulder in a forward flexed position as these may place undue stress on the posterior stabilization. Instead, closed kinetic chain (CKC) shoulder exercises should be limited to the plane of the scapula to maintain glenohumeral congruency and minimize posterior stress.
- A home exercise program should also be discussed to ensure continued therapy throughout this phase.
- The patient should progress to Phase III upon completion of forward flexion to 120° and active internal and ER strength of at least 4/5 on manual muscle testing.

Phase III (weeks 8 to 12): Strengthening Phase

- Phase III is focused on maintaining full shoulder ROM and initiating a focused strengthening program. The patient should aim to achieve full ROM by the 8-week mark, at which point the emphasis may be shifted to strengthening.
- Pulleys and wand exercises may be used to maintain ROM during this phase (Figure 2-27). IR may be progressed as tolerated at this time, as the posterior structures are fully healed. Nevertheless, aggressive passive stretching, especially in IR, should be avoided.
- Scapular strengthening is progressed at this point with the goal to restore normal scapulothoracic motion and function. This function will aid to center the glenohumeral joint and facilitate shoulder strengthening. Isotonic strengthening of the trapezius, serratus, levator scapulae, and rhomboids are conducted. Scapular elevation, retraction, and protraction are also promoted with shrugs, rowing, and serratus punch, respectively (Figure 2-28).
- Latissimus dorsi strengthening should also be performed in a protective arc of 0° to 90° to optimize scapular function and improve glenohumeral compressive stability.
- Focused shoulder strengthening in internal and ER is initiated using elastic band resistance with the shoulder in a neutral position with the scapula stabilized.
- Active shoulder abduction in the plane of the scapula should also progress according to the relative strength of the rotator cuff. The shrugged scapular position should be avoided during shoulder abduction because this may promote rotator cuff inflammation and impede rehabilitation progress. In this circumstance, shoulder abduction should be delayed until scapula strengthening, active forward flexion, and IR and ER strength are sufficient to allow shrug-free shoulder abduction. Notably, active abduction should be performed with the shoulder in full ER to avoid impingement of the greater tuberosity under the acromion.
- Finally, proprioception and endurance rehabilitation should be incorporated when strength has sufficiently progressed in all planes of motion. Humeral head control drills, including rhythmic stabilization, may be used. Neuromuscular control patterns should be initiated in challenging positions.
- Upper extremity ergonometry and isokinetic training may facilitate speed, endurance, and muscular coordination. Isokinetic testing may also be used to identify deficient areas that may require selective rehabilitation.
- Patients should progress to Phase IV only with pain-free, full shoulder ROM, normal glenohumeral rhythm, and isokinetic strength in IR and ER equal to 85% of the contralateral shoulder.

FIGURE 2-27. Maintenance of glenohumeral range of motion during Phase III is crucial to minimize stiffness and reduce pain. Pulleys can be used in this regard as demonstrated here.

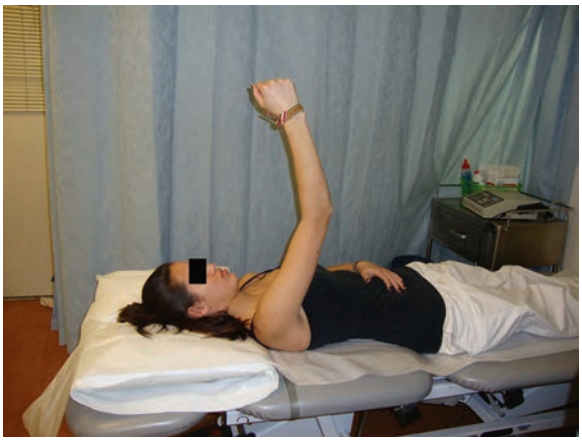

FIGURE 2-28. The serratus punch can be effectively used to allow scapular stabilization during active forward flexion of the shoulder in the supine position. The elbow should begin in the fully flexed position and should actively extend as the shoulder is forward flexed. This exercise facilitates deltoid strengthening and glenohumeral range of motion.

Phase IV (weeks 12 to 18): Sport-Specific Conditioning

- Return to football participation requires a carefully constructed reintroduction program. The athlete must be able to fully perform position-specific functional demands with no limitation in neuromuscular function before participation.
- Eccentric strengthening is particularly useful in this population to maximize strength and minimize the time required before return to play. A functional plyometric exercise program should be constructed including increasing stress and progressive overload. Bench press is instituted at this time with a wide grip requirement to minimize posteriorly directed forces (Figure 2-29).
- Endurance training is also progressed, including neuromuscular drills to fatigue completion. Lower extremity proprioception, strengthening, and endurance exercises are also incorporated in this phase to ensure that the athlete regains normal timing and endurance to minimize upper extremity compensation.
- Sport-specific exercises are also incorporated in this phase to gradually reintegrate the athlete into functional activities.
- Care should be taken throughout this phase to avoid overload or excessive fatigue of the shoulder. Increased pain or inflammation may hinder progress and predispose the athlete to developing a shoulder contracture. If increased pain occurs during this phase, the athlete should reduce the functional repetitions and avoid strengthening until the pain is well controlled. At this time, gradual incorporation of the prior program may once again begin.
- Activity restrictions are maintained for the football athlete for at least 4 to 6 months, and participation in collision play is restricted for at least 6 months.

FIGURE 2-29. Incorporation of the bench press as a strengthening exercise may begin in Phase IV (typically at week 12). A wide-based grip should be used to facilitate a concentric glenohumeral articulation, which will improve compressive forces and minimize posterior forces.

Evidence

Badge R, Tambe A, Funk L: Arthroscopic isolated posterior labral repair in rugby players. *Int J Shoulder Surg* 3:4–7, 2009.

A previous study conducted over a 5-year period of 142 elite rugby players with posterior shoulder capsulolabral injury and operative stabilization demonstrated constant score improvement from 66 to 99. Oxford instability score improved from 52.2 to 12.3. Return to play at the preinjury level was documented at a mean of 4.3 months following repair and a similar rehabilitation protocol. (Level IV evidence)

Eckenrode BJ, Logerstedt DS, Sennett BJ: Rehabilitation and functional outcomes in collegiate wrestlers following a posterior shoulder stabilization procedure. *J Orthop Sports Phys Ther* 39:550–559, 2009.

Five division I wrestlers with a mean age of 20.2 years were treated with focused physical therapy including range of motion, strengthening, plyometrics, neuromuscular re-education, and sport-specific training. Postsurgical outcomes improved from an immediate postoperative Penn Shoulder Score ranging from 37 to 74/100 to a score ranging from 81 to 91/100. Four of the five players were able to return to wrestling with no recurrence. (Level IV evidence)

Radkowski CA, Chhabra A, Baker CL, 3rd, et al: Arthroscopic capsulolabral repair for posterior shoulder instability in throwing athletes compared with nonthrowing athletes. *Am J Sports Med* 36:693–699, 2008.

Previous data regarding both throwing and nonthrowing athletes documented significant improvements in stability, range of motion, strength, pain, and function following stabilization. Good to excellent results were documented in 93% and 89% of throwers and nonthrowers, respectively. Throwing athletes were less likely than nonthrowing athletes to return to play with 55% versus 71%, respectively. (Level II evidence)

Savoie FH, 3rd, Holt MS, Field LD, et al: Arthroscopic management of posterior instability: evolution of technique and results. *Arthroscopy* 24:389–396, 2008.

One hundred and thirty-six shoulders in 131 patients with posterior instability who had failed at least 6 months of rehabilitation were studied following posterior stabilization and postoperative directed rehabilitation. Outcomes were documented with a 97% stability and success on the Neer-Foster scale. Similar rehabilitation techniques were employed in this study. (Level IV evidence)

Williams RJ, 3rd, Strickland S, Cohen M, et al: Arthroscopic repair for traumatic posterior shoulder instability. *Am J Sports Med* 31:203–209, 2003.

Mean follow-up 5.1-year outcome data from male patients (28.7 years) following arthroscopic stabilization for traumatic posterior shoulder instability documented 92% pain and instability elimination, with a mean L'Insalata shoulder score of 90.0 and 96% overall patient satisfaction. All patients were able to return to unlimited athletic activity at 6 months post-operatively. (Level IV evidence)

Multiple Choice Questions

QUESTION 1. The patient should use the shoulder immobilizer immediately postoperatively and for the first _____ week(s).

A. 1
B. 2
C. 3
D. 4

QUESTION 2. During the range of motion phase of rehabilitation, closed kinetic chain exercises should be performed

A. with the shoulder in the forward flexed position.
B. with the shoulder in full internal rotation.
C. with the shoulder positioned in the plane of the scapula.
D. with the shoulder in full external rotation.

QUESTION 3. Scapular exercises should be performed

A. only during Phase IV—sport-specific conditioning.
B. throughout all of the phases.
C. during Phases III and IV but not during Phases I and II
D. during Phases I and II but not during Phases III and IV

QUESTION 4. During Phase IV—sport-specific conditioning, if the patient experiences mild pain and inflammation during repetition exercises, he or she should

A. take NSAIDs and continue to increase the repetitions because this is a normal response to rehabilitation.
B. stop repetition exercises until pain is absent and then reincorporate gradually to minimize inflammation.
C. change repetition exercises to strengthening only exercises.
D. obtain immediate radiograph because the athlete likely sustained an acute injury.

Answer Key

QUESTION 1. Correct answer: **D** (see Phase I: Rehabilitation)

QUESTION 2. Correct answer: **C** (see Phase II: Rehabilitation)

QUESTION 3. Correct answer: **B** (see Phase I–IV: Rehabilitation)

QUESTION 4. Correct answer: **B** (see Phase IV: Rehabilitation)

Chapter 3

Multidirectional Shoulder Instability

INTRODUCTION

Bryan Warme, MD, and Scott A. Rodeo, MD

Epidemiology

- Multidirectional instability (MDI) of the shoulder has various definitions in the literature. Shoulder instability can be categorized into anterior, posterior, or inferior directions. Generally speaking, instability in any two or more of these directions or combination of directions supports a diagnosis of MDI. Furthermore, instability without associated trauma is a characteristic of MDI.

Age

- MDI is a relatively rare condition, and it is unknown whether there is a specific age of an athlete during which there is increased vulnerability to manifesting the associated symptoms. This condition appears to be more common in younger individuals.

Sex

- It has been suggested that atraumatic MDI may be more common in female athletes, but this anecdotal evidence is not supported by formal studies.

Sport

- Swimming has been associated with a higher percentage of athletes with MDI than other sports. There may be a degree of acquired laxity that develops over time in swimmers due to repetitive overhead activity. There is likely also an element of congenital, underlying generalized ligamentous laxity in these athletes (Figure 3-1). Athletes with increased shoulder laxity may have a mechanical advantage in various swimming strokes, thus leading to selection for swimming.

Position

- Swimming strokes that require extremes of range of motion may increase the likelihood of having athletes with MDI.

Pathophysiology

Intrinsic Factors

- MDI is a complex shoulder condition that remains poorly understood. The underlying pathology is capsular laxity.
- Systematic connective tissue disorders can predispose an athlete to MDI. Examples of this include Ehlers-Danlos and Marfan syndromes.
- Abnormal muscle activation patterns of the deltoid and periscapular musculature adversely affect the dynamic shoulder stabilizers, leading to scapulothoracic dyskinesis and resultant abnormal kinematics, thereby contributing to MDI.

Extrinsic Factors

- It is unclear whether there is an etiologic relationship between competitive swimming and MDI, although it is possible that repetitive overhead activity can lead to glenohumeral laxity. Swimming is a unique sport in that there is constant shoulder motion against resistance (water) at extremes of shoulder motion.

Traumatic Factors

- Shoulder instability in general has a spectrum of causes from purely traumatic to completely atraumatic. MDI lies on the atraumatic end of the spectrum, but

FIGURE 3-1. Generalized laxity in a swimmer demonstrated by bilateral knee hyperextension.

FIGURE 3-2. Physical examination of a shoulder with MDI demonstrating a positive "Sulcus Sign," indicative of inferior instability. *(From Altchek DW, Warren RF, Skyhar MJ, Ortiz G: T-plasty modification of the Bankart procedure for multidirectional instability of the anterior and inferior types. J Bone Joint Surg Am 73:105–112, 1991.)*

traumatic causes can underlie shoulder instability in more than one direction.
- Matsen developed the "TUBS" and "AMBRI" acronyms to describe the two ends of this instability spectrum: Traumatic vs. MDI.

Traumatic	Atraumatic
Unidirectional	Multidirectional
Bankart lesion	Bilateral
Surgical stabilization	Rehabilitation
	Inferior capsular shift

Classic Pathological Findings

- Patulous, redundant, or dysfunctional capsule
- Scapular dyskinesis, which may be primary or secondary

Clinical Presentation

History

- Classically, there is no traumatic etiology underlying shoulder instability.
- A history of asymptomatic shoulder laxity may become symptomatic without an apparent traumatic event.
- The typical complaint is pain, although some athletes will report a sense that the shoulder "slips" or "feels loose."

Physical Examination

Abnormal Findings

- 2+ Instability (symptomatic laxity) in more than a single direction (anterior, posterior, or inferior). The shoulder should translate to and over the rim of the glenoid with testing and reproduce symptoms of "instability."
- Bilateral shoulder instability without a traumatic etiology.
- Sulcus sign suggesting inferior laxity (Figure 3-2).
- Jerk test suggesting posterior instability.
- Apprehension suggesting anterior instability.
- Generalized laxity can suggest underlying connective tissue disorder (e.g., elbow hyperextension or the ability to touch the thumb to the forearm).

Pertinent Normal Findings

- Normal neurological and vascular exams (which can be compromised during episodes of instability).
- Patient is not able to voluntarily dislocate.

Imaging

- Bony injuries such as Hill-Sachs or bony Bankart lesions seen on plain film suggest a traumatic etiology rather than atraumatic MDI.
- Magnetic resonance imaging (MRI) can show a "patulous" capsule in MDI. MRI may also show capsular thickening, which reflects adaptive remodeling due to repetitive episodes of plastic deformation of the capsule (Figure 3-3).

Arthroscopic Examination

- Capsular redundancy and a positive "drive through" sign are hallmarks of MDI on diagnostic arthroscopy (Figure 3-4).

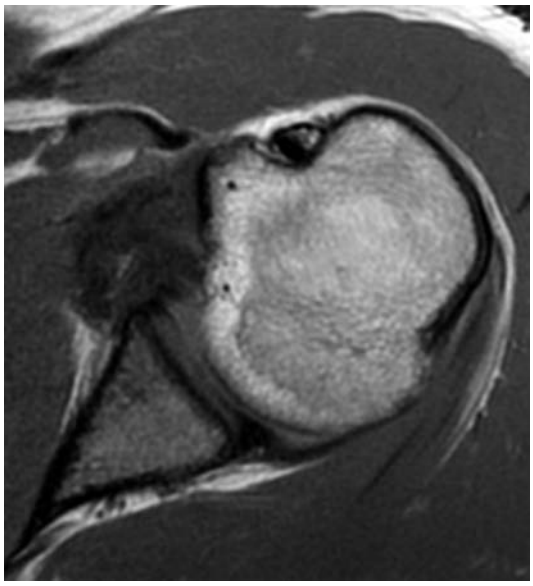

FIGURE 3-3. Capsular remodeling as seen on MRI can reflect repetitive plastic deformation.

Differential Diagnosis

- Traumatic unidirectional instability—look for traumatic lesions on radiographs and instability in only one direction.
- Posterior shoulder dislocation due to seizure/convulsion—again, confirm instability only in the posterior direction.
- Voluntary dislocation with or without underlying psychiatric condition—these patients may have MDI, but these underlying diagnoses can make it difficult to achieve a stable outcome, regardless of treatment modality.

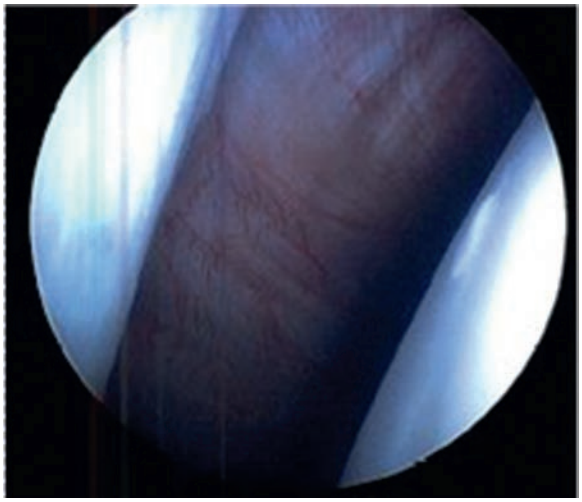

FIGURE 3-4. Postive "drive through" sign on arthroscopy indicative of shoulder laxity.

Treatment

Nonoperative Management

- Rehabilitation is the mainstay of treatment for MDI. Most treating physicians recommend a minimum of 6 to 12 months of rehabilitation before considering any surgical intervention in MDI.
- Pain-relieving modalities such as nonsteroidal antiinflammatory drugs (NSAIDs) and selective use of injections can be used adjunctively with rehabilitation if necessary.
- Exercises aimed at improving coordination of shoulder muscle activation can improve dynamic shoulder stability.
- Ultimately, activity modification may be necessary to exclude those shoulder positions for which subluxation events are most likely.

Guidelines for Choosing among Nonoperative Treatments

- Proprioception training and scapular stabilization exercises are important when the athlete is unable to actively control the humeral head concentrically on the glenoid.
- Cessation of the offending sport is at the discretion of the athlete.
- Pain-relieving modalities should be used conservatively, and opioid pain medication should only be used in acute settings for short periods of time.

Surgical Indications

- There are no absolute indications for surgical stabilization of MDI.
- Relative indications for surgery are failure of extended rehabilitation and trials of activity modification and/or cessation of the affecting sport.
- Ultimately, surgery for MDI is less predictable than for traumatic, unidirectional instability. The athlete must be an informed patient, appreciating the unpredictability of the surgery and the potential complications. Furthermore, the surgeon must be confident that improved stability can be achieved through an operation if surgery is to be indicated.

Aspects of History, Demographics, or Exam Findings That Affect Choice of Treatment

- History of voluntary dislocation, especially in the setting of an underlying psychiatric condition, predicts a poor surgical outcome. In these cases, treatment should consist of rehabilitation exclusively. If the underlying psychiatric condition resolves, then surgery can be considered if extended rehabilitation has failed to improve stability.
- If there is a traumatic injury underlying MDI, earlier surgical intervention can be considered to concomitantly address the traumatic injury (e.g., Bankart lesion) and the MDI (e.g., patulous capsule).

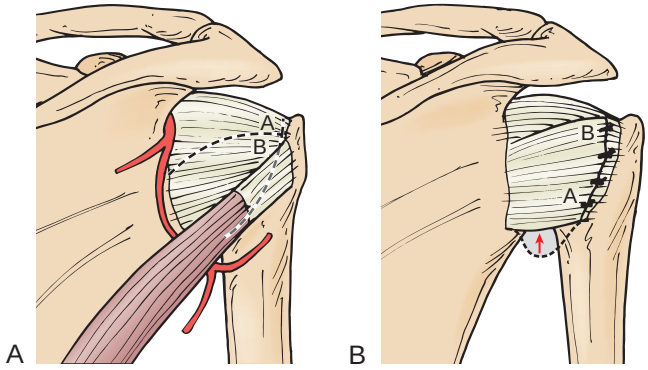

FIGURE 3-5. Open inferior capsular shift, as proposed by Neer. *(Redrawn from Neer CS 2nd, Foster CR: Inferior capsular shift for involuntary inferior and multidirectional instability of the shoulder. A preliminary report. J Bone Joint Surg Am 62:897–908, 1980.)*

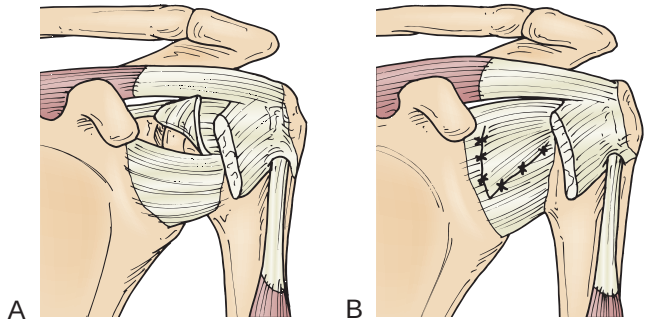

FIGURE 3-6. T-plasty modification of the inferior capsular shift, as proposed by Altchek. *(Redrawn from Altchek DW, Warren RF, Skyhar MJ, Ortiz G: T-plasty modification of the Bankart procedure for multidirectional instability of the anterior and inferior types. J Bone Joint Surg Am 73:105–*112, 1991.)

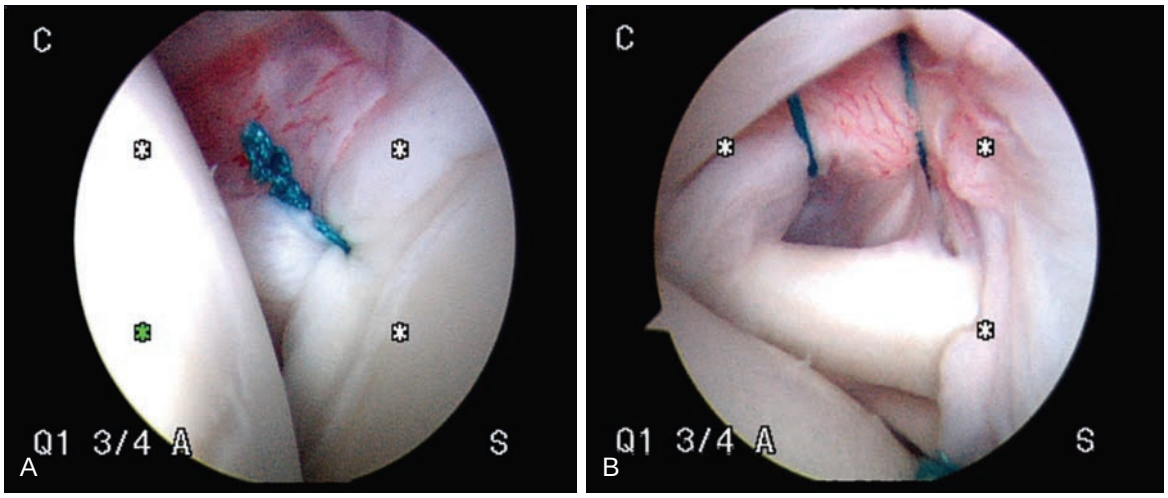

FIGURE 3-7. Arthroscopic capsular placation (**A**) and rotator interval closure (**B**).

Aspects of Clinical Decision Making When Surgery is Indicated

- The directions of instability are important to surgical planning. Although both open and arthroscopic techniques have been described for MDI, open techniques have traditionally been the mainstay of surgical intervention for MDI. The direction of instability influences the decision to open the shoulder either anteriorly or posteriorly. Most surgical repairs are now done arthroscopically.
- A combination of open and arthroscopic approaches can be used if both anterior and posterior instability are present to limit the open aspect of the surgery to a single incision. Alternatively, both anterior and posterior incisions can be used to allow open stabilization of both anterior and posterior stabilization (Figures 3-5, 3-6, and 3-7).

Evidence

Altchek DW, Warren RF, Skyhar MJ, et al: T-Plasty modification of the Bankart procedure for multidirectional instability of the anterior and inferior types. *J Bone Joint Surg Am* 73:105–112, 1991.

A retrospective study of 42 shoulders that underwent T-plasty modification of the capsular shift. Satisfaction was rated as excellent in 95% of cases. The average loss of external rotation after surgery was 4° with the arm at the side and 5° degrees with the arm abducted. (Level IV evidence).

Burkhead WZ, Jr, Rockwood CA, Jr: Treatment of instability of the shoulder with an exercise program. *J Bone Joint Surg Am* 74:890–896, 1992.

This study highlights the importance of differentiating "traumatic" instability of the shoulder from "atraumatic" instability. Only 12/74 (16%) cases of traumatic shoulder instability responded with a good/excellent result to rehabilitation alone, compared with 53/66 (80%) of shoulders with atraumatic instability. (Level IV evidence).

Matsen FA, 3rd, Thomas SC, Rockwood CA, Jr: Anterior glenohumeral instability. In Rockwood CA, Matsen FA, editors: *The shoulder*, Philadelphia, 1990, WB Saunders, pp 547–551.

The spectrum between traumatic and atraumatic causes of shoulder instability are discussed, and the acronyms "TUBS" and "AMBRI" are described in this reference. (Level V evidence).

McFarland EG, Kim TK, Park HB, et al: The effect of variation in definition on the diagnosis of multidirectional instability of the shoulder. *J Bone Joint Surg Am* 85:2138–2144, 2003.

This study evaluated four different classification systems of MDI and found that the criteria used to make the diagnosis of MDI significantly affected the distribution of the diagnosis. The study also demonstrated that the use of laxity testing tends to overestimate the diagnosis. (Level III evidence).

Morris AD, Kemp GJ, Frostick SP: Shoulder electromyography in multidirectional instability. *J Shoulder Elbow Surg* 13:24–29, 2004.

This study demonstrated abnormal muscle activation patterns in shoulders with MDI compared with controls. The paper supports the idea that impaired coordination of the shoulder muscles and inefficiencies of the dynamic stabilizers play a role in MDI. (Level III evidence).

Neer CS, 2nd, Foster CR: Inferior capsular shift for involuntary inferior and multidirectional instability of the shoulder. A preliminary report. *J Bone Joint Surg Am* 62:897–908, 1980.

This is the classic article that first described the condition and named it MDI. It is a retrospective study of 40 shoulders with MDI and describes Dr. Neer's inferior capsular shift technique for surgical stabilization. (Level IV evidence).

Rowe CR, Pierce DS, Clark JG: Voluntary dislocation of the shoulder. A preliminary report on a clinical, electromyographic, and psychiatric study of twenty-six patients. *J Bone Joint Surg Am* 55:445–460, 1973.

A clinical, radiographic, electromyographic, and psychiatric study that determined that patients with significant psychiatric problems did poorly after surgical or nonsurgical treatment unless their psychiatric problem had resolved. (Level IV evidence).

Multiple-Choice Questions

QUESTION 1. MRI of a shoulder with MDI often reveals:

A. Fatty infiltration of the rotator cuff
B. Bone edema adjacent to a Hill-Sachs lesion
C. Concomitant acromioclavicular (AC) joint arthrosis
D. Patulous capsule

QUESTION 2. According to Matsen et al., two factors that are more closely associated with MDI than traumatic shoulder instability include:

A. Bankart and Hill-Sachs lesions
B. Multidirectionality and bilaterality
C. Traumatic etiology and unidirectionality
D. Shoulder weakness and paresthesias

QUESTION 3. Which of the following patient attributes predicts a poor surgical outcome after MDI stabilization?

A. Age less than 20
B. Smoking history
C. Underlying psychiatric condition
D. BMI greater than 35

QUESTION 4. The mainstay of treatment for MDI should be:

A. Surgical stabilization
B. Rehabilitation
C. Pain medication
D. Benign neglect

Answer Key

QUESTION 1. Correct answer: **D** (see Clinical Presentation)

QUESTION 2. Correct answer: **B** (see Clinical Presentation and Evidence)

QUESTION 3. Correct answer: **C** (see Treatment)

QUESTION 4. Correct answer: **B** (see Treatment)

NONOPERATIVE REHABILITATION OF MULTIDIRECTIONAL SHOULDER INSTABILITY

John T. Cavanaugh, PT, MEd, ATC, SCS, and Scott A. Rodeo, MD

GUIDING PRINCIPLES OF NONOPERATIVE REHABILITATION

- Communicate with referring physician
- Treat patient as an individual
- Consider physiological healing restraints
- Develop strong base of support: Scapular strengthening
- Identify direction of greatest instability
- Incorporate exercises high in neuromuscular activation
- Functional progression

Clinical Pearls

- Patients referred for physical therapy with the diagnosis of MDI often present with varied symptoms. Some patients may present acutely following an episode of instability, whereas others present relatively asymptomatic with full range of motion (ROM) and normal strength on physical examination.
- Throughout the rehabilitation course an emphasis is placed on neuromuscular training to train the shoulder's dynamic stabilizers to engage when

needed to aid in stability. These neuromuscular exercises are encouraged as early as deemed appropriate in the rehabilitation program.
- The patient needs to be treated as an individual and treated based on information gained from their history, subjective complaints, radiographic imaging, physical examination, and the direction of the referring physician.

Phase I (weeks 0 to 8)

Clinical Pearls

- A thorough physical examination can identify deficits in ROM, flexibility, laxity, and strength. Scapular dyskinesis, winging, and atrophy can also be observed. Apprehension and stability testing provide the rehabilitation specialist with valuable information as it pertains to the direction of greatest instability (Figure 3-8).
- Patients may very well present with only symptoms in overhead sports activities; e.g., baseball and swimming. These patients may present on initial examination with full ROM and normal strength and scapulohumeral rhythm. Their laxity exam along with subjective complaints and history confirm their diagnosis.
- These patients begin their rehabilitation program at a more advanced level, incorporating exercise and activities found in Phases II and III of the general guideline.

FIGURE 3-8. Load and shift laxity testing.

Protection

- During the first phase of rehabilitation, care is taken to allow for healing and recovery from trauma (if applicable). The patient/athlete who complains of microinstability is treated predominantly based on symptoms.
- For the first-time dislocator, sling immobilization may be indicated for up to 4 weeks after an instability episode.
- Immobilization for less than 2 weeks for patients who report an episode of subluxation or recurrent dislocation.
- Patient/athlete is advised to avoid symptomatic positions that provoke apprehension.
- Modification of daily activities is emphasized: i.e., no heavy lifting or overhead activities of daily living (ADL).

TIMELINE 3-1: Nonsurgical Rehabilitation after Treatment of Multidirectional Shoulder Instability

PHASE I (weeks 0 to 8)	PHASE II (weeks 8 to 14)	PHASE III (weeks 14 to 20)
• Treatment-based on evaluation • Sling immobilization less than 2 weeks after episode of instability • Ice, electrical stimulation as needed • NSAIDs • Activity modification • AROM/AAROM • Flexibility exercises • Scapular stabilization/strengthening exercises (PRE) • CKC manual perturbation exercises • Humeral head control exercises • Deltoid/rotator cuff isometrics • Scaption (PRE as tolerated) • Upper-body ergometer • Soft tissue massage • Total body strengthening (TBS)/total arm strengthening (TAS)/total leg strength (TLS) activities as recommended and tolerated	• Treatment based on evaluation • Ice, electrical stimulation as needed • Flexibility exercises • Scapular stabilization/strengthening exercises (PRE) • Rhythmic stabilization exercises • Scaption (PRE) • IR/ER TheraBand/isokinetic exercises • PNF exercises • CKC manual perturbation exercises • Functional exercises: Keiser/pulley systems • BodyBlade • Upper-body ergometer • Plyometrics • Soft tissue massage • TBS/TAS/TLS activities as recommended and tolerated	• Treatment based on evaluation • Ice, electrical stimulation as needed • Flexibility exercises • Scapular stabilization/strengthening exercises (PRE) • Rhythmic stabilization exercises • Scaption (PRE) • IR/ER TheraBand/isokinetic exercises • IR/ER TheraBand 90/90 • PNF exercises • CKC manual perturbation exercises • BOSU® ball CKC stabilization with perturbations • Military press • Chest press • Functional exercises: Keiser/pulley systems • Bodyblade (overhead) • Upper-body ergometer • Plyometrics (overhead) • Soft tissue massage • Sport-specific training • TBS/TAS/TLS activities as recommended and tolerated

Management of Pain and Swelling

- During the posttraumatic period the daily use of cryotherapy and antiinflammatory medication are recommended.
- Electrical stimulation in the form of transcutaneous electrical nerve stimulation (TENS) can be used to assist in pain control.
- NSAIDs as needed.

Techniques for Progressive Increase in Range of Motion

Clinical Pearl

- ROM deficits are addressed with respect to the direction of instability and the timetable set forth by the referring physician. For example, for patients whose recent episode entailed an anterior subluxation, external rotation (ER) will be initially limited to 30° and forward flexion (scapular plane) limited to 90°. Full ROM should be restored by 8 weeks after trauma.

Manual Therapy Techniques

- Gentle active assisted range of motion (AAROM) in scapular plane (if needed).

Soft Tissue Techniques

- Soft tissue massage: scapular musculature.

Stretching and Flexibility Techniques for the Musculotendinous Unit

- ER is regained via a supine wand exercise.
- Forward flexion by supine active-assistive exercise, at first with the assistance of the noninvolved upper extremity, progressing to using a wand.
- Internal rotation (IR) via a towel-pass exercise while the patient attempts to pass a towel around his/her back. IR is then progressed to a towel-stretch exercise.

Other Therapeutic Exercises

- Core-stability exercises.
- Lower-extremity strengthening without use of upper extremity.
- Distal upper-extremity strengthening (forearm, wrist, hand) exercises.

Activation of Primary Muscles Involved

- Exercises are performed for the following muscle groups:
  - Serratus anterior, rhomboids
  - Trapezius muscles
  - Levator scapulae
  - Deltoid muscles
  - Rotator cuff musculature
  - Humeral positioners

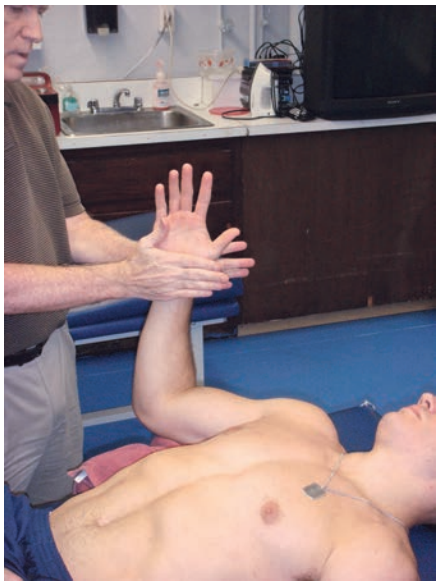

FIGURE 3-9. Neuromuscular dynamic stability exercises.

Sensorimotor and Neuromuscular Dynamic Stability Exercises

- Manual humeral head control exercises where the patient needs to react to the direction of force provided by the rehabilitation specialist (perturbation exercises) attempt to reestablish neuromuscular pathways to provide dynamic stability of the glenohumeral joint (Figure 3-9).

Open and Closed Kinetic Chain Exercises

- Closed kinetic chain (CKC) stabilization exercises using a physioball are included for patients whose symptomatic direction of instability is anterior (Figure 3-10).

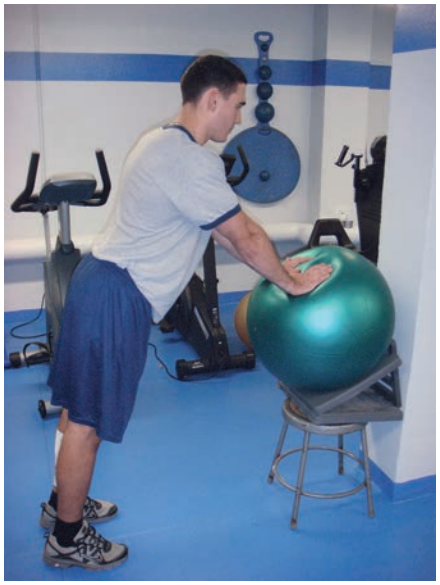

FIGURE 3-10. CKC stabilization exercises using a physioball.

FIGURE 3-11. Manual scapular stabilization exercises performed sidelying with the humerus positioned in neutral rotation.

Techniques to Increase Muscle Strength, Power, and Endurance

- Deltoid isometrics are initiated as symptoms allow.
- Early scapular strengthening is initiated as soon as these exercises are asymptomatic. Specific techniques used include manual resistance and rhythmic stabilization to scapular musculature. This technique can be started early on with the patient sidelying and the involved upper extremity supported in a neutral rotated position (Figure 3-11).
- As symptoms subside during this phase, scapular retraction isometrics and isotonic exercises are introduced as supine "serratus" punches (Figure 3-12).
- When scapulothoracic rhythm normalizes, scapular plane elevation "scaption" is performed and advanced in a progressive resistive exercise (PRE) fashion (Figure 3-13).
- IR and ER isometrics are initiated in a modified neutral position and performed submaximally.
- Upper-body ergometer (as symptoms allow).

FIGURE 3-12. Serratus anterior exercise performed supine.

FIGURE 3-13. Forward elevation in the scapular plane ("scaption").

Milestones for Progression to the Next Phase

- Full AROM and passive ROM.
- Scapulohumeral rhythm normalized throughout AROM as measured by visual observation, assuring symmetry, lack of dynamic scapula winging, and hiking.
- Sufficient scapular strength base: Demonstration of strength gains via PRE in proportion to body type/size.
- 5/5 Manual muscle testing throughout involved upper extremity (scapular muscles, humeral head positioners, and rotator cuff muscles).

Phase II (weeks 8 to 14)

Clinical Pearls

- Many patients/athletes with MDI may very well enter their rehabilitation program at an advanced level as described here in Phase II. This advanced phase emphasizes the need to clinically evaluate the athlete to properly challenge the shoulder complex.
- Dynamic neuromuscular control about the glenohumeral joint is crucial for optimal performance in sports. EMG studies have demonstrated that patients with MDI exhibit altered functioning of the humeral head positioners and dynamic stabilizers of the glenohumeral joint during functional and complicated movements.
- Because ROM and muscle strength have been normalized before this phase is entered, a greater emphasis is placed on training the neuromuscular structures throughout the shoulder complex during this phase.

Protection

- Activity modification in ADL, avoiding motions that bring on symptoms (pain, instability) e.g., overhead movements.

Management of Pain and Swelling

- Ice and electrical stimulation (TENS) as needed.

Techniques for Progressive Increase in Range of Motion

Manual Therapy Techniques

- Continue humeral head control/rhythmic stabilization exercises.
- Proprioceptive neuromuscular facilitation (PNF) patterns with manual resistance (D1, D2) (Figure 3-14).

Soft Tissue Techniques

- Soft tissue massage to scapular musculature.

Stretching and Flexibility Techniques for the Musculotendinous Unit

- Address inflexibility issues on an individual basis: e.g., pectoralis minor tightness, glenohumeral IR deficits (GIRD) (thixotrophy of the infraspinatus and teres minor).

Other Therapeutic Exercises

- Lower-extremity strengthening program, running, plyometrics specific to sport.
- Core-stability program.
- Wrist and elbow strengthening, especially for throwing athletes.

Activation of Primary Muscles Involved

- Scapular stabilizers (serratus anterior; rhomboids; upper, middle, and lower trapezius; levator scapulae).

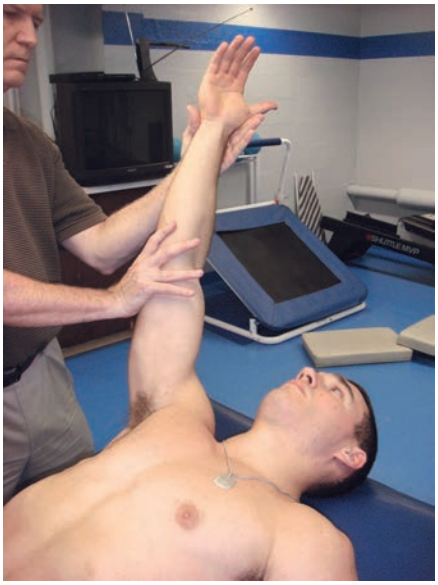

FIGURE 3-14. Manual resistance with PNF D2 pattern.

- Glenohumeral stabilizers (deltoid, humeral head positioners, rotator cuff musculature).

Sensorimotor and Neuromuscular Dynamic Stability Exercises

- Rhythmic stabilization.
- Humeral head control exercises.
- PNF exercises.
- Scapular stabilization exercises, CKC using a physioball on wall: bilateral → unilateral → manual perturbations.
- Bodyblade (below horizontal).

Techniques to Increase Muscle Strength, Power, and Endurance

Open and Closed Kinetic Chain Exercises

- IR/ER TheraBand (modified neutral).
- IR/ER isokinetics (modified neutral).
- Scaption with weights (PRE).
- Ball stabilization on wall.
- Serratus "punches" (PRE).
- Prone "hitch-hiker" (middle trapezius muscle strengthening).
- Prone lower-trapezius strengthening (PRE).
- Biceps/triceps (PRE).
- Row machine (PRE).
- Chest press machine (PRE) (limit arc) to symptom-free ROM.
- Latissimus dorsi pulldown machine (PRE) (limit arc) to symptom-free ROM.
- Upper-body ergometer.

Functional Exercises

- D1/D2 PNF patterns with TheraBand or resistance exercise machines.
- Resistance exercise machine or pulley system: reciprocal flexion.

Plyometrics

- Two-handed chest press toss vs. plyoback.

Sport-Specific Exercises

- Baseball, tennis, volleyball, golf: scaption, trunk rotation exercises seated on physioball.
- Swimming: prone PRE exercises; e.g., lower trapezius, "hitch-hiker," shoulder extension on physioball (Figure 3-15).

Milestones for Progression to the Next Phase

- Lack of apprehension with overhead movements.
- IR/ER isokinetic test greater than 75% limb symmetry.
- 0/10 pain in all ADL.

FIGURE 3-15. "Hitch-hiker" exercise performed prone on physioball.

Phase III (weeks 14 to 20)

Clinical Pearls

- With the athlete relatively asymptomatic and having achieved a sufficient strength base, he/she is now ready to challenge the shoulder complex with more demanding exercises that mimic the demands of their individual sport.
- During this phase, emphasis is placed on increasing strength, power, and endurance as well as a gradual return to sport.
- Valuable information can be gained from isokinetic testing, so that any deficits or muscle imbalances across the glenohumeral joint can be addressed in the final phase of rehabilitation.
- Intensity and volume should be structured and closely monitored to avoid overuse symptoms from developing.

Management of Pain and Swelling

- Ice and electrical stimulation (TENS) as needed.

Techniques for Progressive Increase in Range of Motion

Manual Therapy Techniques

- Continue humeral head control/rhythmic stabilization exercises.
- PNF patterns with manual resistance (D1, D2).

Soft Tissue Techniques

Continue soft tissue massage to upper extremity as needed.

Stretching and Flexibility Techniques for the Musculotendinous Unit

- Continue to address inflexibility issues on an individual basis: e.g., pectoralis minor tightness, GIRD (thixotrophy of the infraspinatus and teres minor).

Other Therapeutic Exercises

- Lower-extremity strengthening program, running, plyometrics specific to sport.
- Core-stability program.
- Wrist and elbow strengthening, especially for throwing athletes.

Activation of Primary Muscles Involved

- Scapular stabilizers (serratus anterior; rhomboids; upper, middle, and lower trapezius; levator scapulae), glenohumeral stabilizers (deltoid, humeral head positioners, rotator cuff musculature).

Sensorimotor and Neuromuscular Dynamic Stability Exercises

- Rhythmic stabilization.
- Humeral head control exercises (give some specific examples of exercises to accomplish this).
- PNF exercises.
- Scapular stabilization exercises, CKC using a physioball on wall: unilateral with manual perturbations.
- Bodyblade (above horizontal).
- BOSU ball upper-extremity stabilization, bilateral → unilateral with perturbations (Figure 3-16).

Techniques to Increase Muscle Strength, Power, and Endurance

Open and Closed Kinetic Chain Exercises

- IR/ER TheraBand (modified neutral and 90°/90°).
- IR/ER isokinetics (modified neutral).
- Scaption with weights (PRE).
- Unilateral ball stabilization on wall.
- Serratus "punches" (PRE).
- Prone "hitch-hiker" (middle trapezius).
- Prone lower-trapezius strengthening (PRE).

FIGURE 3-16. Upper-extremity stabilization using BOSU® ball (foot taps for perturbations).

- Biceps/triceps (PRE).
- Row machine (PRE).
- Chest press machine (PRE).
- Latissimus dorsi pulldown machine (arc) (PRE).
- Military press (PRE).
- Bench press (wide grip).
- Upper-body ergometer.

Plyometrics

- Advance to overhead "soccer throw," diagonal toss (overhead) vs. plyoback.
- D2 deceleration with plyoball off wall (throwers).
- Unilateral plyoball toss: supine → standing (90/90) vs. plyoback.

Functional Exercises

- D1/D2 PNF patterns with TheraBand or resistance exercise machines.
- Resistance exercise machine or pulleys system: reciprocal flexion.

Sport-Specific Exercises

- Baseball, tennis, volleyball, golf: Scaption, military press, trunk rotation exercises seated on physioball.
- Swimming: Prone PRE exercises; e.g., lower trapezius, "hitch-hiker," shoulder extension on physioball.
- Resistance exercise machine or pulley system to replicate sport-specific movements: e.g., forehand/backhand tennis, polling cross-country skiing movement.
- Interval throwing program (baseball).
- Tennis: ground strokes → overhead volleys/serving (monitor volume).
- Volleyball: Overhead serving/spiking (monitor volume).
- Swimming: breaststroke → freestyle before advancing to backstroke/butterfly (monitor volume).

Milestones for Progression to Advanced Sport-Specific Training and Conditioning

- Asymptomatic (apprehension/pain) with overhead sport-specific ovements.
- IR/ER isokinetic test greater than 90% limb symmetry.
- Independent with home/gym therapeutic exercise program for maintenance and progression of strength, power, endurance gains made in physical therapy.

Criteria for Abandoning Nonoperative Treatment and Proceeding to Surgery or More Intensive Intervention

- Continued pain, apprehension, or complaints of instability during ADL and/or sport-specific exercises and movements.
- Poor compliance with rehabilitation resulting in continued symptoms.

Tips and Guidelines for Transitioning to Performance Enhancement

- Care is taken to avoid overtraining and incorporating rest and cross training into the treatment regimen.
- The athlete should take note to initially avoid combining weight training and sport-specific training, e.g., throwing, swimming, tennis strokes on the same day. As symptoms allow, sport-specific training can be performed on consecutive days.
- Communication with the athlete's strength and conditioning coach or whoever will be responsible for the continuation of care is vital to ensure a safe, noncomplicated return to sport.

Performance Enhancement and Beyond Rehabilitation: Training/Trainer and Optimization of Athletic Performance

- It is vital to communicate with the athlete's coach that upon to return to team practice, the athlete returning from injury is not be treated the same as team players who are otherwise deemed healthy.
- Volume and repetitions need to be modified for the individual who has returned to the team following his/her course of rehabilitation.
- Bracing for sports such as football and lacrosse may be recommended by the physician on an individual basis (Figure 3-17).

FIGURE 3-17. Shoulder stabilizer brace (Breg Inc., Vista, CA).

Specific Criteria for Return to Sports Participation: Tests and Measurements

- Asymptomatic (apprehension/pain) with overhead sport-specific movements.
- IR/ER isokinetic test > 90% limb symmetry (muscular strength, power, and endurance).
- Isokinetic test: ER to IR ratio > 70%.
- Independent with home/gym therapeutic exercise program for maintenance and progression of strength, power, and endurance gains made in physical therapy.
- Physician clearance.

Evidence

Burkhead WZ, Jr, Rockwood CA, Jr: Treatment of instability of the shoulder with an exercise program. *J Bone Joint Surg Am* 74:890–896, 1992.

Authors reported that when using a conservative rehabilitation program for atraumatic shoulder instability, 66 (86%) of their patients obtained good to excellent results. (Level III evidence).

Cordasco FA, Wolfe IN, Wootlen ME, et al: An electromyographic analysis of the shoulder during a medicine ball rehabilitation program. *Am J Sports Med* 24:386–392, 1996.

The authors studied the electromyographic activity of the shoulder girdle musculature during a two-handed medicine ball throw. High levels of activity were identified during the acceleration phase of the throw. Their findings support the use of medicine ball training as a bridge between static resistive training and dynamic throwing in the rehabilitation of the throwing athlete. (Level IV evidence).

Hawkes DH, Alizadehkhaiyat O, Fisher AC, et al: Normal shoulder muscular activation and co-ordination during a shoulder elevation task based on activities of daily living: an electromyographic study. *J Orthop Res* 30:53–60, 2012.

Upper-limb functional status was assessed in 12 healthy male volunteers using the Functional Impairment Test-Hand, Neck, Shoulder and Arm test (FIT-HaNSA). Electromyography was then used to study the activity and coordination of 13 muscles around the shoulder during a dynamic movement task based on the shelf-lifting task in FIT-HaNSA. The study concluded that the deltoid, adductor, and rotator cuff muscles all contribute to the muscular component of glenohumeral joint stability. (Level IV evidence).

Illyes A, Kiss RM: Electromyographic analysis in patients with multidirectional shoulder instability during pull, forward punch, elevation and overhead throw. *Knee Surg Sports Traumatol Arthrosc* 15:624–631, 2007.

This study compared the EMG activity from eight different muscles of patients with multidirectional shoulder instability and a control group during pull, forward punch, elevation, and overhead throw activities. Test results suggested that, in patients with multidirectional shoulder instability, the various motions are performed in a different way. The results give rise to the assumption that the centralization of the glenohumeral joint and the reduction of instability are attempted to be ensured by increasing the role of rotator cuff muscles and decreasing the role of the deltoid, biceps brachii, and pectoralis major muscles. The time difference between the peaks of normalized voluntary electrical activity was shown to be significantly greater in the patients with MDI than in the control group. (Level III evidence).

Morris AD, Kemp GJ, Frostick SP: Shoulder electromyography in multidirectional instability. *J Shoulder Elbow Surg* 13:24–29, 2004.

The study examined shoulder muscle activity in MDI and multidirectional laxity (MDL) of the shoulder. Six muscles (supraspinatus, infraspinatus, subscapularis, anterior deltoid, middle deltoid, and posterior deltoid) were investigated by use of intramuscular dual fine-wire electrodes in seven normal shoulders, five MDL shoulders, and six MDI shoulders. Each subject performed five types of exercises on an isokinetic muscle dynamometer. Abnormalities in the deltoid rather than the muscles of the rotator cuff were demonstrated. Altered patterns of shoulder girdle muscle activity and imbalances in muscle forces support the theory that impaired coordination of shoulder girdle muscle activity and inefficiency of the dynamic stabilizers of the glenohumeral joint are involved in the etiology of MDI. (Level III evidence).

Multiple-Choice Questions

QUESTION 1. For athletes who have sustained a recurrent episode of instability, sling immobilization should be used for no greater than:

A. 2 weeks
B. 4 weeks
C. 6 weeks
D. 8 weeks

QUESTION 2. For athletes who have sustained an episode of anterior instability, which motion will initially be limited?

A. IR
B. ER
C. Horizontal adduction
D. Flexion to 45°

QUESTION 3. All of the following exercises strengthen in isolation one of the scapular muscles, except:

A. Supine "punch"
B. Prone "hitch-hiker"
C. Shrugs
D. CKC ball stabilization on wall

QUESTION 4. In determining strength assessment for return to sport, IR/ER isokinetic testing should reveal a limb symmetry of:

A. 70%
B. 80%
C. 90%
D. 100%

QUESTION 5. Toward the latter stages of rehabilitation, an athlete transitions into a sport-specific training (throwing, swimming, etc.) program. Such training should initially be performed.

A. Every day
B. Every other day
C. Every 3 days
D. Once a week

Answer Key

QUESTION 1. Correct answer: **A** (see Phase I)

QUESTION 2. Correct answer: **B** (see Phase I)

QUESTION 3. Correct answer: **D** (see Phase II)

QUESTION 4. Correct answer: **C** (see Phase III)

QUESTION 5. Correct answer: **B** (see Phase III)

POSTOPERATIVE REHABILITATION AFTER TREATMENT OF MULTIDIRECTIONAL SHOULDER INSTABILITY

John T. Cavanaugh, PT, MEd, ATC, SCS, and Scott A. Rodeo, MD

Indications for Surgical Treatment

- Persistent symptoms of instability with ADL and/or sports activity following a comprehensive rehabilitation program
  - Symptoms may include either pain or apprehension
- Generalized ligamentous laxity may increase risk of failure of conservative management
- Glenoid bone loss increases risk of persistent instability and need for surgical treatment

Brief Summary of Surgical Treatment

Major Surgical Steps

- Basic principle of surgery is to address the underlying pathology
  - Labral reattachment as needed
  - Appropriate capsular tensioning and glenohumeral joint capsular volume reduction
  - Address glenoid or humeral head bone loss as indicated

Factors That May Affect Rehabilitation

- Open vs. arthroscopic approach
- Subscapularis tenotomy will require postoperative protection
- Glenoid bone grafting (Latarjet or Bristow procedure) should be considered
- Remplissage (infraspinatus tenodesis for large Hills-Sachs lesion) requires delayed initiation of active ER to allow tendon-to-bone healing

GUIDING PRINCIPLES OF POSTOPERATIVE REHABILITATION

- Protect surgical correction
- Early controlled ROM
- Patient education
- Treat patient/athlete as an individual
- Follow a functional progression of therapeutic exercise
- Criteria-based guideline

Phase I (days 0 to 14): Immediate Postoperative Period[1]

Clinical Pearls

- This first phase of rehabilitation is designed to allow maximal protection to the surgical correction performed.
- Postoperative pain is controlled with the use of cryotherapy, analgesics, and NSAIDs.
- The patient is educated to use his/her sling at all times, with the exception of self-care and distal AROM exercises.
- Proper donning and doffing of the sling is instructed as to aid in the protection of the surgical correction.
- It is very important for the patient to perform elbow AROM so as to avoid the development of a flexion contracture.

Goals

- Pain control
- Decrease swelling
- Independent donning/doffing of sling
- Prevent elbow flexion contracture

Protection

- Sling immobilization with an abduction pillow (so as to approximate neutral rotation in the scapular plane) is used at all times, except for self-care, hygiene, etc.

Management of Pain and Swelling

- Analgesic and NSAID medications
- Cryotherapy: Game-ready cryotherapy system (Figure 3-18).
- Electrical stimulation for pain control, i.e., TENS, interferential current (IFC) estim (as needed)
- Patient education
- Proper sling donning/doffing
- Positioning for comfort/sleeping

[1]*Prehabilitation, if appropriate, is described in the Nonoperative Rehabilitation section of this chapter.*

FIGURE 3-18. Game-ready cryotherapy system.

Therapeutic Exercises

- AROM exercises for elbow, wrist, and hand
  - Elbow ROM exercises: Flexion/extension, supination/pronation performed supine with involved upper arm supported with rolled towel approximating plane of the scapula. Emphasis on full active extension is encouraged
  - Hand gripping and active wrist flexion/extension AROM exercises
- Cardiovascular exercise using a stationary bicycle is encouraged, particularly for the athletic patient.

Activation of Primary Muscles Involved in Injury Area or Surgical Structures

Biceps/triceps/supinators/pronators/wrist extensors and flexors/hand intrinsic via distal AROM exercises

Milestones for Progression to the Next Phase

- Postoperative pain decreased
- Incisions well healed/no sign of infection
- No reported incidence of trauma that would indicate disruption of surgical correction

Phase II (weeks 2 to 6 postoperatively)

Clinical Pearls

- ROM is achieved via active-assisted and passive exercises.
- Any PROM exercises are performed without complaints of pain.
- Care is given to ensure patient performs these exercises in the scapular plane.
- As ROM improves, hydrotherapy using exercises in water at/below the patients shoulder level ensures a safe environment for ROM gains.

Goals

- Protect surgical correction
- Decrease pain/swelling
- Improve glenohumeral ROM (scapular plane): ER/IR → 30°, forward flexion (FF) → 120°
- Reestablish humeral head and scapula control
- Independent home exercise program

Protection

- Sling immobilization is continued at all times except for therapeutic exercises, self-care, hygiene, etc. At 4 to 5 weeks postoperatively, the sling may be discontinued in areas deemed to ensure a safe environment (home, office, etc.). This lifted restriction will be

TIMELINE 3-2: **Postoperative Rehabilitation after Treatment of Multidirectional Shoulder Instability**

PHASE I (weeks 0 to 2)	PHASE II (weeks 2 to 6)	PHASE III (weeks 6 to 12)

• Sling immobilization
• PT modalities:
  • Game-ready cryotherapy system
• TBS/TAS/TLS activities as recommended and tolerated
	• Sling immobilization
	• PT modalities
	• AAROM exercises, scapular plane:
	  • ER → 30°
	  • IR → 30°
	  • FF → 120°
	• Codman's exercises
	• Scapular exercises, manual/isometrics
	• Week 4:
	  • Pool therapy
	  • Deltoid isometrics (submaximal)
	  • IR/ER isometrics (submaximal)
	• TBS/TAS/TLS activities as recommended and tolerated
		• D/C sling
		• PT modalities as needed
		• AAROM exercises:
		  • ER → 60°
		  • IR → 45°
		  • FF → 160°
		• Joint mobilizations (gentle) as needed
		• TBS/TLS activities as recommended. and tolerated
		• Scapular exercises (PREs)
		• FF (scapular plane) "scaption": PREs
		• Biceps/triceps PREs
		• Glenohumeral extension: theraband/PREs (below 90° elevation)
		• IR/ER strengthening: Theraband/PREs
		• Humeral head control exercises: Rhythmic stabilization
		• Airdyne/upper-body ergometer
		• Scapular stabilization exercises: CKC (below 90° elevation)
		• CKC perturbation exercises

determined by gains in ROM, patient comfort level, and physician's preference.

Management of Pain and Swelling

- Cryotherapy: Ice packs, game ready
- Moist heat packs before mobilization exercises
- Electrotherapy (TENS, IFC) if indicated
- Analgesic/NSAID medication as needed

Techniques for Progressive Increase in Range of Motion

Manual Therapy Techniques

- ROM precautions: IR 30°/ER 30° (scapular plane), horizontal adduction 0°, scapular plane elevation to 120°
- PROM (pain-free) exercises to glenohumeral joint (limitations as mentioned above), PROM exercises performed supine with scapula stabilized, gentle grade I glenohumeral joint mobilizations
- Careful attention to protect posterior capsule from unnecessary stress
- Side-lying scapula AROM, AAROM, and PROM exercises (scapular elevation, depression, retraction, and protraction) to restore normal scapulothoracic mobility

Soft Tissue Techniques

- Scar mobilization to postsurgical incisions once closed.
- Soft tissue massage (scapular musculature)

Stretching and Flexibility Techniques for the Musculotendinous Unit

- Codman's exercise, emphasizing proper techniques.
- Wand exercise ER, performed supine (scapular plane) (Figure 3-19)
- AAROM exercise FF (scapular plane) performed supine using noninvolved upper extremity. Exercise progressed to using wand as ROM and humeral head control is established.
- AAROM forward flexion (scapular plane) using pulleys as ROM approximates 120° technique emphasized to discourage compensatory shrugging of shoulder girdle.

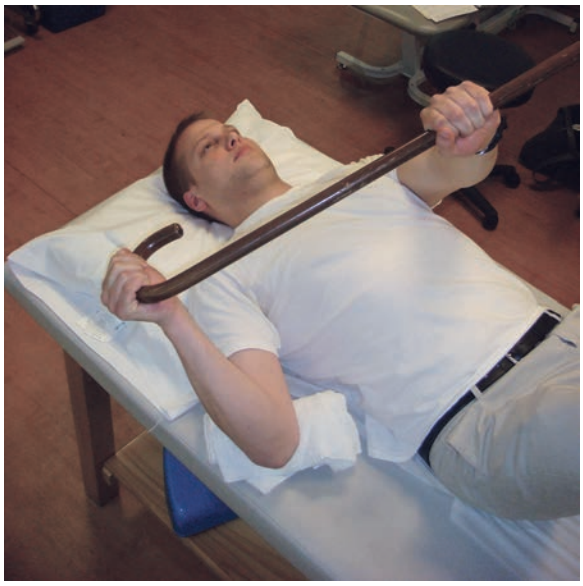

FIGURE 3-19. Wand exercise for ER in scapular plane.

Other Therapeutic Exercises

- Cardiovascular exercise using a stationary bicycle and/or elliptical machine
- Distal strengthening: wrist flexors/extensors with PRE
- Core-stabilization exercises
- Lower-extremity strengthening: CKC (body weight)/open kinetic chain (OKC) (PRE)
- Pool therapy exercises are initiated: AAROM scaption, scapular retraction/protraction, horizontal abduction/adduction (0°)

TIMELINE 3-2 Postoperative Rehabilitation after Treatment of Multidirectional Shoulder Instability (Continued)

PHASE IV (weeks 12 to 20)	PHASE V (weeks 20 to 30)

• PT modalities as needed
• AAROM exercises:
  • ER → 75°
  • IR → 60° (protect posterior capsule)
  • FF → 170°
• Mobilizations as needed:
  • Scapular exercises (PREs)
• FF, scapular plane, ("scaption"): PREs
• Biceps/triceps PREs
• Glenohumeral extension: Theraband/PREs (greater than 90° elevation)
• IR/ER strengthening: Theraband/PREs/isokinetics
• Humeral head control exercises: Rhythmic stabilization
• Scapular stabilization exercises: CKC
• CKC perturbation exercises
• Airdyne/upper-body ergometer
• Chest press (arc)
• PNF exercises: Manual/theraband/PRE
• TBS/TAS/TLS activities as recommended and tolerated
• Upper-extremity sport-specific activities
	• PT modalities as needed
	• Progress ROM to WNL
	• Flexibility exercises
	• Mobilizations as needed
	• Sleeper stretch IR
	• Scapular exercises (PREs)
	• FF (scapular plane) "scaption": PRE
	• Biceps/triceps PRE
	• Glenohumeral extension theraband/PRE (greater than 90° elevation)
	• IR/ER strengthening: Theraband/PRE/isokinetics: 90/90
	• Isokinetic test
	• Humeral head control exercises: Rhythmic stabilization
	• Scapular stabilization exercises: CKC/unilateral
	• CKC perturbation exercises
	• Airdyne/upper-body ergometer
	• Chest press
	• Military press: PRE
	• PNF exercises: Manual/TheraBand/PRE
	• Plyometrics: Below horizontal, progressing to overhead
	• TBS/TAS/TLS activities as recommended and tolerated
	• Sport-specific training/monitor volume
	• Interval throwing program
	• Swimming

FIGURE 3-20. Side-lying AROM and resisted scapula exercises.

Activation of Primary Muscles Involved in Injury Area or Surgical Structures

- Side-lying AROM and resisted scapula exercises to initiate the reestablishment of scapular stability (Figure 3-20)
- Humeral head control exercise IR/ER (supine/scapular plane) to reeducate rotator cuff musculature to reestablish neuromuscular control of dynamic stabilizers
- Submaximal isometrics: Anterior/middle/posterior deltoid performed in neutral rotation (short lever arm/elbow at 90° flexion)
- Submaximal isometrics: Rotator cuff musculature. ER/IR performed in modified neutral (scapular plane), once 30° of passive ER/IR is attained.
- Scapular retraction isometrics
- Postural exercises/awareness

Sensorimotor Exercises

- Humeral head control exercises/rhythmic stabilization (manual)

Neuromuscular Dynamic Stability Exercises

- Lower-extremity balance activities: stable surface → unstable surface, bilateral support → unilateral support. Add perturbations when appropriate

Phase III (weeks 6 to 12 postoperatively)

Clinical Pearls

- Gradual restoration of IR and horizontal adduction is begun in this phase.
- The clinician should continue to respect the healing response of the posterior capsule.
- ROM exercise should continue to be performed in the scapular plane throughout this phase.
- Scapular musculature strengthening is emphasized during this phase to develop a stable/strong base for the more demanding exercises and sport-specific activities to follow in later stages of this rehabilitation program.

Goals

- Improve PROM: (scapular plane) elevation → 160°, ER → 60°, IR → 45°, horizontal adduction → 20°
- Improve scapulohumeral rhythm to within normal limits (WNL) less than 90° elevation (scapular plane)
- Independent with home therapeutic exercise program

Protection

- Sling is gradually discontinued from week 6 to week 8, depending on functional status and living/working environment

Management of Pain and Swelling

- Moist heat (before exercise)
- Cryotherapy (after exercise and as needed)
- NSAIDs
- Oral analgesics as needed

Techniques for Progressive Increase in Range of Motion

Manual Therapy Techniques

- ROM Precautions: IR 45°/ER 60° (scapular plane), horizontal adduction 20°, scapular plane elevation to 160° PROM (pain-free) exercises to glenohumeral joint (limitations as mentioned above) PROM exercises performed supine with scapula stabilized.
- Gentle grade I glenohumeral joint mobilizations
- Careful attention to protect posterior capsule from unnecessary stress

Soft Tissue Techniques

- Continue soft tissue massage: scapular musculature, latissimus dorsi, and pectoralis major/minor
- Continue scar mobilization to post surgical incisions as needed

Stretching and Flexibility Techniques for the Musculotendinous Unit

- Wand exercise for forward elevation is advanced to pulleys when athlete demonstrates PROM of 120° elevation and good humeral head control. Proper technique is emphasized so as to avoid any compensatory shoulder shrugging
- Pool exercises incorporate horizontal abduction to 20°

Other Therapeutic Exercises

- Lower-extremity strengthening continues with OKC and CKC exercises with PRE
- Upper-extremity strengthening (besides specific exercises listed below) include airdyne bicycle and upper-body ergometers
- Cardiovascular conditioning includes treadmill walking, stationary bicycle, elliptical trainer, StairMaster and versa climber

Activation of Primary Muscles Involved in Injury Area or Surgical Structures

- Humeral head control exercises: IR/ER (supine/scapular plane) to reeducate rotator cuff musculature to re-establish neuromuscular control of dynamic stabilizers.
- Rhythmic stabilization of humeral positioners at 110° elevation (scapular plane)

  Strengthening emphasis during this phase is placed on the scapular musculature. Isolated strengthening of the trapezius muscles, rhomboids, and serratus anterior are performed via PRE, such as scapular retraction on a row machine, supine punches (Figure 3-21), prone horizontal abduction, and bilateral ER with TheraBand (elbows bent to 90°/at side). Closed-chain exercises are initiated with weight shifts (wide-based hand position to approximate scapular plane and avoid direct load to posterior capsular), progressing to physioball stabilization against a plyoback (below 90°elevation).
- Forward plane elevation in the scapular plane (scaption) is initiated upon the athlete demonstrating normal scapulothoracic rhythm. Progressive resistance is applied and progressed as tolerated (Figure 3-22).
- Isolated rotator cuff strengthening for ER/IR is progressed to TheraBand once 60° of ER and 45° of IR are attained. This exercise is performed in a modified neutral position. (towel in axilla)
- Resisted bicep and tricep muscular strengthening

Sensorimotor Exercises

- Rhythmic stabilization, supine (scapular plane, progressing to multiangle humeral positioning)
- CKC stabilization exercises (physioball stabilization below 90° on a plyoback), progressing to perturbations.

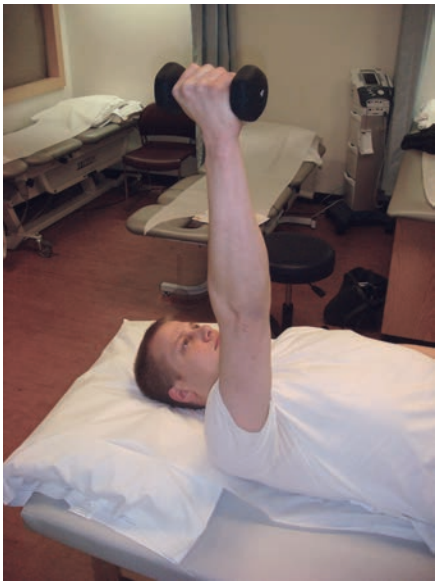

FIGURE 3-21. Supine "punches" for serratus anterior muscle strengthening.

FIGURE 3-22. Forward plane elevation in the scapular plane (scaption).

Open and Closed Kinetic Chain Exercises

- Described above

Techniques to Increase Muscle Strength, Power, and Endurance

- Progressive resistance for the exercises discussed above
- Aggressive strengthening as tolerated for scapula musculature
- Light resistance for isolated rotator cuff exercises and scaption exercise (respecting long lever arm)

Neuromuscular Dynamic Stability Exercises

- Described above

Milestones for Progression to the Next Phase

- PROM: (scapular plane) elevation → 160°, ER → 60°, IR → 45°, horizontal adduction → 20°
- Scapulohumeral rhythm to WNL less than 90° elevation (scapular plane)

Phase IV (weeks 12 to 20 postoperatively)

Clinical Pearls

- It is imperative that full ROM be attained during this phase of rehabilitation in order for the athlete to safely return to sport on schedule.
- This is achieved via PROM, AAROM, and flexibility exercises.
- Not only will full ROM be required for sports participation, particularly in the overhead athlete, but full ROM will be needed for aggressive strengthening (isokinetics, plyometrics), which will be introduced to the rehabilitation program in this phase.

Goals

- Improve ROM to WNL
- Improve muscle strength to 5/5 throughout involved upper extremity
- Restore scapulohumeral rhythm throughout ROM
- Full ADL

Management of Pain and Swelling

- Cryotherapy (after exercise and as needed)
- NSAIDs as needed
- Oral analgesics as needed

Techniques for Progressive Increase in Range of Motion

Manual Therapy Techniques

- Progress ROM to full PROM as tolerated
- Glenohumeral joint mobilizations

Soft Tissue Techniques

- Continue soft tissue massage: scapular musculature, latissimus dorsi, and pectoralis major/minor
- Continue scar mobilization to postsurgical incisions as needed
- Massage therapist consult if needed

Stretching and Flexibility Techniques for the Musculotendinous Unit

- Wand ER stretching 90°/90°
- End-range FF stretch (doorway)
- Towel stretch (IR)
- Posterior capsule stretch
- "Sleeper" stretch (IR) (Figure 3-23)

Other Therapeutic Exercises

- Lower-extremity strengthening continues with OKC and CKC exercises with PRE
- Upper-extremity strengthening/conditioning: airdyne, upper-body ergometers, rowing ergometer

FIGURE 3-23. "Sleeper" stretch" for IR.

FIGURE 3-24. ER/IR Isokinetic strengthening (modified neutral position).

- Cardiovascular conditioning includes treadmill running, stationary bicycle, elliptical trainer, StairMaster, and versa climber

Activation of Primary Muscles Involved in Injury Area or Surgical Structures

- Progress upper-extremity strengthening (PRE): Row (scapular retraction), chest press, latissimus dorsi pulldown, biceps, triceps
- Progress scapular musculature strengthening (PRE) via OKC (isolated) and CKC (stabilization) exercises: Physioball stabilization is progressed to 90° elevation, then to unilateral (involved) stabilization with a plyoball
- Scaption (long lever arm) PRE, monitoring correct form
- ER/IR strengthening using isokinetics (moderate → fast speeds/modified neutral positioning) (Figure 3-24)
- ER/IR strengthening progressed to 90/90 position using TheraBand when ROM is WNL
- PNF (D2/D1) patterns with manual resistance progressing to TheraBand

Sensorimotor Exercises

- Continue humeral head control and rhythmic stabilization exercises at various ROM positions
- CKC scapular stabilization with perturbations

Open and Closed Kinetic Chain Exercises

- Pushup progression (CKC) is initiated using wide base of support (protect posterior capsule from direct sagital plane load) wall pushups → pushups (angle) → floor pushups.

Techniques to Increase Muscle Strength, Power, and Endurance

- Consider changing repetitions/program should athlete participate more than 5 days/week, i.e., strengthening sets 3 × 10, 2 × 10, 1 × 10 to prevent overuse symptoms from presenting and to add variety to program.
- Continue lower-extremity strengthening, flexibility balance programs
- Progress core strengthening

Neuromuscular Dynamic Stability Exercises

- Rhythmic stabilization exercises as described above. Progress to less stable positioning, i.e., sitting/standing

Plyometrics

- Initiate chest pass below 90° on plyoback
- Lower-extremity plyometrics

Sport-Specific Exercises

- Lower-extremity drills (sport-specific), i.e., agility, hopping, bounding
- Upper-extremity sport-specific activities permitted at 4 months should ROM and muscle strength be WFL, e.g., baseball (fielding ground balls/hitting; noninvolved lead shoulder before involved lead shoulder), golf (chipping/putting), volleyball (bumping/setting), swimming (breaststroke), tennis (ground strokes)

Milestones for Progression to the Next Phase

- Full ROM
- Muscle strength 5/5 throughout involved upper extremity
- Normal scapulohumeral rhythm throughout ROM

Phase V (weeks 20 to 30 postoperatively)

Clinical Pearls

- Having met the goals of restoring full ROM throughout the earlier phases, the goal in this last phase of rehabilitation is to ensure that the athlete has the sufficient amount of strength, power, endurance, and flexibility to meet the demands of his/her specific sport.
- A periodization approach to rehabilitation is taken, whereas the athlete performs varied workouts throughout the week.
- Sport-specific training one day (throwing, swimming, etc.), weight training on another day.
- Volume of weight training should be monitored, as should volume of sport-specific activity (throws, yardage swam, etc.).
- The athlete needs to be closely monitored for signs of overuse.
- Rehabilitative programs often need to be adjusted if and when subjective complaints present.

Goals

- Improve muscle strength, power, and endurance greater than 90% limb symmetry via isokinetic testing ER/IR
- ER/IR ratio within 85% of contralateral upper extremity
- Maximize flexibility so as to meet the demands of specific sport
- Lack of apprehension, instability, and pain with sport-specific movements
- Independent with home and gym therapeutic exercise programs

Management of Pain and Swelling

- Cryotherapy (after exercise and as needed)
- NSAIDs as needed
- Oral analgesics as needed

Techniques for Progressive Increase in Range of Motion

Manual Therapy Techniques

- Continue above treatment strategies to maintain ROM and enhance flexibility
- Glenohumeral joint mobilizations
- Cervical/thoracic mobilizations as needed

Soft Tissue Techniques

- Continue soft tissue massage: Scapular musculature, latissimus dorsi, and pectoralis major/minor
- Continue scar mobilization to postsurgical incisions as needed

Stretching and Flexibility Techniques for the Musculotendinous Unit

- Continue upper-extremity stretching program as part of warmup and cool-down portions of rehabilitation program.

Other Therapeutic Exercises

- Lower-extremity strengthening continues with OKC and CKC exercises with PRE and plyometrics
- Upper-extremity strengthening/conditioning: Airdyne, upper-body ergometers, rowing ergometer
- Cardiovascular conditioning includes running, stationary bicycle, elliptical trainer, StairMaster and versa climber

Activation of Primary Muscles Involved in Injury Area or Surgical Structures

- Continue PRE to involved upper extremity

Sensorimotor Exercises

- Continue rhythmic stabilizations at different angles

Open and Closed Kinetic Chain Exercises

- Continue exercises as listed earlier (PRE)
- Front raises (below 90°), lateral raises (below 80°)
- Pushups on BOSU® ball
- PNF patterns with TheraBand sitting on physioball → perturbations

Techniques to Increase Muscle Strength, Power, and Endurance

- Incorporate training programs to days specific to strength (low reps), power (speed), and endurance (high reps), i.e., periodization
- Velocity spectrum training with isokinetics
- Initiate bench press (wide grip) PRE. It is not realistic for the athlete to match their personal best with bench pressing until greater than 1 year after operation

Neuromuscular Dynamic Stability Exercises

- CKC stabilization on BOSU® ball: Bilateral support (eyes open → eyes closed) → perturbations → unilateral support (eyes open → eyes closed) → perturbations

Plyometrics

- Bilateral overhead throws ("soccer throws") against plyoback
- 90/90 toss/catch (supine) of plyoball with rehabilitation specialist
- Unilateral (involved extremity) throws with plyoball 90/90 against plyoback
- Deceleration D2 PNF pattern off wall with plyoball (throwing athletes)

Sport-Specific Exercises

- Continue lower-extremity drills (sport-specific), i.e., agility, hopping, bounding
- Upper-extremity sport-specific activities progressed to overhead activities, e.g., interval throwing program (baseball), high irons → middle irons → low irons (golfer), serving/spiking (volleyball), freestyle → backstroke → butterfly (swimming), and serving (tennis). These activities should not be performed on consecutive days, with symptoms and volume closely monitored

Milestones for Progression to the Next Phase

- Muscle strength, power, and endurance greater than 90% limb symmetry via isokinetic testing ER/IR
- ER/IR ratio within 85% of contralateral upper extremity
- Flexibility in line with the demands of specific sport
- Lack of apprehension, instability, and pain with sport-specific movements
- Independent with home and gym therapeutic exercise programs

Criteria for Return to Sport

General

- Muscle strength, power, and endurance greater than 90% limb symmetry via isokinetic testing ER/IR (dominance corrected)
- ER/IR ratio within 85% of contralateral upper extremity
- Flexibility in line with the demands of specific sport
- Lack of apprehension, instability, and pain with sport-specific movements
- Independent with home and gym therapeutic exercise programs

Sport-Specific

Return to sports should follow a progression protecting the surgical correction. ROM and muscle strength should approach near normal ranges before initiating sport-specific activities. Dominance should be taken into consideration when evaluating isokinetic measures because dominance has been shown to yield 10% greater torque values.

- Baseball: Hitting will preclude throwing. A right-handed hitter with a surgically repaired right shoulder will be allowed to hit before a right-handed hitter with a surgically repaired left shoulder.
- Tennis: Ground strokes with proper technique are allowed before overhead volleys and serving
- Swimming: Breaststroke will be allowed before freestyle. Volume of activity closely monitored

After Return to Sport

Continuing Fitness or Rehabilitation Exercises

- Upper- and lower-extremity strengthening exercises
- Flexibility exercises
- Core-stabilization program

Exercises and Other Techniques for Prevention of Recurrent Injury

- Continue to challenge the neuromuscular/proprioceptive element of the rehabilitation program to better condition the dynamic shoulder stabilizers so that they are prepared to provide stability to the glenohumeral joint during joint loading
- Compliance with home/gym therapeutic exercise program for maintenance and advancement of strength and flexibility gains.

Evidence

Baker CL, 3rd, Mascarenhas R, Kline AJ, et al: Arthroscopic treatment of multidirectional shoulder instability in athletes: a retrospective analysis of 2- to 5-year clinical outcomes. *Am J Sports Med* 37:1712–1720, 2009.

The authors evaluated 40 patients (43 shoulders) with MDI of the shoulder treated via arthroscopic means at a mean of 33.5 months postoperatively. Postoperative rehabilitation with early ROM was used. Ninety-one percent of patients had full or satisfactory ROM, 98% had normal or slightly decreased strength, and 86% were able to return to their sport with little or no limitation. (Level IV evidence).

Ellenbecker TS, Davies GJ: The application of isokinetics in testing and rehabilitation of the shoulder complex. *J Athl Train* 35:338–350, 2000.

Clinical use of upper-extremity isokinetic training and testing reviewed. (Level IV evidence).

Nyiri P, Illyés A, Kiss R, et al: Intermediate biomechanical analysis of the effect of physiotherapy only compared with capsular shift and physiotherapy in multidirectional shoulder instability. *J Shoulder Elbow Surg* 19:802–813, 2010.

This study compared the kinematic parameters and activity pattern of muscles around the glenohumeral joint in MDI treated by only physiotherapy (N-32) and by capsular shift and physiotherapy (N-19), before and after treatment. (N-50) healthy shoulders were used as the control. The physiotherapy strengthened the muscles, but regression lines remained monolinear. Capsular shift and physiotherapy resulted in bilinear regression lines, and normal relative displacement between the rotation center of scapula and humerus was restored. After surgery and physiotherapy the activity pattern of muscles was almost normal. (Level III evidence).

Speer KP, Cavanaugh JT, Warren RF, et al: A role for hydrotherapy in shoulder rehabilitation. *Am J Sports Med* 21:850–853, 1993.

Clinical rationale for using a hydrotherapy rehabilitation program in the early postsurgical rehabilitation period.(Level IV evidence).

Voigt C, Schulz AP, Lill H: Arthroscopic treatment of multidirectional glenohumeral instability in young overhead athletes. *Open Orthop J* 3:107–114, 2009.

This prospective case series of nine young overhead athletes (10 shoulders) evaluates the outcome and the return to sports of young overhead athletes with a persistent, symptomatic, MDI with hyperlaxity treated with an arthroscopic anteroinferior capsular plication and rotator interval closure. At the final follow-up all patients were satisfied; Rowe Score showed 7 "excellent" and "good" results; Constant Score was "excellent" and "good" in 6 and "fair" in 1 patient. Seven of nine patients returned to their previous sports, three of nine at a reduced level. (Level IV evidence).

Voight ML, Thomson BC: The role of the scapula in the rehabilitation of shoulder injuries. *J Athl Train* 35:364–372, 2000.

This clinical update article contains information on the pathomechanics, evaluation, and thorough coverage of rehabilitation methods to optimize scapular function. (Level V evidence).

Multiple-Choice Questions

QUESTION 1. Following surgical correction for MDI, sling immobilization is continued at all times except for therapeutic exercises, self-care, hygiene, etc., until how many weeks postoperatively?

A. 1 to 2 weeks
B. 2 to 3 weeks
C. 3 to 4 weeks
D. 4 to 5 weeks

QUESTION 2. Following surgical correction for MDI, glenohumeral elevation ROM exercises are limited to which of the following planes for the first 12 postoperative weeks?

A. Frontal
B. Scapular
C. Sagital
D. Coronal

QUESTION 3. Following surgical correction of MDI, the posterior capsule is protected from undue stress. IR is limited to 30° in the scapular plane until:

A. 2 weeks
B. 6 weeks
C. 10 weeks
D. 12 weeks

QUESTION 4. Isolated rotator cuff strengthening for ER is progressed from isometric to TheraBand once ____ of ER is achieved.

A. 20°
B. 40°
C. 60°
D. 80°

QUESTION 5. Muscle strength criteria for return to sport of the involved external and internal rotators should exceed ____ limb symmetry.

A. 60%
B. 70%
C. 80%
D. 90%

Answer Key

QUESTION 1. Correct answer: **D** (see weeks 2 to 6)

QUESTION 2. Correct answer: **B** (see weeks 6 to 12)

QUESTION 3. Correct answer: **B** (see weeks 2 to 6)

QUESTION 4. Correct answer: **C** (see weeks 6 to 12)

QUESTION 5. Correct answer: **D** (see weeks 20 to 30)

BEYOND BASIC REHABILITATION: RETURN TO SWIMMING AFTER TREATMENT OF MULTIDIRECTIONAL SHOULDER INSTABILITY

Polly de Mille, RN, MA, RCEP, CSCS, John T. Cavanaugh, PT, MEd, ATC, SCS, and Scott A. Rodeo, MD

Introduction

ASPECTS OF SWIMMING THAT REQUIRE SPECIAL ATTENTION IN REHABILITATION

- Repetitive movement in an overhead position that requires:
  - Full ROM
  - Adequate muscle strength of the core, scapula, and rotator cuff muscles to meet the demands of swimming
  - Adequate neuromuscular control of the glenohumeral joint
- Large training volumes, year round
- The shoulder is inherently susceptible to injury in overhead sports. For swimmers, shoulder pain is the most common musculoskeletal complaint. It has been reported that competitive swimmers may undergo as many as 16,000 shoulder revolutions per week. Microtrauma is thereby inevitable, with 66% of elite swimmers reporting a shoulder injury at one point in their career.[1]
- Shoulder surgery in the management of "swimmers shoulder" to include debridement, partial release of the coracoacromial ligament, and bursectomy have yielded less than remarkable results.[2]
- Stabilization surgery in swimmers who have failed a nonoperative course of treatment has been reported to be a viable intervention. Return to preinjury training volume, however, is questionable.[3]

Phase I: Advanced Strength and Conditioning Programs (Box 3-1)

Periodization

- Linear
  - Linear periodization will allow the athlete to reestablish a base of strength and endurance in the

BOX 3-1 Advanced Rehabilitation Program

- Prone scapula strengthening for middle and lower trapezius muscles (Figure 3-25).
- IR and ER isokinetic strengthening in a 90/90 position (Figure 3-26).
- Closed kinetic chain stabilization exercises using perturbations (Figure 3-27).
- Prone 90/90 ball catches emphasizing posterior rotator cuff eccentric strengthening (Figure 3-28).

FIGURE 3-25. Prone scapula strengthening for middle and lower trapezius muscles.

FIGURE 3-26. IR and ER isokinetic strengthening in a 90/90 position.

FIGURE 3-27. Closed kinetic chain stabilization exercises using perturbations.

FIGURE 3-28. Prone 90/90 ball catches emphasizing posterior rotator cuff. Eccentric strengthening.

hypertrophy and strength phase followed by the development of power. Undulating periodization programs may be appropriate in subsequent training macrocycles.
- Macrocycles
- The return to swimming macrocycle may take 6 to 12 months depending on the response of the individual athlete to the progressions in each mesocycle.
- Mesocycles
  - Hypertrophy/endurance phase, 3 to 5 weeks
  - Strength phase, 3 to 5 weeks
  - Power phase, 3 to 5 weeks
- Microcycles
  - Gradual increase in sets/reps over the 3- to 5-week cycle
  - Recovery built in to each week, e.g., recovery day following hard training day

Program Design/Performance Training Program

Sport-Specific Concepts of Integrated Training

- The goal is to return the athlete to a full training load and successful return to competition. Because muscle weakness, muscle imbalances, lack of flexibility, and faulty mechanics may all place the athlete at risk of injury, it is critical to keep the following principles in mind when designing the training plan.
- Performance enhancement training techniques require a solid foundation of overall strength, core stability, mobility, and cardiorespiratory fitness to prevent possible injury.
- All swimming strokes involve the entire body and require generating force against water. Building the components of mobility, strength, and neuromuscular control will allow the athlete to generate power while reducing drag. This requires a training program that integrates the following concepts.
- Training continuum
  - A gradual progression will give the athlete the best chance to be able to tolerate the high volume of shoulder revolutions involved in training for competitive swimming by creating a base of overall muscular strength and endurance before progressing to higher intensity and sport-specific performance enhancement techniques.
- Training with optimum posture
  - The streamline position is a key factor in reducing drag in the water, so all dry-land exercises should be done with attention to optimum posture.
- Core training
  - Core strength is essential for good swimming technique—rotation in the water, propulsion from the kick and streamline position
- Cardiorespiratory training
  - The volume of cardiorespiratory training done on land would gradually transition to swim training as the upper extremity and trunk musculature gains strength and endurance and can tolerate increasing volume of repetitions.

Olympic Lifts Used in the Training Program

- Snatch
- Clean

Training Principles Used in the Design of the Program

- Because the athlete may have lost overall conditioning as a result of the injury and recovery, a gradual progression will allow the athlete to reestablish a foundation of overall fitness before sport-specific training. The following principles would apply to both the dry-land and water programs.
  - Principle of progression
  - Principle of overload
  - Principle of variation
  - Principle of individualization
  - Principles of specific adaptations to imposed demands (SAID)

Application of Acute Training Variables

- Repetitions
  - Hypertrophy/endurance phase: 10 to 20 reps
  - Strength phase: 4 to 8 reps
  - Power phase: 2 to 5 reps
- Sets
  - Hypertrophy phase: 3 to 6 sets
  - Strength phase: 3 to 5 sets
  - Power phase: 3 to 5 sets
- Rest interval
  - Hypertrophy/endurance: less than 60 seconds
  - Strength phase: 2 minutes
  - Power: 2 minutes
- Intensity
  - Hypertrophy/endurance: 60% to 85% of one-repetition maximum (1RM)
  - Strength: less than 85% of 1RM
  - Power: 75% to 85% of 1RM
- Repetition tempo
  - Hypertrophy: moderate tempo (2/0/2)
  - Strength: moderate/fast
  - Power: fast/explosive
- Training frequency
  - 3 to 4 days

FIGURE 3-29. Unilateral pulldown prone on stability ball.

- Training duration
  - Less than 60 minutes per session
  - 3 to 5 weeks per cycle
- Training volume
  - Hypertrophy: 36 to 75 repetitions/exercise
  - Strength: 18 to 24 repetitions/exercise
  - Power: 12 to 20 repetitions/exercise
- Specific exercises used in the training
  - Latissimus dorsi pulldown
  - Standing pulldown
  - Unilateral pulldown prone on stability ball or with rotation in side plank position (Figures 3-29 and 3-30)
  - Pullups
  - Chinups
  - Row
  - Bench press
  - Unilateral incline press
  - Pushups
  - Serratus punch
  - Upper-body step-up (Figure 3-31) or crab walk
  - Scapular retraction with ER
  - Standing IR/ER
  - IR/ER in catch position
  - Scaption
  - Prone Y, T

FIGURE 3-30. Unilateral scapula strengthening with trunk rotation in plank position.

FIGURE 3-31. Upper-body step-ups.

  - Wrist flexion and extension
  - Standing triceps extensions (bi- and unilateral)
  - Lower body
    - Squats/lunges (with rotation), step-ups
    - Calf raises/dorsiflexion
  - Cleans
  - Snatch
  - Push press
  - Core
    - Planks/planks on stability ball
    - Side planks
    - Ball rotations against wall
    - Dead bug
    - Bird dog
    - Leg drop to each side
    - Crunches, with rotation
    - Russian twists
    - Supermans
  - All exercises are not performed in each session. Loads are at the level that allows the athlete to complete the desired repetitions with proper form.

Application of Chronic Training Variables

- Volume is increased before intensity in both water and dry-land training.
- In the dry-land strength and conditioning program, the hypertrophy phase would be performed early preseason followed by strength/power.
- During the competition phase, the volume of dry-land training is decreased and more power-based exercises are included. The decreased volume of dry-land training allows for the increase in sport-specific swim training.
- In all phases of training, loads should be adjusted to allow the athlete to maintain optimal form during each repetition of each exercise.
- Because maintaining a streamline position is critical for swimmers, postural alignment is essential in all dry-land training exercises. If excessive lordosis or kyphosis occurs when performing any exercise, the set should be terminated and the load adjusted to allow the athlete to perform the recommended number of repetitions with good form.
- When body weight exercises (pushups, pull-ups, or chinups) are performed, assistance may be provided to

ensure optimal alignment for the recommended number of repetitions.
- All dry-land training should lead to improvements in the swimmer's ability to apply force in a streamlined position.

Phase II: Performance Enhancement Training Techniques

Periodization

- Linear
  - This phase would follow the linear progression from hypertrophy/endurance to strength to power.
  - This linear progression would reestablish a base of conditioning needed to perform the higher intensity performance enhancement exercises with proper form.
- Macrocycles
  - The return to swimming macrocycle may take 6 to 12 months depending on the response of the individual athlete to the progressions
- Mesocycles
  - Hypertrophy/endurance phase 3 to 5 weeks
  - Strength phase, 3 to 5 weeks
  - Power phase, 3 to 5 weeks
  - Performance enhancement techniques, 2 to 4 weeks
- Microcycles
- Gradual increase in sets and reps over each week
- Training should be performed on nonconsecutive days to allow adequate recovery

Program Design/Performance Training Program

Sport-Specific Concepts of Integrated Training

- Training continuum
- Flexibility/joint mobility for joint stability
- Training with optimum posture
- Sensorimotor and balance training
- Core training
- Cardiorespiratory training
- Multiplanar training activities
- Training for optimum muscle balance
- Training for optimum muscle functional strength
- Training for optimum muscle functional power
- Neuromuscular dynamic stability exercises
- Training for speed, agility, quickness (SAQ)
- Plyometric training
- Functional training
- Sport-specific training
- Stength: Power supersets. The resistance exercises are high intensity to increase the "force" side of the power equation.
- The plyo exercises focused on enhancing the "velocity" side of the power equation.

Olympic Lifts Used in the Training Program

- Snatch
- Power clean

Training Principles Used in the Design of the Program

- Principle of progression
- Principle of overload
- Principle of variation
- Principle of individualization
- Principles of SAID

Application of Acute Training Variables

See Phase 1: Advanced Strength and Conditioning leads to Performance Enhancement. Plyometric and strength/power training would be included to further enhance performance as well as further improve proprioception and kinesthesia. These techniques focus on both high force and high velocity to increase power.
- Repetitions
  - Plyo: 8 to 12
  - Superset of strength and power exercise:
    - Strength: 1 to 5
    - Power: 8 to 10
- Sets
  - Plyo: 2 to 3
  - Strength: 3 to 5
  - Power: 3 to 5
- Rest interval
  - Plyo: 0 to 60 seconds
  - Strength: 1 to 2 minutes
  - Power: 3 to 5 minutes
- Intensity
  - Plyo: body weight, medicine ball
  - Strength: 85% to 100% 1RM
  - Power: 10% BW or 30% to 45% 1RM
- Repetition tempo
  - Plyo: As fast as possible
  - Strength: controlled
  - Power: as fast as possible
- Training frequency
  - 2 to 3 times/week on nonconsecutive days
- Training duration
  - Less than 60 minutes
  - 2 to 4 weeks
- Training volume
  - Plyo: 16 to 36 repetitions per exercise
  - Strength: 3 to 20 reps per exercise
  - Power: 24 to 40 reps per exercise
- Specific exercises used in the training
  - Plyo:
    - 90° to 180° jump turn
    - Bounding
    - Streamline jump (Figure 3-32)
    - Tuck jumps
    - Figure-of-eight medicine ball pass and throw (Figure 3-33)
    - Plyo sit up with chest pass
    - Explosive rotational medicine ball wall throw
    - Medicine ball squat with chest throw
    - Medicine ball supine catch and throw
    - ER catch and toss
    - 90/90 ball drop
    - Overhead medicine ball throw

FIGURE 3-32. Streamline jump.

- Strength: Power
  - Barbell squat: Jump squat or power step up
  - Dumbbell Split squat: Power lunges
  - Bench press: Medicine ball chest pass double or single arm
  - Lat pulldown: Medicine ball soccer throw (Figure 3-34)

Application of Chronic Training Variables

- The focus of this phase of training would focus on increasing power.
- The preceding mesocycles should have established a solid base of strength.
- The resistance exercises in this phase would be high intensity to increase the "force" side of the power equation.

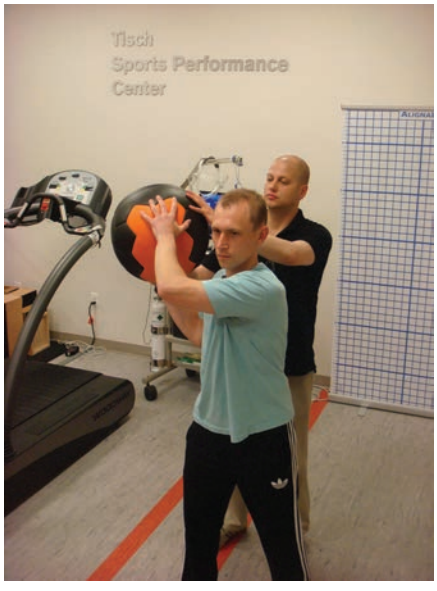

FIGURE 3-33. Figure-of-eight medicine ball catch and throw.

FIGURE 3-34. Medicine ball soccer throw.

- The plyo exercises as well as the power exercises that superset with the strength exercises are focused on enhancing the "velocity" side of the power equation.
- This phase of training would be done leading up to competition.

Phase III: Sport-Specific Training

Periodization

- Linear
  - A linear progression in return to swimming is aimed at establishing ideal technique and sport-specific endurance before progressing to higher intensity swim sets and the use of hand paddles.
- Macrocycles
  - The return to swimming macrocycle may take 6 months or more depending on the athlete's tolerance for the increases in training volume and intensity
- Mesocycles
  - General endurance: 6 to 8 weeks
  - Anaerobic development: 3 to 5 weeks
  - Event-specific training: 2 to 4 weeks
- Microcycles
  - In the endurance phase, there would be a gradual increase in frequency and volume of swim workouts, with the intensity remaining fairly low. Each workout should include technique drills to establish proper form as the training load increases. Greater focus on kick sets in the early weekly microcycles can allow for a gradual increase in training load for the shoulder. A lower volume recovery/adaptation microcycle can be used before transitioning to the next mesocycle or as needed during the mesocycle if the athlete develops soreness or loses form during the training session.
  - In the anaerobic development cycle, the athlete will be working on maintaining form at race pace. Beginning with 25-yard sprints will allow the coach to assess the tolerance for high intensity work before progressing the reps and distance of the high-intensity sets.

Program Design/Performance Training Program

Sport-Specific Concepts of Integrated Training

- Training continuum
- Flexibility/joint mobility for joint stability
- Training with optimum posture: Streamline position that has been incorporated into all dry-land training exercises should be the focus in sport-specific training to reduce drag
- Core training: Core strengthening exercises done in dry-land training should translate to the ability to maintain optimal form while swimming
- Cardiorespiratory training: The linear progression provides for establishing a base of cardiorespiratory endurance before focusing on anaerobic development. The aerobic base allows for quicker recovery between anaerobic sets.
- Multiplanar training activities
- Training for optimum muscle balance
- Training for optimum muscle functional strength
- Training for optimum muscle functional power
- Neuromuscular dynamic stability exercises
- Training for SAQ
- Plyometric training
- Functional training
- Sport-specific training

Training Principles Used in the Design of the Program

- Principle of progression: the athlete will progress volume (total yardage, % of swim- vs. kick-only yardage, and intensity)
- Principle of overload: The volume and intensity are gradually increased to create a stimulus adequate to elicit training adaptations without overloading the athlete to the point of injury or overtraining. The optimal rate of overload will vary with each athlete and in the return to swimming after injury phase; this will demand frequent and close communication between the athlete and coach.
- Principle of variation: Varying drills, volume, intensity, and strokes will result in greater overall conditioning as well as limit the possibility of creating muscle imbalances and overload
- Principle of individualization: Athletes will have individual rates of adaptation to training loads and will require careful supervision to return to high volumes of training without a further injury
- Principles of SAID: The training program will gradually become more event specific. The initial sport-specific training will focus on general endurance and technique development and gradually transition to higher intensity and event-specific training.

Application of Acute Training Variables

- Use of fins, paddles, tubing, baskets, and swim ergometers may be incorporated into sport-specific drills.
- This would be highly individualized depending on the swimmer's stroke, event, training history, age, and level of fitness.

FIGURE 3-35. Unilateral power assessment on swim ergometer.

- The use of hand paddles should be discouraged until shoulder strength is at or near preinjury levels.
- As with all previous phases, progression of volume and intensity of swim training is dependent on the ability to complete a given training session with good form and without pain before, during, or after the session.
- Repetitions
- Sets
- Rest interval
- Intensity
- Repetition tempo
- Training frequency
- Training duration
- Training volume
- Specific exercises used in the training
  - Sculling
  - Swimming against elastic tubing
  - Vertical kicking
  - Swim bench or swim ergometer (Figure 3-35)
    - Unilateral intervals for comparison of peak power, mean power, and power decay
  - Fins, hand paddles, pull-buoys

Application of Chronic Training Variables

Throughout season

Sports Performance Testing

General Information

- General history
- Subjective questionnaires
- Medical history
- Sports injury history
- Surgical history
- Chronic conditions/medications

Specific Criteria for Progression to the Next Stage to Determine Readiness for Swimming

Objective tests

- Physiological assessments
  - Lactate
    - Throughout season

  - Heart rate
    - Resting, submaximal at target velocities, maximal
    - Throughout season
- Body-composition tests
  - Preseason
  - Midseason
  - Precompetition
- Static/dynamic postural assessments
  - Video stroke analysis
  - Throughout season
  - Dynamic muscle performance testing
    - Isokinetic swim bench
    - 4, 8, and 12 weeks after return to swimming
- Sport-specific testing
  - Stroke count
  - Stroke length
  - Start time
  - Turn time
  - Finish time
  - Split time
  - Velocity

Criteria to Determine Readiness for Sport

- Absence of pain
- Full symmetrical ROM as evaluated by the coach or certified athletic trainer (ATC); visual physical exam.
- Ability to maintain form throughout training session (both water and dry land)
  - The coach should observe mechanics during the training session; (videotaped analysis both above and underwater can be helpful here) to detect changes in form with fatigue. The point at which any asymmetries in form develop during a training session should be noted and the volume and intensity limited to the level at which the athlete can maintain form.
- Adaptation to training load—able to increase volume, intensity, or velocity within each phase of training

Specific Criteria for Release to Unsupervised Complete Participation in Swimming

- *Strength:* At or near preinjury levels or symmetrical with unaffected side MMT by trainer; ability to perform equal sets, reps, and load in unilateral upper-body strength-training exercises
- *Power:* Symmetrical with unaffected side (isokinetic swim bench testing; if swim bench is available, side-to-side measures of peak power, mean power output, and power decay in a 30-second sprint can be compared[4])
- *ROM:* At or near preinjury levels or symmetrical with unaffected side
- *Joint stability:* No instability (evaluated by coach or team trainer)
- No tenderness, inflammation, swelling, or effusion on affected side
  - Assessed by observation, examination, and regular interview with athlete
- Ability to consistently maintain proper shoulder mechanics despite a fatiguing workout assessed by close observation during workouts and over- and underwater videotaped analysis if available
- Asymptomatic after full training session
- At or near preinjury level of sport-specific skills

Recommended Ongoing Exercises

- ER/IR standing and in catch position
- Scapular retraction
- Shoulder extension
- Prone T, Y
- Latissimus dorsi pulldown
- Serratus punch
- Core strengthening

Evidence

Bak K, Magnusson SP: Shoulder strength and range of motion in symptomatic and pain-free elite swimmers. *Am J Sports Med* 25:454–459, 1997.

Differences in shoulder strength and ROM were examined in two matched groups of elite swimmers: Group 1 with unilateral shoulder pain related to swimming and a control group with no current or history of shoulder pain. Concentric and eccentric IR torques were reduced in painful shoulders. Both groups exhibited increased external ROM and reduced internal ROM. (Level IV evidence).

Brushøj C, Bak K, Johannsen HV, et al: Swimmers' painful shoulder arthroscopic findings and return rate to sports. *Scand J Med Sci Sports* 17:373–377, 2007.

Retrospective study of 18 competitive swimmers who all had undergone shoulder arthroscopy for therapy-resistant shoulder pain were evaluated with respect to operative findings and ability to return to swimming. Most common finding at arthroscopy: Labral pathology [11 (61%)] and subacromial impingement [5 (28%)]. Operative procedures included debridement in 11 swimmers, partial release of the coracoacromial ligament in 4, and bursectomy in 4. Sixteen (89%) responded to the follow-up evaluation. Nine swimmers (56%) were able to compete at preinjury level after 4 (2 to 9) months. (Level IV evidence).

Creighton DW, Shrier I, Schultz R, et al: Return-to-play in sport: a decision-based model. *Clin J Sport Med* 20:379–385, 2010.

A three-step decision-based return-to-play model is proposed including health status, participation risk, and decision modifiers. (Level V evidence).

Crewther B, Cronin J, Keogh J: Possible stimuli for strength and power adaptation: acute mechanical responses. *Sports Med* 35:967–989, 2005.

This article reviews the metabolic responses to different training regimens (hypertrophy vs. power). Hypertrophy sessions elicit greater blood lactate responses than do dynamic power sessions. The authors conclude that mechanisms underpinning muscular adaptation remain highly speculative.

Lorenz DS, Reiman MP, Walker JC: Periodization: current review and suggested implementation for athletic rehabilitation. *Sports Health* 2:509–518, 2010.

This review article of 91 articles related to periodization discusses relevant training variables, methods of periodization, and periodization program outcomes. The authors conclude that despite the evidence in the strength-training literature supporting periodization programs, there

is a considerable lack of data in the rehabilitation literature about program design and successful implementation of periodization into rehabilitation programs. (Level IV evidence).

McCarty EC, Ritchie P, Gill HS, et al: Shoulder instability: return to play. *Clin Sports Med* 23:335–351, 2004.

This review article focuses on the return to play for competitive individuals after a glenohumeral dislocation or reconstructive surgery for shoulder instability. (Level IV evidence).

Montgomery SR, Chen NC, Rodeo SA: Arthroscopic capsular plication in the treatment of shoulder pain in competitive swimmers. *HSS J* 6:145–149, 2010.

Retrospective study of 18 shoulders in 15 competitive swimmers treated with arthroscopic capsular plication 80% (12/15) of patients who returned to competitive swimming; 20% (3/15) were able to return to their preinjury training regimen volume. All patients subjectively reported improved pain after surgery. The average American Shoulder and Elbow Society score was 78±16 (average, standard deviation). The average L'Insalata score was 82±11. (Level IV evidence).

Newton RU, Hakkinen K, Hakkinen A: Mixed-methods resistance training increases power and strength of young and older men. *Med Sci Sports Exerc* 34:1367–1375, 2002.

Effects of 10 weeks of a periodized resistance-training program designed to increase muscle size, strength, and maximal power on isometric squat strength; time course of force development; muscle fiber characteristics; muscle activation (iEMG); and force and power output during squat jumps were compared in young men (30 ± 5 years, N = 8) and older men (61 ± 4 years, N = 10). Although the results of this study confirm age-related reductions in muscle strength and power, the older men did demonstrate capacity similar to that of young men for increases in these variables via an appropriate periodized resistance-training program that includes rapid, high-power exercises. (Level IV evidence).

Pabian PS, Kolber MJ, McCarthy JP: Postrehabilitation strength and conditioning of the shoulder: an interdisciplinary approach. *J Strength Cond Res* 33:42–55, 2011.

This article outlines the entire spectrum of recovery from common shoulder pathologies from injury to postrehabilitation program design. (Level IV evidence).

Pink MM, Tibone JE: The painful shoulder in the swimming athlete. *Orthop Clin North Am* 31:247–261, 2000.

This article reviews mechanisms of injury, diagnostic tools, subtle signs of injury, and optimal treatment with the focus on the freestyle stroke. (Level V evidence).

Sein ML, Walton J, Linklater J, et al: Shoulder pain in elite swimmers: primarily due to swim-volume-induced supraspinatus tendinopathy. *Br J Sports Med* 44:105–113, 2010.

This article reviews causes of shoulder pain in elite swimmers. Data indicate supraspinatus tendinopathy induced by large amounts of swimming training is major cause. (Level IV evidence)

Swaine IL: Time course of changes in bilateral arm power of swimmers during recovery from injury using a swim bench. *Br J Sports Med* 31:213–216, 1997.

Thirteen competitive swimmers were tested using a swim bench power test at 4, 8, and 12 weeks after return to training after an average 3.7-week absence because of injury. Peak power output, mean power output, and power decay for each arm during 30 seconds of exercise were measured. Differences in bilateral arm power output after injury persist for at least 8 weeks after return to swimming training. (Level IV evidence).

Swanik KA, Lephart SM, Swanik CB, et al: The effects of shoulder plyometric training on proprioception and selected muscle performance characteristics. *J Shoulder Elbow Surg* 11:579–586, 2002.

Twenty-four female D1 swimmers were evaluated before and after a 6-week plyometric training program. Proprioception and kinesthesia were assessed for IR and ER at 0°, 75°, and 90% of subjects maximum ER. Biodex II was used to assess strength at 60°, 240°, and 450°/seconds. Two-way analysis of variance showed significant improvement ($p < 0.05$) in proprioception, kinesthesia, and selected muscle performance characteristics. (Level IV evidence).

Multiple-Choice Questions

QUESTION 1. What is an appropriate level of intensity for an athlete beginning the hypertrophy phase of a strength and conditioning program?

A. 85% to 95% of one-repetition maximum (1RM)
B. Body weight
C. 60% to 85% of 1RM
D. 50% of 1RM

QUESTION 2. What is a benefit of upper-body plyometric exercises following shoulder injury?

A. Increase in strength
B. Improvement in proprioception
C. Muscle hypertrophy
D. Decrease in pain

QUESTION 3. What is the nature of the strength and conditioning program during the competition phase?

A. Low volume, high intensity
B. Low volume, low intensity
C. High volume, low intensity
D. High volume, high intensity

QUESTION 4. Which is an example of a strength:power superset?

A. Deadlift: barbell squat
B. Biceps curl: triceps kickback
C. Bench press: medicine ball chest pass
D. Power lunges: jumping rope

QUESTION 5. Which of the following would NOT be an appropriate criterion for allowing a swimmer to return to training without supervision?

A. Strength symmetrical to unaffected side
B. Ability to complete training sessions
C. Absence of pain
D. ROM symmetrical to unaffected side

Answer Key

QUESTION 1. Correct answer: **C** (see Phase I)

QUESTION 2. Correct answer: **B** (see Phase II)

QUESTION 3. Correct answer: **A** (see Phase I, Chronic Variables)

QUESTION 4. Correct answer: **C** (See Phase II—Performance Enhancement Techniques)

QUESTION 5. Correct answer: **B** (see Sports Performance Testing)

Chapter 4

Superior Labral Pathology (SLAP/Long Head Biceps)

INTRODUCTION

Thomas J. Gill IV, MD, Kaitlin M. Carroll, BS, and Amee L. Seitz, PT, PhD, DPT, OCS

Background

- Superior labral tears were originally described by Andrews et al. in 1985 as lesions that involve the labrum from the anterior portion of the superior glenoid notch to the posterior glenoid, including the anchor of long head of the biceps tendon.
- Superior Labrum Anterior to Posterior (SLAP) tears. SLAP tears are frequently associated with concurrent shoulder pathology, including anterior and posterior Bankart tears, full and partial thickness rotator cuff tears, and acromioclavicular joint arthrosis.

Epidemiology

Age
- 20 to 50 years

Sex
- Male

Sport
- Baseball
- Football
- Tennis
- Javelin
- Wrestling

Position
- Pitchers
- Linebackers
- Offensive linemen

Pathophysiology

Intrinsic Factors

- Composed of fibrocartilaginous tissue, the labrum serves as an anchor point for the capsuloligamentous structures of the shoulder. The labrum deepens the concavity of the glenoid cavity to provide added stability to the glenohumeral joint.
- The pathology includes the attachment point of the long head of the biceps tendon (Figure 4-1).
- The anterior superior labrum frequently extends into the MGHL or IGHL rather than inserting onto glenoid margin (Figure 4-2).
- Functional importance:
  - Possible humeral head depressor
  - Restraint to external rotation in abduction
  - Helps maintain anterior stability of the shoulder joint
- Eccentric contraction of biceps muscle can tear the superior labrum at the biceps anchor.
- Deceleration phase of throwing places high eccentric stresses on the superior labrum, while the late cocking phase of throwing place high "peel-back" forces on the posterosuperior labrum.
- SLAP tears are often implicated as a cause of shoulder pain, weakness, and worsening athletic performance, especially in overhead athletes.
- Understanding the anatomy of the labrum is essential in the diagnosis and treatment of SLAP tears,

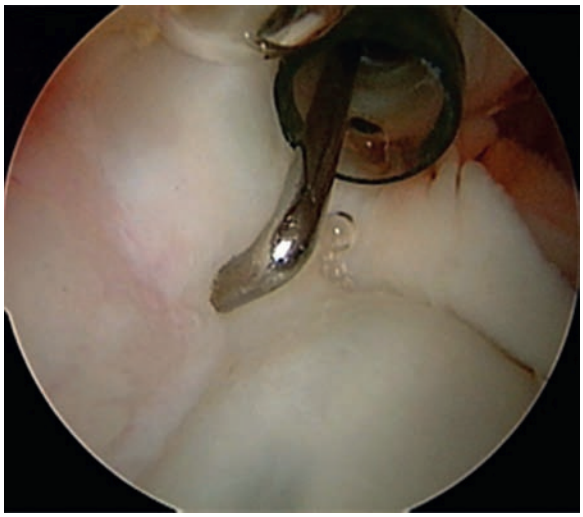

FIGURE 4-1. The pathology of the labrum includes the attachment of the long head of the biceps tendon.

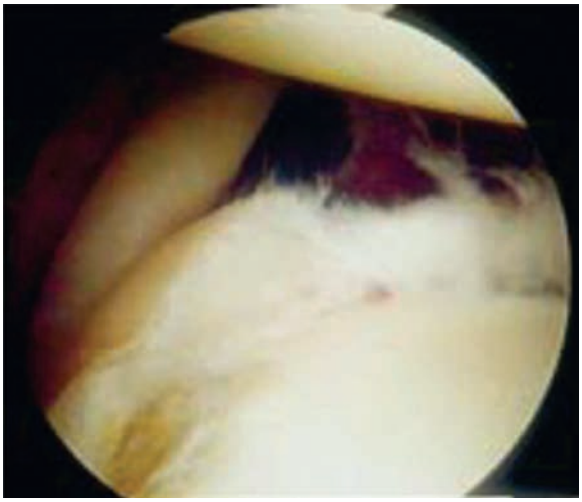

FIGURE 4-3. Type I SLAP tear.

particularly with respect to differentiating normal from abnormal labral morphologies. In addition, extensive SLAP tears may occur anteriorly and posteriorly, leading to associated instability symptoms as well.

- The labrum serves as an anchor point for the capsuloligamentous structures of the shoulder while increasing the radius of curvature of the glenoid cavity. By doing so, it provides added glenohumeral stability, as well as the attachment point for the long head of biceps tendon at the superior glenoid tubercle.

Traumatic Factors

- Falling on an outstretched arm
- Direct blow to the shoulder
- Sudden pull or lifting a heavy object
- Forceful overhead motions
- Compression injuries

Classic Pathological Findings

SLAP lesions are typically classified into four basic types:

- Type I SLAP tears consist of superior labral fraying, without instability of the biceps anchor (Figure 4-3). These lesions are seldom symptomatic, and have unclear clinical significance
  - Fraying and degeneration of the edge
  - Firmly attached labrum and biceps anchor
- Type II SLAP lesions are the most commonly symptomatic and repairable type of SLAP tear (Figure 4-4). They can occur by the "peel-back" phenomenon, repetitive eccentric biceps contractions, or from a fall on an outstretched arm. Type II tears involve detachment of the

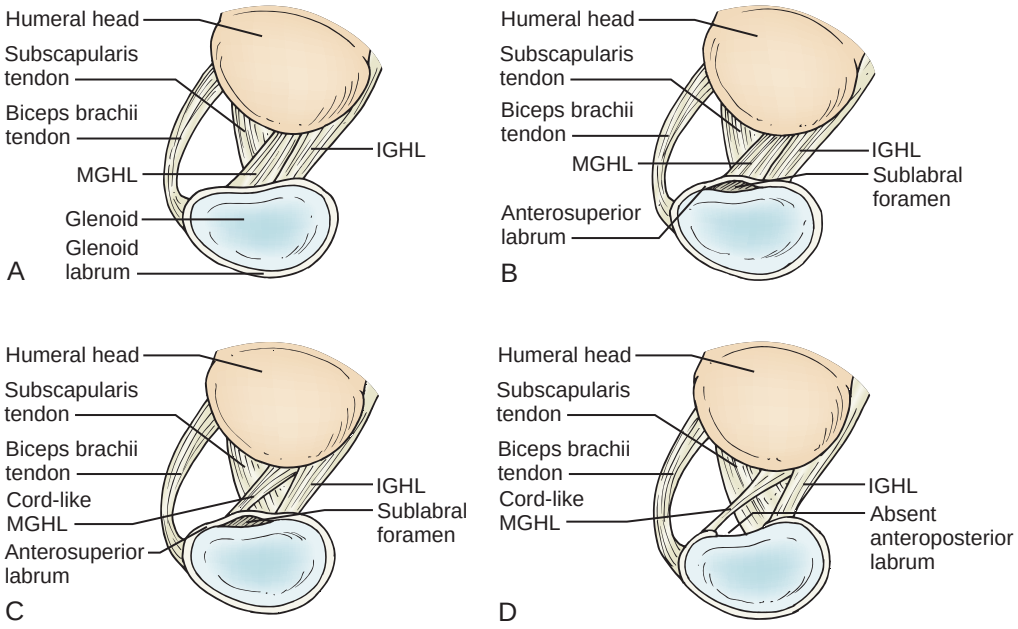

FIGURE 4-2. The anatomic position of the anterior superior labrum and its extension into the MGHL and IGHL.

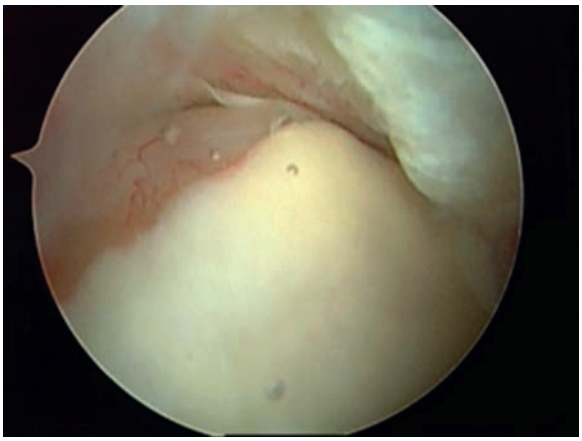

FIGURE 4-4. Type II SLAP tear.

superior labrum from the supraglenoid tubercle, and result in an unstable biceps anchor/attachment
  - Labrum and biceps anchor are detached
  - Complex arches away from glenoid neck
- Type III tears involve a bucket-handle detachment of the labrum in which the actual biceps origin remains stable (Figure 4-5). Complaints of shoulder "catching," "locking," or "stabbing pain" are common.
  - Bucket handle tear
  - Remaining portion of biceps and labrum are still well attached at their insertion
- Type IV SLAP lesions include a bucket handle tear of the labrum where the tear extends into the substance of the biceps tendon (Figure 4-6)
  - Portions of the labrum displaceable into glenohumeral joint

Clinical Presentation

History

- Diagnosing a clinically relevant SLAP tear can be difficult.

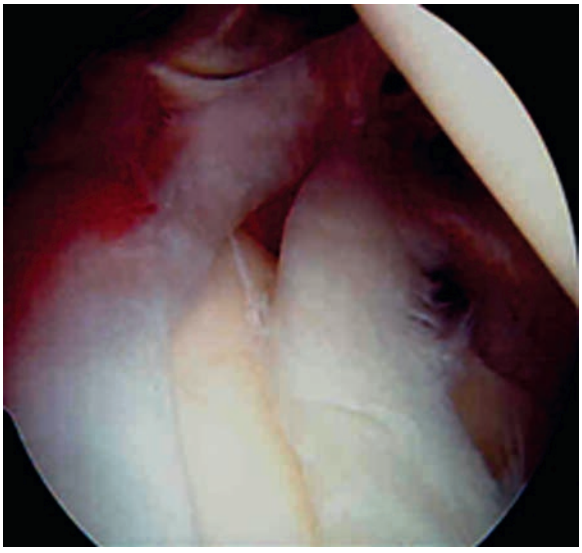

FIGURE 4-5. Type III SLAP tear.

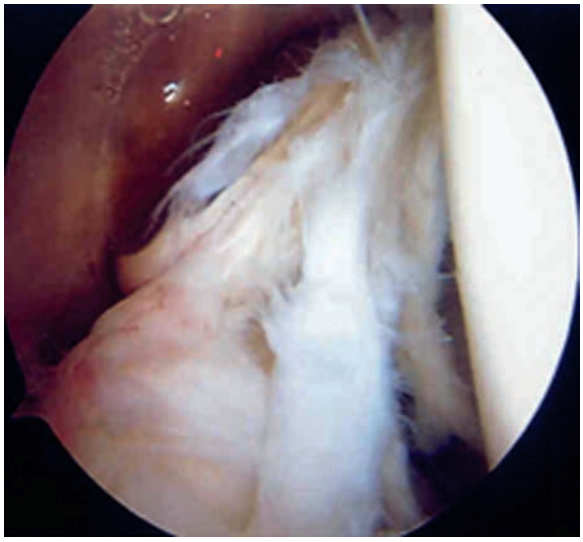

FIGURE 4-6. Type IV SLAP tear.

- Complaints of shoulder pain and weakness, especially with throwing, are typical.
- A history of a traction or repetitive throwing or overhead activity may help in the diagnosis.
- Athletes will frequently present with symptoms of pain, clicking, weakness or even instability.
- Pain, usually with overhead, lifting, or traction type of activities.
- Pain reaching out to the side.
- Occasional night pain or pain with daily activities.
- A sense of instability or the shoulder "feeling out of place."
- Decreased range of motion and strength.
- The symptoms are usually worse with the arm in the abducted and externally rotated position ("peel-back" position) as seen in the late cocking phase of throwing, or during an overhead serve in tennis.
- Although a fall on an outstretched arm can also cause a SLAP tear, a history of trauma is typically not present in overhead athletes.
- Athletes with type III SLAP tears often present with catching, locking or "dead-arm" type symptoms that can be confused with instability, due to the bucket handle tear catching between the humerus and glenoid.
- There are multiple physical examination tests that have been described to diagnose SLAP tears. These tests include: Speed's test, Yergason's test, O'Brien's test, Jobe's relocation test, active compression test, pain provocation test, crank test, anterior slide, apprehension test with the arm abducted to 90° in maximum external rotation, and tenderness in the rotator interval.
- The active compression test (O'Brien's test) has been shown to be a predictable and clinically useful sign in the diagnosis of SLAP tears.
- Throwing athletes complain of loss of velocity, control, and decreased confidence.
- SLAP tears often mimic the same symptoms as rotator cuff tears.

Physical Examination

Abnormal Findings

- Positive O'Brien's test ("active compression test")
- Pain with apprehension test
- Clicking
  - Compression and internal and external rotation

Pertinent Normal Findings

- Negative load and shift test
- No true "apprehension" with apprehension testing
- Rotator cuff strength testing is typically normal, although some false-positive weakness on empty can testing can occur

Imaging

- Plain radiographs
- Magnetic resonance imaging
  - Technological advancements in MRI have improved our ability to confirm the diagnosis of a superior labral tear. However, MRI findings must always be interpreted in the context of the athlete's history and physical examination. Incidental findings of labral tears on MRI are common in overhead athletes.
  - MRI arthrography (MRA): an injection of contrast (usually gadolinium) into the joint before the MRI scan has been shown to facilitate diagnosis.

Differential Diagnosis

- Pathologies such as rotator cuff tears and AC joint sprains/arthritis can cause false positive physical examination tests.
  - Patients typically complain of pain when reaching out to the side or behind them, as opposed to the classic overhead pain found with rotator cuff tears.
- An isolated sublabral foramen, a sublabral foramen with a cord-like middle glenohumeral ligament, and a cord-like middle glenohumeral ligament with the absence of tissue at the anterosuperior labrum (also termed the "Buford complex").
  - These variations can be seen in 10% to 15% of all shoulders and should not be mistaken for a SLAP tear.
  - As a general rule of thumb, labral variations are generally not thought to be "pathologic" if it occurs between 12 and 3 o'clock in a right shoulder, or between 9 and 12 o'clock in a left shoulder.

Treatment

Nonoperative Management

- Stretching
- Formal physical therapy
- Strengthening
- Cortisone injections
- Activity modification

Guidelines for Choosing Among Nonoperative Treatments

- Injections used for patients with associated pain on impingement testing
- Selective AC joint injection used to help differentiate AC joint pathology from true SLAP tear
- Stretching used in patients with associated glenohumeral internal rotation deficit (GIRD)

Surgical Indications

- Treatment options include superior labral repair, biceps tenodesis, or biceps tenotomy
- Absolute—failure to respond to rehabilitation after 6 months and symptoms deemed relative to the SLAP region
- Relative—inability to return to premorbid level of play

Aspects of History, Demographics, or Exam Findings that Affect Choice of Treatment

- Surgical treatment more commonly used for patients with an acute injury (e.g., fall on an outstretched arm), or with significant pain/weakness on examination that is not responsive to rehabilitation
- Nonoperative treatment preferred for pitchers and overhead athletes unless they cannot return to play due to their symptoms

Aspects of Clinical Decision Making When Surgery is Indicated

- Marked pain/weakness on O'Brien's testing
- Inability to throw
- Loss of velocity/accuracy when throwing

Evidence

Andrews JR, Carson WG, Jr, McLeod WD: Glenoid labrum tear related to the long head of the biceps. *Am J Sports Med* 13:337–341, 1985.

A retrospective review of 73 baseball pitchers who underwent shoulder arthroscopies of their dominant shoulder for tears of the glenoid labrum. At the time of the arthroscopy, the tendon of the long head of the biceps originated from the superior portion of the glenoid labrum and the tear was visible where anterosuperior portion of the labrum tore off the glenoid. (Level IV evidence)

Bencardino JT, Beltran J, Rosenberg ZS, et al: Superior labrum anterior-posterior lesions: Diagnosis with MR arthrography of the shoulder. *Radiology* 214:267–271, 2000.

Study of 52 patients who underwent arthroscopy and open surgery 12 days to 5 months after MR arthrography. The MR arthrography showed correlation between surgical classifications of SLAP tears and SLAP lesions diagnosed at the time of MR arthrography. (Level IV evidence)

Ilahi OA, Labbe MR, Cosculluela P: Variants of the anterosuperior glenoid labrum and associated pathology. *Arthroscopy* 18:882–886, 2002.

This prospective, case series of 20 shoulders that compared the incidence of Buford complex and sublabral foramen with

superior labral pathology. The incidence of the Buford complex and sublabral foramen is higher than previous described and they are correlated with superior labral pathology. (Level IV evidence)

Kim TK, Queale WS, Cosgarea AJ, et al: Clinical features of the different types of SLAP lesions: An analysis of one hundred and thirty-nine cases. *J Bone Joint Surg Am* 85A:66–71, 2003.

A prospective case series of 544 arthroscopic procedures, of which 139 procedures demonstrated a SLAP lesion. At the conclusion of this study, the pathology of SLAP lesions and clinical findings vary depending on the patient population and tears are both isolated and associated with concomitant pathologies. (Level IV evidence)

Nam EK, Snyder SJ: The diagnosis and treatment of superior labrum anterior and posterior (SLAP) lesions. *Am J Sports Med* 31:798–810, 2003.

In this review, the authors discuss the definitive treatment and examination for SLAP lesions based on previous literature. In conclusion, the SLAP tear is hard to diagnose and treat and the treatment of SLAP tears is dependent on the type of SLAP lesion. (Level V evidence)

Parentis MA, Glousman RE, Mohr KS, et al: An evaluation of the provocative test for superior labral anterior posterior lesions. *Am J Sports Med* 34:265–268, 2006.

A series of 132 consecutive shoulder arthroscopy patients were preoperatively examined using a variety of shoulder tests to determine the most accurate test to diagnose a SLAP tear. Although some tests were more specific to type I tears and others more specific to type II tears, the study concluded that there is no single test that can accurately determine a SLAP lesion. (Level IV evidence)

Snyder SJ, Karzel RP, Del Pizzo W, et al: SLAP lesions of the shoulder. *Arthroscopy* 6:274–279, 1990.

A retrospective review of 700 shoulder arthroscopies was performed and identified 27 patients with a SLAP tear. The preoperative imaging tests did not accurately diagnose the SLAP lesions. In conclusion, this study suggest that the treatment for SLAP lesions is arthroscopic surgery. (Level IV evidence)

Williams MM, Snyder SJ, Buford D, Jr: The Buford complex–the "cord-like" middle glenohumeral ligament and absent anterosuperior labrum complex: A normal anatomic capsulolabral variant. *Arthroscopy* 10:241–247, 1994.

A retrospective review of 200 shoulder arthroscopy videos were reviewed to study the anterosuperior glenoid quadrant. In 3 of the 200 patients, it was noted that that patients had a "cord-like" middle glenohumeral ligament. This unusual variant in the anatomy was noted to cause confusion between a labral tear and an anatomic abnormality. (Level IV evidence)

Multiple-Choice Questions

QUESTION 1. What concomitant pathologies are NOT associated with SLAP tears?

A. Rotator cuff tear
B. Bankart tear
C. Clavicle fracture
D. Acromioclavicular arthritis

QUESTION 2. List the traumatic factors that contribute to a SLAP tear.

A. Falling on an outstretched arm
B. Sudden pull or lifting a heavy object
C. Forceful overhead motions
D. All of the above

QUESTION 3. Which test is the most widely used to diagnose SLAP tears?

A. O'Brien's test
B. Speed's test
C. Yergason's test
D. Jobe's test

QUESTION 4. In what sport is a SLAP tear most commonly found?

A. Soccer
B. Baseball
C. High Jump
D. Lacrosse

QUESTION 5. What type of SLAP tear is often associated with catching, locking, or "dead-arm" type symptoms?

A. Type I
B. Type II
C. Type III
D. Type IV

Answer Key

QUESTION 1. Correct answer **C** (see Epidemiology)

QUESTION 2. Correct answer: **D** (see Pathophysiology)

QUESTION 3. Correct answer: **A** (see Clinical Presentations)

QUESTION 4. Correct answer: **B** (see Epidemiology)

QUESTION 5. Correct answer: **C** (see Clinical Presentation)

NONOPERATIVE REHABILITATION OF SLAP TEARS

Amee L. Seitz, PT, PhD, DPT, OCS, Alex J. Petruska, Jr., PT, SCS, and Thomas J. Gill IV, MD

GUIDING PRINCIPLES OF NONOPERATIVE REHABILITATION

- A proportion of overhead athletes with SLAP tears, regardless of type, will be able to return to full function and sport with rehabilitation. The patho-anatomical diagnosis is not predictive of outcome.
- A comprehensive examination to identify and address all potential contributing factors and impairments is necessary to optimize the outcome of nonoperative rehabilitation of superior labrum anterior to posterior (SLAP) SLAP tears.
- Rehabilitation of SLAP tears should be individualized to the specific underlying impairments that contribute to movement disorder that vary among athletes.
- Where an athlete begins along the phases of rehabilitation and time frames for progression outlined in this chapter is dependent upon the pain, reactivity of shoulder structures, extent of movement impairments, and individualized patient response.
- Although it is not necessary to follow the specific time frames outlined for each phase, it is essential to meet the milestones/criteria to advance to the next phase of rehabilitation.

Phase I (weeks 0 to 4)

Protection

- Athlete should be instructed in joint protection strategies including positioning the shoulder with pillows in the "loose pack" position to sleep and during application of cryotherapy.
- Athlete should be instructed to avoid activities that provoke symptoms and limit use of upper extremity below shoulder height and in front of scapular plane.

Management of Pain and Swelling

- Ice intermittently, as needed up to 4 to 5 times per day 15 to 20 minutes at a time
- Nonsteroidal antiinflammatory medications as prescribed by the surgeon
- A TENS unit or electrical stimulation may be used to reduce pain. Using TENS for 20 minutes at a time has been shown to reduce nociceptive responses and pain perception.[1] Electrical stimulation has also been shown to suppress inflammatory responses at the cellular level in vitro.[2]
- An evaluation by the sports medicine physician for a subacromial steroid injection may be helpful to reduce pain or address any plateaus in progression to meet Phase I rehabilitation goals in a 4-week period.

Techniques for Progressive Increase in Range of Motion

- Phase I rehabilitation is designed to restore normal and pain-free AA/AROM of the shoulder. Athletes that do not present with AROM limitations and minimal to no pain with ROM may progress immediately to Phase II.
- ROM progressions are not limited by time frames and should be guided by the athlete's tolerance.
- For athletes with A/PROM limitations, ROM progression should begin with restoring internal and external rotation with the arm at the side and elevation in the scapular plane.

TIMELINE 4-1: **Nonoperative Rehabilitation of SLAP Tears**

PHASE I (weeks 1 to 4)	PHASE II (weeks 4 to 8)
• Activity modifications and positioning for comfort • PT modalities • AAROM exercises all plans as tolerated • Mobilizations grade I-II GH joint and soft tissue mobilization as needed • Thoracic spine mobilizations/manipulations as needed • Submaximal isometrics for GH joint muscles per pain tolerance • TBS/TAS/TLS activities as tolerated	• PT modalities as needed • PROM-full all planes including horizontal adduction and IR • Posterior-inferior GH and scapulothoracic mobilizations II-IV as needed • TBS/TAS/TLS activities as recommended and tolerated • Scapular exercises—PREs • TAS—biceps/triceps PREs • Glenohumeral exercises—PREs • Rotator cuff exercises—PREs • PNF exercises proximal resistance • OKC Rhythmic stabilization exercises • CKC exercises • CKC manual perturbation exercises

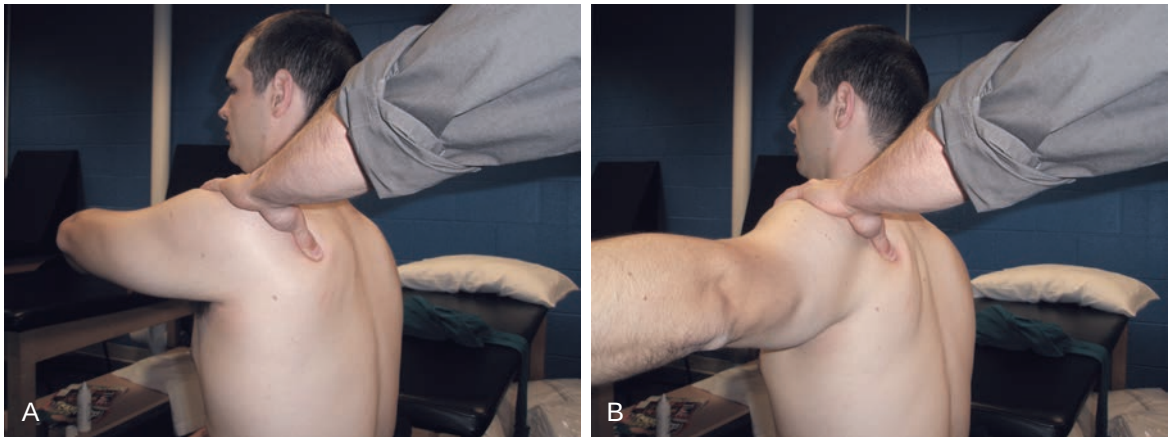

FIGURE 4-7. Manual therapy technique to address soft tissue impairments in the infraspinatus with application of pressure to infraspinatus (**A**) in flexion and move into (**B**) horizontal abduction of the shoulder.

- Once full A/PROM in elevation, and full IR and ER at the side is achieved, athletes can be progressed with internal and external rotation gradually to 90° of abduction.

Manual Therapy Techniques

- Grade I to II glenohumeral mobilizations inferior and posterior for pain in midrange to assist with ROM progression.
- Thoracic spine manipulation or grade III to IV mobilization for extension and rotation mobility and to reduce pain.[3-5]

Soft Tissue Techniques

- Pectoralis minor active release or preferred soft tissue technique as needed to normalize muscle length to restore adequate scapular posterior tilt.[6] Minimum length can be determined by supine assessment of acromion distance from bed should be equal bilaterally.
- Rotator cuff, specifically infraspinatus (Figure 4-7) and/or subscapularis, soft tissue release techniques as needed.
- Biceps soft tissue release techniques as needed.

Stretching and Flexibility Techniques for the Musculotendinous Unit

- Normalize full passive glenohumeral ROM within pain tolerance in all planes starting external/internal rotation in neutral progressing to 45° and 90° of abduction
- T-Bar/stick exercises for AAROM in ER with the arm at side in standing (Figure 4-8) progressing to 90° abduction in supine (Figure 4-9)
- Elbow and wrist ROM stretching
- IR behind the back internal rotation stretching (Figure 4-10)
- Horizontal adduction[7] stretching AAROM (Figure 4-11)
- Thoracic spine extension AROM over 4-inch foam roll
- Initiate hip stretching ABD/IR/ER/flexion as needed. Adequate hip motion will permit normal mechanics with throwing/pitching reducing unwarranted strain at the shoulder.

Other Therapeutic Exercises

- Nonimpact light aerobic activity (bike, elliptical, StairMaster) within pain tolerance
- Lower extremity resistance training is indicated

TIMELINE 4-1 Nonoperative Rehabilitation of SLAP Tears (Continued)

PHASE III (weeks 8 to 12)	PHASE IV (weeks 12 +)
• PROM-maintain full motion • Mobilizations as needed • TBS/TAS/TLS activities as recommended and tolerated • Scapular exercises—PREs • TAS—biceps/triceps PREs • Glenohumeral exercises—PREs • Rotator cuff exercises—PREs • Complete Thrower's 10 plus program • PNF exercises distal resistance • OKC rhythmic stabilization exercises • CKC exercises • CKC manual perturbation exercises • Overhead strengthening exercises • Selected (below shoulder height) sport-specific exercises initiated	• PROM-maintain full motion • Mobilizations as needed • TBS/TAS/TLS activities as recommended & tolerated • Scapular exercises—PREs • TAS—biceps/triceps PREs • Glenohumeral exercises—PREs • Rotator cuff exercises—PREs • IR/ER exercises at 90° • Thrower's 10 plus program -progress intensity • PNF exercises • OKC rhythmic stabilization exercises • CKC exercises • CKC manual perturbation exercises • Plyometrics—progressing to 90°/90° 1 arm plyos • Overhead strengthening exercises • Unrestricted sport-specific exercises • Overhead athletes initiate an return to sport interval program • Initiate sports enhancement and optimization program

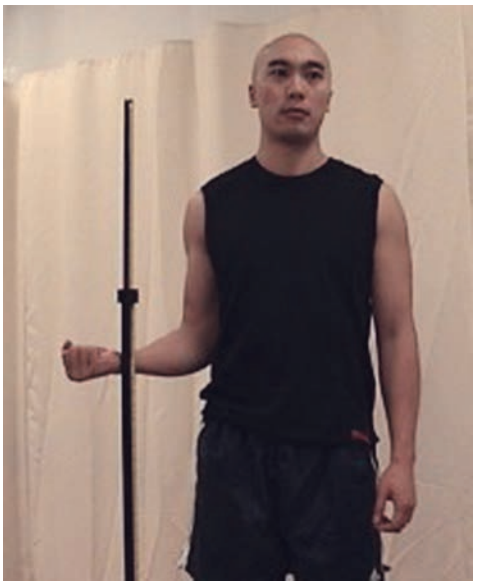

FIGURE 4-8. External rotation active assistive range of motion with the shoulder in neutral.

- Core stability is initiated as able with seated ball exercises and unilateral stance lower extremity reaches and lateral slides on stable surface progressed as technique allows

Activation of Primary Muscles Involved

- Although the focus of this phase of rehabilitation is restoration of normal range of motion, activation of the rotator cuff muscles (IR/ER) with submaximal isometrics is indicated within pain tolerance with the arm at the side progressing to 45° of scapular plane elevation.

Sensorimotor Exercises

- Scapular control exercises with side-lying scapular clock exercises
- Active elevation in scapular plane with mirror and verbal feedback to normalize dynamic scapulohumeral motor control

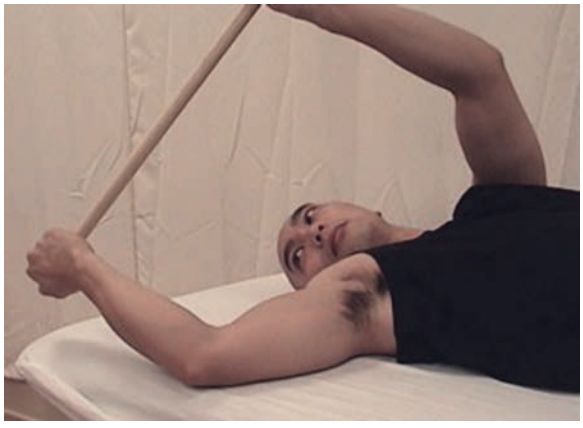

FIGURE 4-9. External rotation active assistive range of motion in 90° abduction.

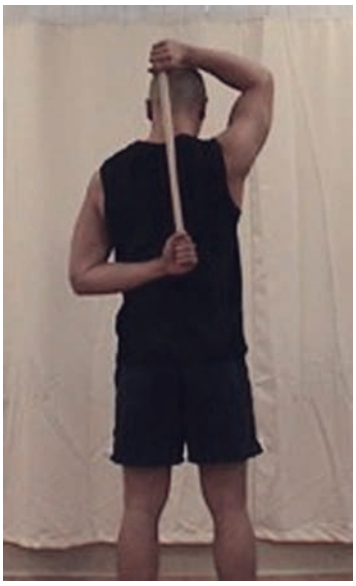

FIGURE 4-10. Internal rotation/behind AAROM with a stick.

Techniques to Increase Muscle Strength, Power, and Endurance

- LE strength training exercises to target hip extensors and rotators
- Elliptical and stair stepper for cardiovascular conditioning

Neuromuscular Dynamic Stability Exercises

- Manual rhythmic stabilization with the arm in pain-free mid-range of motion positions with light resistance

Sport-Specific Exercises

- Overhead athletes should initiate core and lower extremity stability drills progressing to unstable surfaces and in unilateral stance (standing balance, excursions anterior lateral and diagonals) as able with

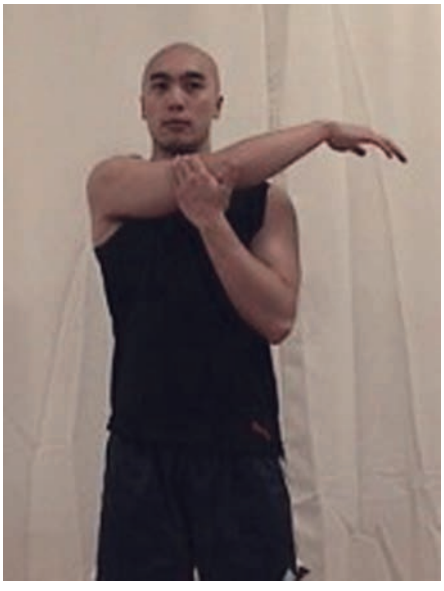

FIGURE 4-11. Horizontal adduction posterior shoulder self-stretching.

good core control. Unstable surfaces require additional core muscle activity and greater challenge to the athlete.

Milestones for Progression to the Next Phase

- Full AROM in all planes of motion, with only mild discomfort at end ranges
- Normal scapulohumeral dynamic control during elevation without resistance as determined by the scapular dyskinesis Test.[8] With this test, the athlete should demonstrate no dysrhythmia or scapular winging during five repetitions of full flexion and abduction.
- Pain minimal to none at rest; minimal increase in pain following exercise

Phase II (weeks 6 to 12)

Protection

- Athletes will be encouraged to minimize painful resisted shoulder motions above shoulder height and behind the plane of the body during daily activities.

Management of Pain and Swelling

- Ice after exercise and as needed 15 to 20 minutes at a time
- Nonsteroidal antiinflammatory medications as prescribed by the surgeon
- TENS unit or electrical stimulation only as needed after exercise

Techniques for Progressive Increase in Range of Motion

- Athletes should have normal AROM but may present with end range restrictions and abnormal arthrokinematics that should be addressed in this phase of rehabilitation.
- Normal inferior glide should be observed in terminal elevation. This can be visually observed with symmetrical skin creases at terminal elevation. Additionally inferior glides can be assessed and compared bilaterally at end range of glenohumeral elevation. Posterior shoulder length should be normalized with at least 20° of horizontal adduction from the vertical while lying supine with the scapula stabilized.
- Glenohumeral total arc of motion should be normalized with the sum of internal and external rotation at 90° of abduction approximating 180°.
- The dominant shoulder in overhead, particularly throwing athletes may demonstrate loss of IR compared to contralateral due to osseous changes of the humerus,[9] but the total arc of internal and external rotation motion should be comparable to the opposite shoulder.

Manual Therapy Techniques

- Common restrictions in posterior and inferior accessory joint motion of the glenohumeral joint should be normalized with grade III mobilizations, mobilizations with movement, and/or terminal ROM stretching. Arthrokinematics with manual accessory motion testing should be assessed in the posterior and inferior direction. Posterior shoulder range of motion can be evaluated with passive horizontal adduction[10] with the scapula stabilized should be greater than 90° or beyond vertical position towards the chest. Internal rotation should be sufficient to allow for the total arc of motion (internal + external rotation ROM) to approximate total arc of motion values for the uninvolved shoulder.[11]
- Manual assisted horizontal adduction stretching while stabilizing the scapula at varying angles of elevation 70° to 100° and IR stretching to appropriately address posterior shoulder soft tissue restrictions.

Soft Tissue Techniques

- Pectoralis minor active release or preferred soft tissue technique as needed to normalize muscle length to restore adequate scapular posterior tilt.[6] Minimum length can be determined by supine assessment of acromion distance from bed should be equal bilaterally
- Continue rotator cuff and/or biceps soft tissue techniques as needed

Stretching and Flexibility Techniques for the Musculotendinous Unit

- Sleeper stretch starting at 45° of flexion progressing to 90° as tolerated (Figure 4-12)
- Bar hang stretch for latissimus and shoulder flexion (Figure 4-13)
- Full pain-free shoulder ROM IR/ER at 90° of abduction
- Continue hip ER/IR/flexion stretching as needed
- Continue thoracic spine extension and rotation stretching as needed

Other Therapeutic Exercises

- Return to all aerobic activity
- Lower extremity resistance training is progressed
- Core stability exercises are progressed to sport-specific positions and conditions

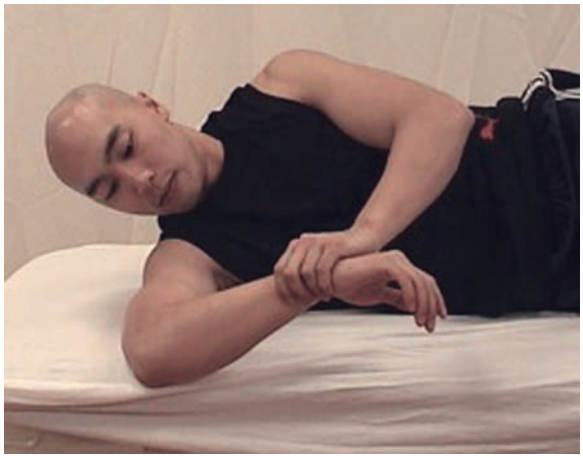

FIGURE 4-12. Sleeper stretch at 90° flexion for posterior shoulder.

FIGURE 4-13. Overhead bar assisted shoulder flexion and latissimus dorsi stretch.

- Total arm strengthening (TAS) is initiated with exercises at or below shoulder height and anterior to scapular plane

Activation of Primary Muscles Involved

Initiate rotator cuff and scapular prone exercises to light isotonic and/or elastic resistance as ROM is normalized without scapular substitution patterns. The scapula should not wing or excessively shrug with any exercise as determined by visual observation.

- Resisted ER in neutral (Figure 4-14)
- Resisted IR in neutral (Figure 4-15)
- Sideling ER (Figure 4-16)
- Shoulder retractions (Figure 4-17)
- Standing "W"s (Figure 4-18)
- Dynamic hug (Figure 4-19)
- Prone rowing (Figure 4-20)
- Prone extension (Figure 4-21)

Sensorimotor Exercises

- Rhythmic stabilization and manual strengthening of the UE with short moment arms/proximal resistance
- The Bodyblade at 0° abduction as well as 90° scapular elevation
- Core stability exercises with manual resistance on stable progressing to unstable surfaces

Open and Closed Kinetic Chain Exercises

- PNF in D1–2 with manual resistance to scapula and humerus with slow reversals
- Closed chain upper extremity PNF in quadruped
- Closed chain rhythmic stabilization in quadruped with hand on ball to provide an unstable surface to challenge the athlete

Techniques to Increase Muscle Strength, Power, and Endurance

- Progression of lower extremity strength training exercises
- Progress to elliptical and stair stepper for cardiovascular conditioning; initiate jogging/running

Plyometrics

- Lower extremity plyometrics can be initiated

Milestones for Progression to the Next Phase

- Normal posterior shoulder flexibility (internal rotation and horizontal adduction). Posterior shoulder range of motion can be evaluated with passive horizontal adduction[10] with the scapula stabilized should be greater than 90° or beyond vertical position towards the chest. Internal rotation should be sufficient to allow for the

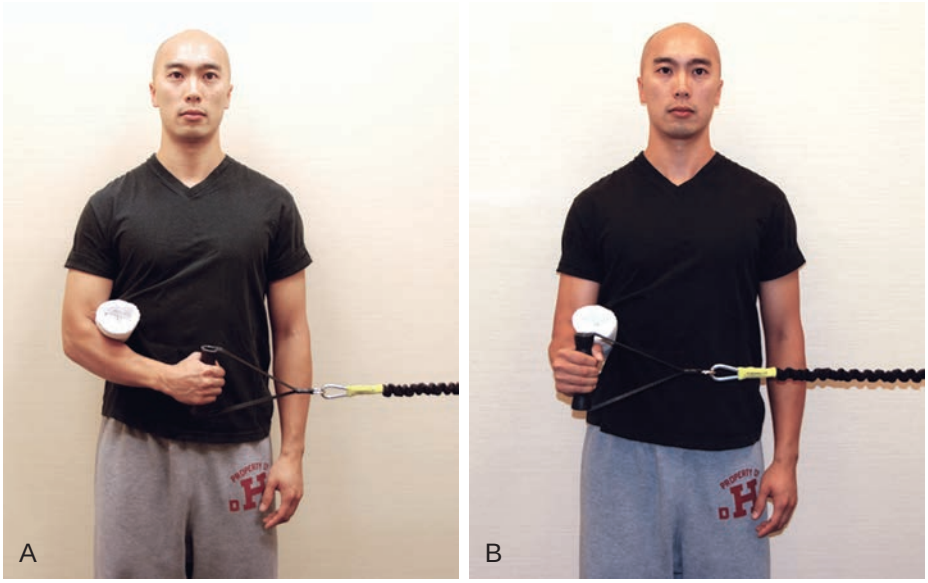

FIGURE 4-14. Resisted external rotation in neutral humeral abduction (**A**) start position and (**B**) end position.

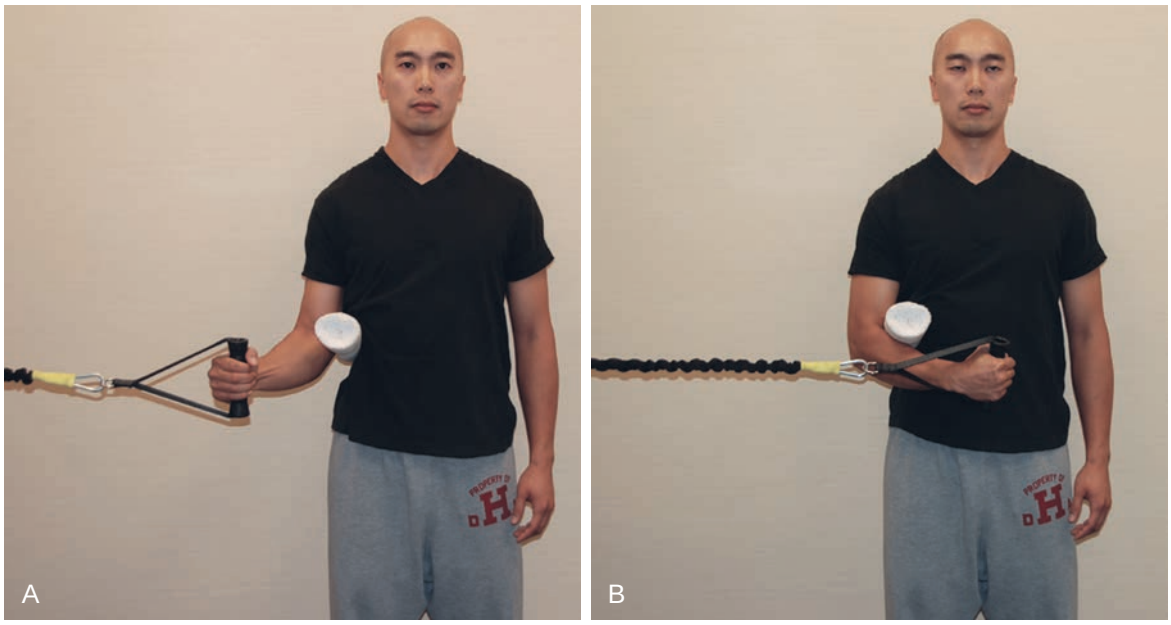

FIGURE 4-15. Resisted internal rotation in neutral humeral abduction (**A**) start position and (**B**) end position.

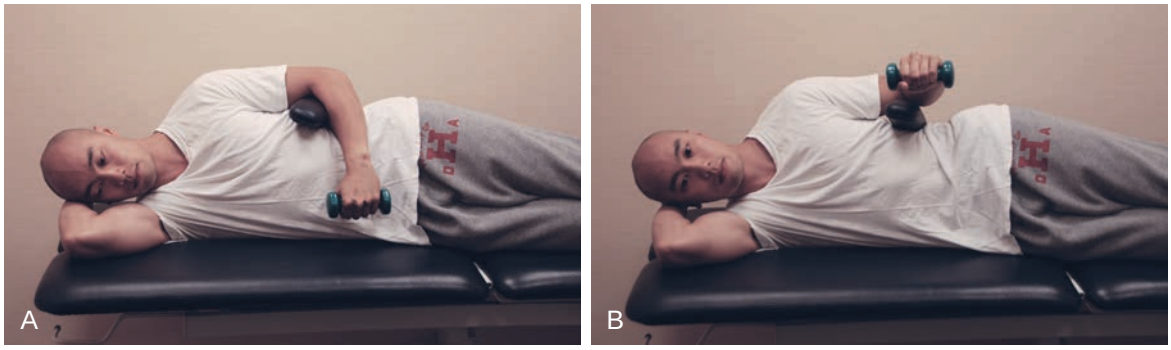

FIGURE 4-16. Side-lying isotonic external rotation (**A**) start position and (**B**) end position.

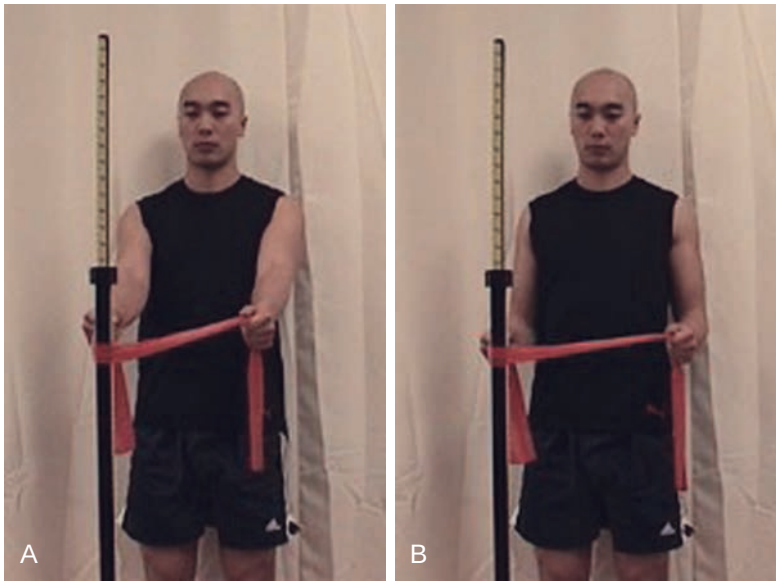

FIGURE 4-17. Resisted shoulder retractions (**A**) start position and (**B**) end position.

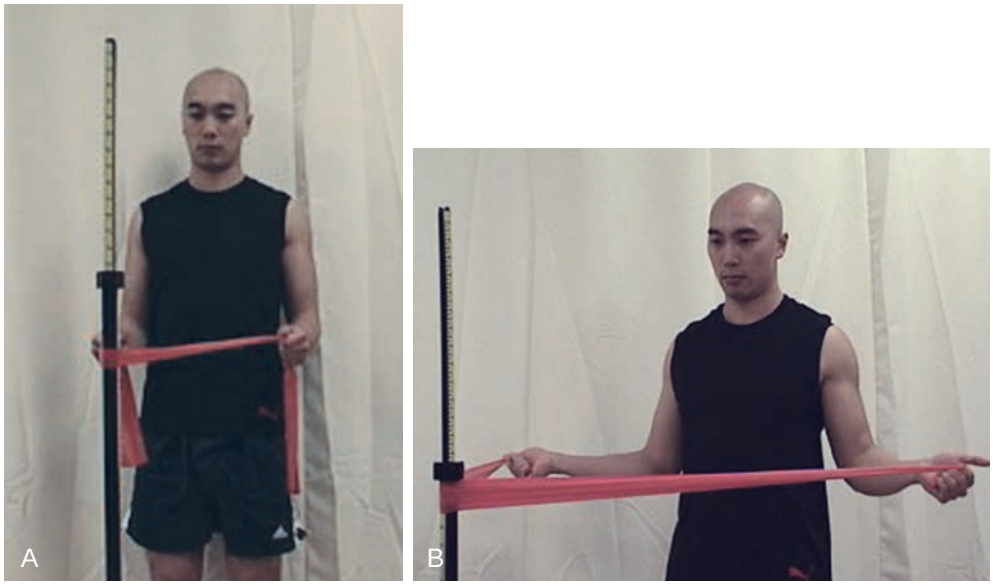

FIGURE 4-18. Standing "W"s (**A**) start position and (**B**) end position.

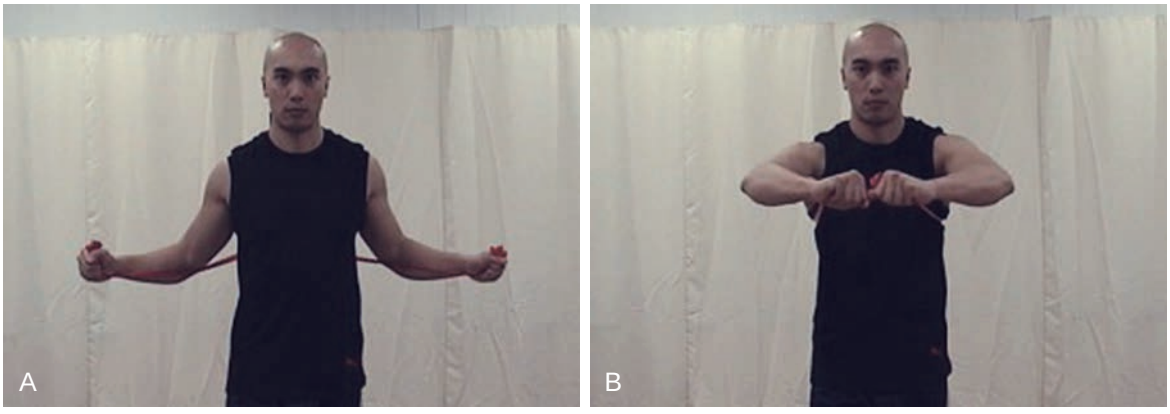

FIGURE 4-19. Dynamic hug strengthening exercise (**A**) start position and (**B**) end position.

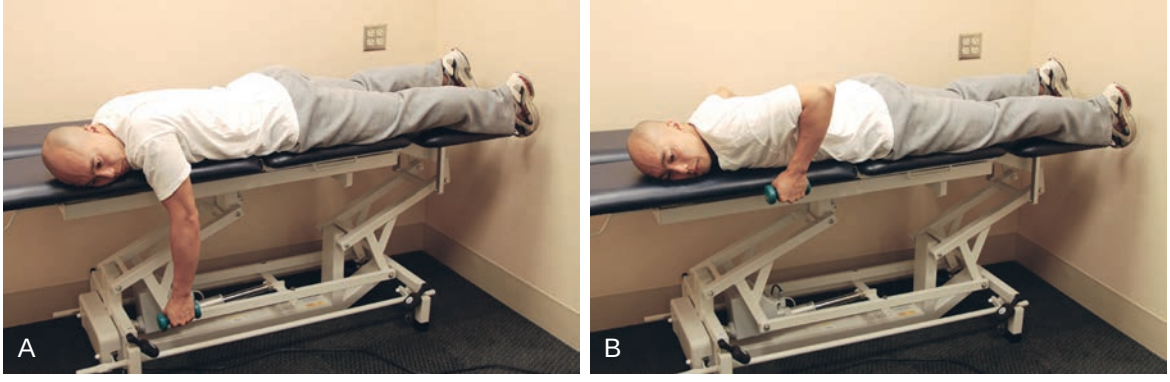

FIGURE 4-20. Prone rowing (**A**) start position and (**B**) end position.

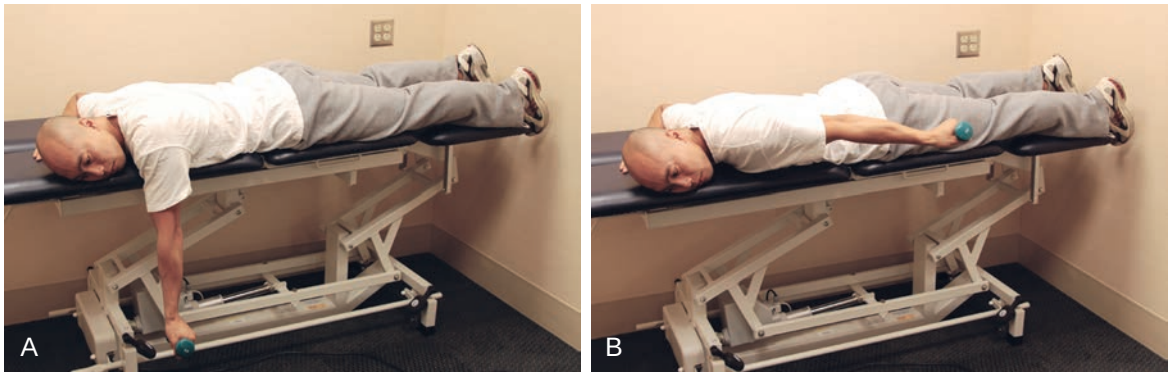

FIGURE 4-21. Prone extension (**A**) start position and (**B**) end position.

total arc of motion (internal + external rotation ROM) to approximate total arc of motion values for the uninvolved shoulder.[11]

- Normal arthrokinematics glenohumeral joint. Arthrokinematics with manual accessory motion testing should be assessed in the posterior and inferior direction with the arm at 90° of abduction and external rotation.
- Normal scapulohumeral motion during active ROM in all planes as determined by the scapular dyskinesis test.[8] With this test, the athlete should demonstrate no dysrhythmia or winging during five repetitions of full flexion and abduction holding 5-lb hand weights.
- Shoulder strength 75% to 80% uninvolved below shoulder height can be assessed with the arm at 0° and 45° of abduction through range of motion with manual resistance of the examiner, but isometrically in multiple ranges with an hand-held dynamometer because an objective measure is more sensitive to detect apparent weakness up to 20% when manual resistance is deemed normal.[12] Isokinetic testing could be used as a more objective measure.
- Normal dynamic trunk and kinetic chain strength and motor control with functional tests including single leg squat or step down with demonstration of neutral varus or valgus alignment of the knee avoidance of pelvic drop and good balance/control, unilateral balance and hold with pitching stance, plank trunk stability with neutral spine for at least 1 minute.

Phase III (weeks 12 to 16)

Management of Pain and Swelling

- Cryotherapy after exercise as needed

Techniques for Progressive Increase in Range of Motion

Manual Therapy Techniques

- Continue grade III glenohumeral joint mobilizations and terminal ROM stretching for posterior shoulder as needed to maintain ROM
- Thoracic spine mobilization/manipulation as needed

Soft Tissue Techniques

- Continue soft tissue techniques to maintain posterior shoulder (infraspinatus and teres minor) muscle extensibility as needed

Stretching and Flexibility Techniques for the Musculotendinous Unit

- Specific stretching following exercise should be continued to maintain shoulder, thoracic spine and hip flexibility
- Continue sleeper stretches
- Shoulder horizontal adduction stretching
- Hip ABD/IR/ER/flexion stretching
- Thoracic spine extension and rotation
- Pectoralis major stretching in doorway or corner[2] (Figure 4-22) with emphasis on scapular retraction and sensation of the stretch in chest not shoulder
- Continue bar hang stretch for latissimus dorsi stretching

Other Therapeutic Exercises

- Progress aerobic activity
- Lower extremity resistance training is progressed
- Core stability exercises are progressed to sport-specific positions and conditions

FIGURE 4-22. Pectoralis major stretch in doorway.

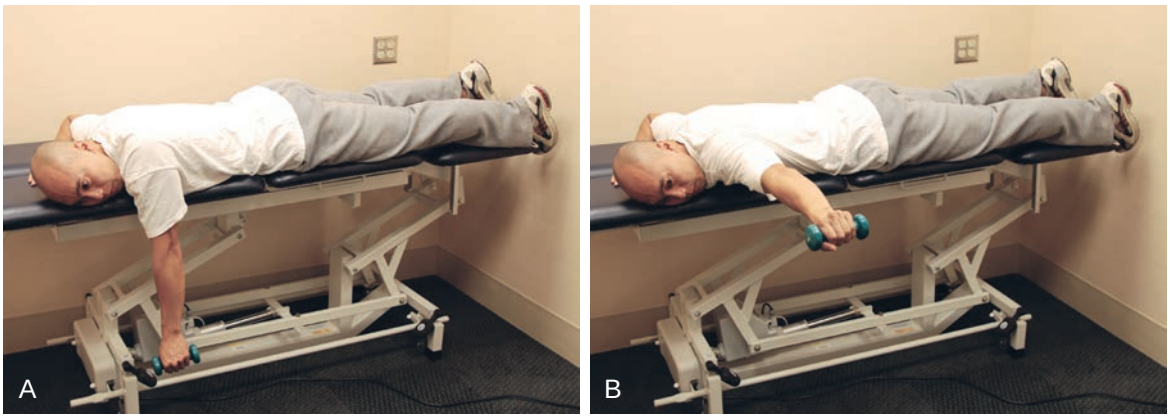

FIGURE 4-23. Prone horizontal abduction "T"s in neutral rotation (**A**) start position and (**B**) end position.

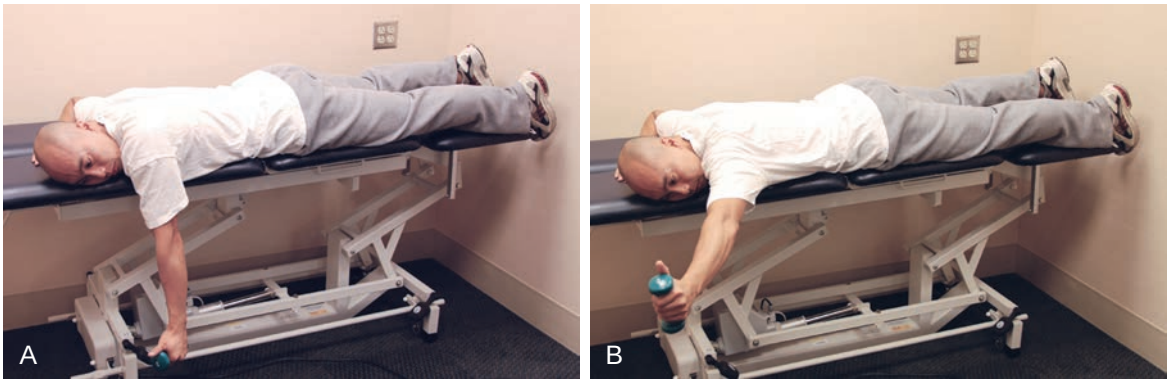

FIGURE 4-24. Prone scaption "Y"s in external rotation at 110° (**A**) start position and (**B**) end position.

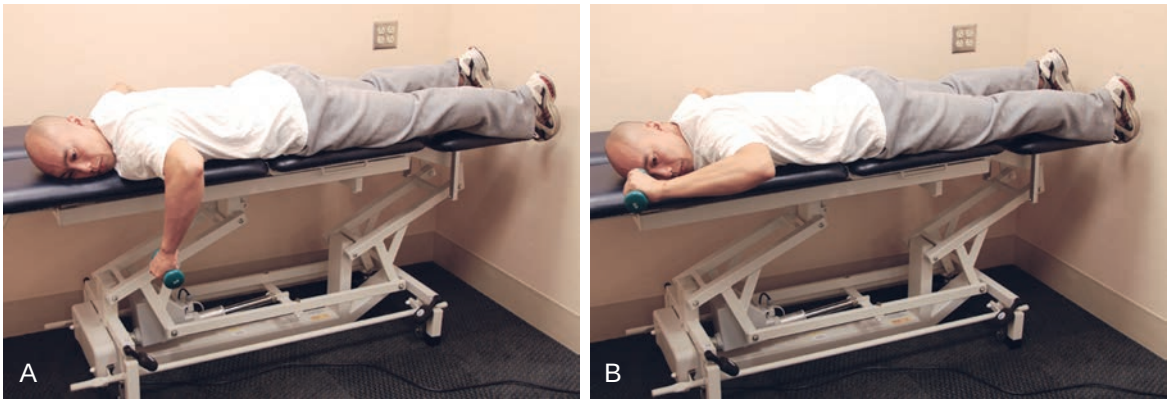

FIGURE 4-25. Prone external rotation at 90° abduction (**A**) start position and (**B**) end position.

- Total arm strengthening initiated with biceps curl, triceps extension, wrist supination, and pronation

Activation of Primary Muscles Involved

Progress shoulder and rotator cuff strengthening to complete a modified Thrower's Ten program[13] with the addition of:

- Prone horizontal abduction "T"s (Figure 4-23)
- Prone scaption "Y"s (Figure 4-24)
- Prone external rotation at 90° abduction (Figure 4-25)
- Shoulder scaption to 90° elevation full can position (Figure 4-26)
- Supine inclined pull ups with scapular retraction[5]

FIGURE 4-26. Scapular plane "full can" elevation to 90°.

Sensorimotor Exercises

- Rhythmic stabilization and manual strengthening of the UE with long moment arms/distal resistance
- The Bodyblade at 0° abduction as well as 90° scapular elevation
- Core stability exercises with manual resistance on stable progressing to unstable surfaces. Progressing to unstable surface requires additional core stability and provides an additional challenge to the athlete.

Open and Closed Kinetic Chain Exercises

- PNF in D1–2 with manual resistance to scapula and humerus with slow reversals and midrange holds.
- Closed chain stability holds in quadruped, plank prone, and side-on stable and unstable surfaces with manual perturbations.

Techniques to Increase Muscle Strength, Power, and Endurance

- Progression of lower extremity strength training exercises.
- Progress to elliptical, stair stepper, jogging/running for cardiovascular conditioning.

Plyometrics

- Light plyometrics with throw at the side (Figures 4-27*A-D*)
- Wall dribbles light resistance overhead and various arm angles (Figure 4-28)
- Decelerations/eccentric control of follow-through in half-kneeling (Figure 4-29)
- Two-hand medicine ball chest pass and side toss
- Continue lower extremity plyometrics with emphasis on frontal plane/lateral movements[14]

Sport-Specific Exercises

- Initiate exercises and sport-specific drills with arm below shoulder height such as fielding drills and base work

Milestones for Progression to the Next Phase

- No complaints of symptoms/pain with exercise, and minimal discomfort after exercise resolves with cryotherapy
- Full pain-free uncompensated AROM of shoulder complex. AROM should be assessed in all planes and considered normal when equal bilaterally
- Excellent core and proximal stability of hips and lower extremity with functional tests such as single leg squat or step down with demonstration of neutral varus or valgus alignment of the knee avoidance of pelvic drop and good balance/control
- Strength of rotator cuff, shoulder and scapular stabilizers at least 80% to 90% uninvolved with isokinetic

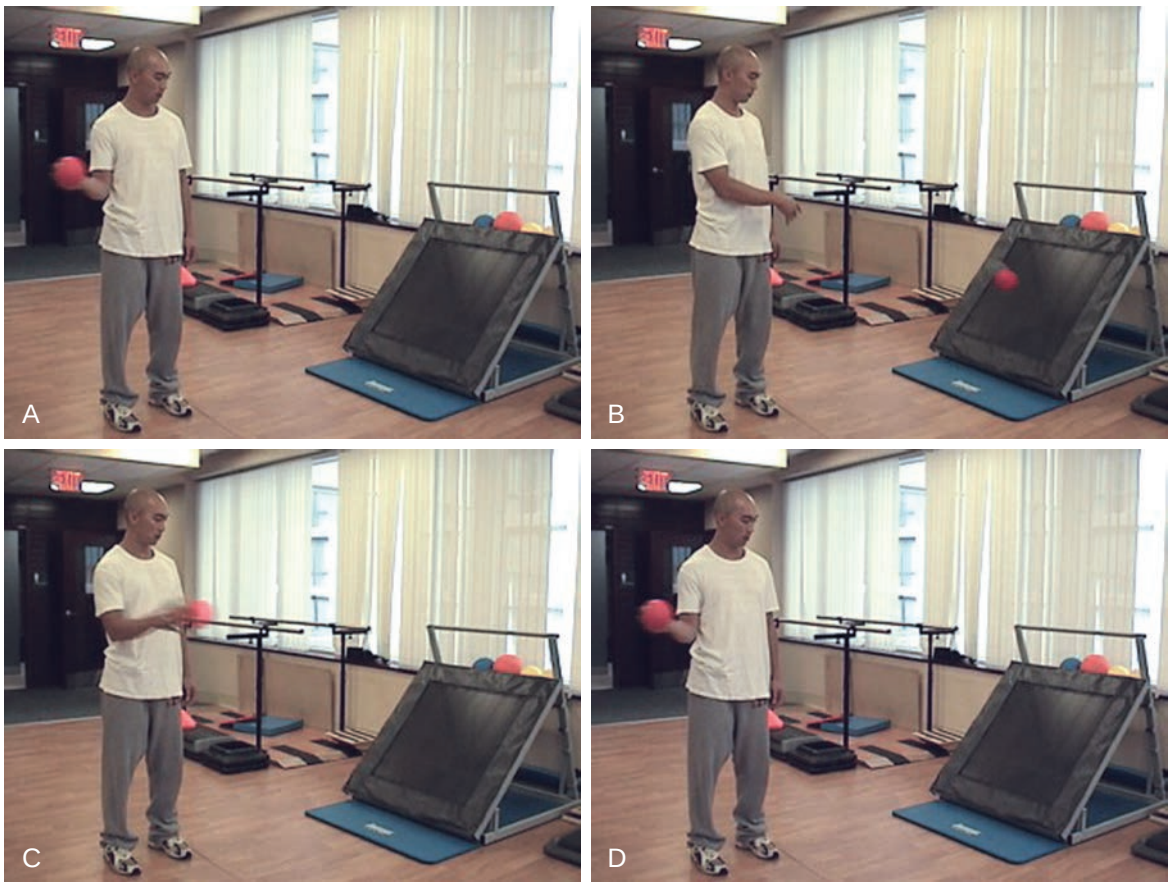

FIGURE 4-27. Plyometrics one arm throw at the side (**A**) wind up, (**B**) release, (**C**) catch, and (**D**) eccentric follow-through.

FIGURE 4-28. Wall dribbles light resistance in various positions (**A**) overhead, (**B**) above 90°, and (**C**) just below 90° abduction.

FIGURE 4-29. Decelerations with eccentric control with (**A**) a catch from a toss behind, and (**B**) eccentric control during follow-through followed by concentric toss behind.

testing, or if unavailable, hand-held dynamometry at multiple arm angles in external rotation, internal rotation and abduction to 90°. Isokinetic testing is preferred.
- Self-report outcome scores >80% such as the Kerlan-Jobe Orthopaedic Clinic[15,16] shoulder and elbow score are more sensitive than regional outcome tools such as the Disability of the Shoulder Arm and Hand.[17]

Phase IV (weeks 16 to 24)

Management of Pain and Swelling

- Cryotherapy with/without electrical stimulation after exercise as needed

Techniques for Progressive Increase in Range of Motion

- Athlete must maintain ROM and flexibility achieved in prior phases
- Strengthening and dynamic plyometric activities progress to more challenging positions of sport in abduction and external rotation

Manual Therapy Techniques

- Continue grade III mobilizations and terminal ROM stretching for posterior shoulder as needed to maintain ROM
- Thoracic spine mobilization/manipulation as needed

Soft Tissue Techniques

- Continue soft tissue techniques to maintain posterior shoulder (infraspinatus and teres minor) muscle extensibility

Stretching and Flexibility Techniques for the Musculotendinous Unit

Specific stretching following exercise should be continued to maintain shoulder, thoracic spine and hip flexibility:
- Sleeper stretches
- Horizontal adduction
- IR/ER/flexion hip stretching

- Thoracic spine extension and rotation. Extension can be facilitated by lying supine over physioball. Rotation can be achieved with side-lying thoracic rotation with hips and lumbar spine flexed to isolate stretch to thoracic region.

Other Therapeutic Exercises

- Progress aerobic activity
- Lower extremity resistance training is progressed
- Core stability exercises are progressed to target deficits noted in sport-specific positions such as unilateral stance in cocking position for pitchers and throwing for fielders
- Total arm strengthening continue; progress with biceps curl, triceps extension, wrist supination and pronation

Activation of Primary Muscles Involved

- Begin sport-specific return to sport progressions (i.e., interval throwing, swimming, tennis programs) and/or collaboration with sports performance specialists once strength, self-report outcome and full uncompensated active and passive ROM goals of this phase are achieved

Sensorimotor Exercises

- Progress rhythmic stabilization and manual strengthening of the UE progressed to long moment arms and distal points of resistance.
- Progress the Bodyblade to 90° abduction and external rotation in bilateral and unilateral stance.
- Progress core stability exercises with manual resistance to unstable surfaces.

Open and Closed Kinetic Chain Exercises

- PNF in D1–2 with manual resistance with fast reversals and terminal holds with perturbations.
- Closed chain PNF in plank and long arc positions progressing to unstable surfaces with emphasis on good scapular control without evidence of winging or shrugging with visual observation.
- Upper extremity closed chain functional training used later for testing. The upper extremity closed chain function test requires the athlete to move their hands alternately back and forth from a pushup position, touching one of two lines at a time placed 3 feet apart on the ground.[18]

Techniques to Increase Muscle Strength, Power, and Endurance

- Progression of LE strength training exercises
- Sport-specific exercises and drills

Plyometrics

Progress plyometrics to unilateral and overhead positions:

- One arm rebounder throwing in abduction (Figure 4-30)
- Progress endurance with wall dribbles at various angles approximating 90° abduction
- Heavy full kinetic chain plyometrics (such as medicine ball floor slams, wall throws, chest pass/side trunk rotation scoop toss/squat throws)
- Continued lower extremity plyometrics with emphasis on frontal plane/lateral movements for throwers

Sport-Specific Exercises

- Initiate return to sport specific interval progressions (throwing/catch, swimming, tennis groundstrokes, etc.) performed on an every-other-day basis
- Athletes should work closely with coaches and trainers to insure proper technique with sport activity, particularly when the athlete is fatiguing
- Pitchers should work with a coach to insure proper mechanics with various types of pitches
- Swimmers should work with a coach to insure proper mechanics with freestyle progressing to other types of swimming strokes
- Tennis players should work with a coach to insure proper mechanics with ground strokes progressing to all types of overhead hits and serves

Milestones for Progression to Advanced Sport-Specific Training and Conditioning

- No symptoms of pain or discomfort during or following exercise
- Functional closed kinetic chain tests (upper extremity, core, lower extremity) are >90% uninvolved or considered normal with good control and accuracy
  - Davies closed kinetic chain upper extremity stability test[19]
  - At least an average of 7 in 3 trials of timed modified pullup for 15 seconds
  - At least an average of 15 in 3 trials of timed pushup for 15 seconds
  - Single arm seated shot put test performed with lower extremities elevated on a chair with a distance of at least 2 m using a 2.72 kg (small softball size) medicine ball
- Strength >90% uninvolved with isokinetic testing or at minimum hand-held dynamometry specific to internal, external, and abduction in multiple arm angles.
- Normal flexibility ROM of posterior shoulder, thoracic spine and hips. Posterior shoulder range of motion can be evaluated with passive horizontal adduction[10] with the scapula stabilized should be greater than 90° or beyond vertical position towards the chest. Internal rotation should be sufficient to allow for the total arc of motion (internal + external rotation ROM) to approximate total arc of motion values for the uninvolved shoulder.[11] Hip flexion ROM should be at least 110° of flexion, and 40° internal rotation.

Criteria for Abandoning Nonoperative Treatment and Proceeding to Surgery or More Intensive Intervention

- Inability to meet milestones/criteria for progression to next phase of rehabilitation in upper limit of time frames specified

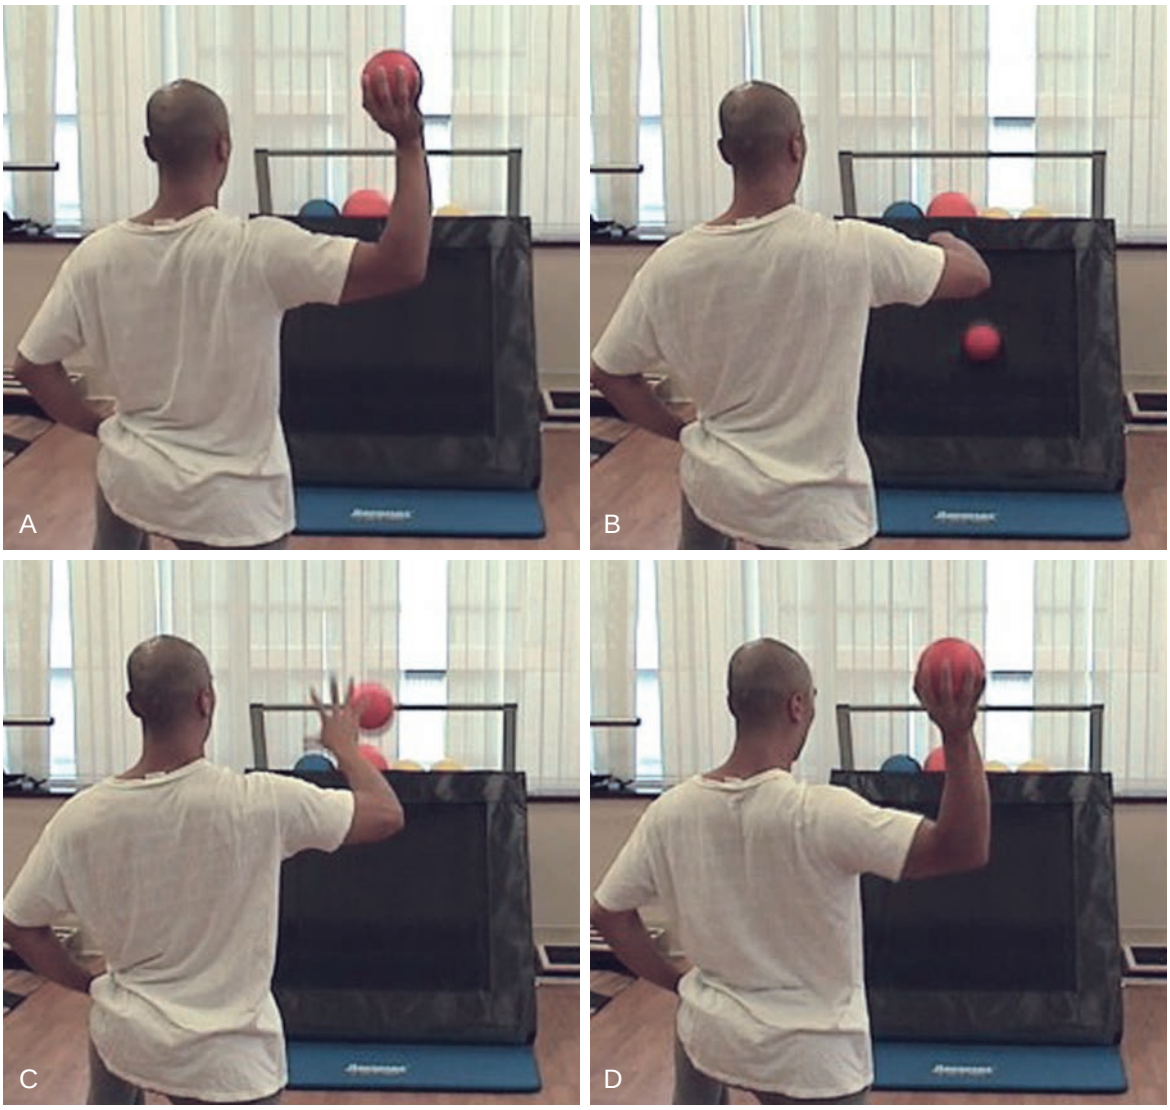

FIGURE 4-30. Plyometrics one arm throw in abducted position (**A**) wind up, (**B**) release, (**C**) catch, and (**D**) eccentric follow-through.

- Pain increases with appropriately phased exercises and does not respond to rest, modalities, ANSAIDS or corticosteroid injection(s)
- Recurrence of injury during any phase of rehabilitation
- Unable to achieve level of performance necessary to successfully return and compete in sport

Tips and Guidelines for Transitioning to Performance Enhancement

- Although skilled rehabilitation of the shoulder and kinetic chain is achieved during Phase I to IV interventions, skill and optimal performance in the specific-sport activities is a necessary component to successful recovery and is frequently overlooked at the end of rehabilitation.
- Performance enhancement further develops the specific skills to optimize performance with the demands required of the athlete's particular specialty within each sport.
- Specialists trained in functional movement screens and evaluation techniques to identify remaining movement dysfunctions and maximize performance are essential to return to sport success. Rehabilitation specialists should work closely with strength and performance enhancement specialists during this final stage of rehabilitation to then transition to a comprehensive performance enhancement program.
- This team approach is optimal for full recovery of the athlete at participating at competitive levels.

Performance Enhancement and Beyond Rehabilitation: Training/ Trainer and Optimization of Athletic Performance

- Performance enhancement and optimization will include a comprehensive program to address performance aspects of the sport including power, strength, accuracy, velocity.

- Performance enhancement should be initiated near the end of rehabilitation in combination or before return to sport progressions are initiated.
- Detailed information regarding sports performance enhancement can be found in the Beyond the basics section.

Specific Criteria for Return to Sports Participation: Tests and Measurements

- Normal uncompensated scapulothoracic and glenohumeral motion under fast and resisted conditions with sport-specific activities. Can observe scapular motion during the functional closed chain upper extremity functional test, and can consult pitching coach to insure adequate mechanics with pitching or throwing. Should assess scapular stability for winging or shrugging with all strengthening exercises and sport-specific drills.
- No symptoms of pain or discomfort during or following exercise
- Maintenance of normal strength and flexibility shoulder, core, lower extremity
  - Shoulder strength >90% uninvolved with isokinetic testing or at minimum hand-held dynamometry specific to internal, external, and abduction in multiple arm angles.
  - Normal posterior shoulder ROM can be maintained with diligent stretching with sleeper stretching and assistance with IR glenohumeral stretching on a daily basis. Passive horizontal adduction[10] with the scapula stabilized should be greater than 90° or beyond vertical position towards the chest. Internal rotation should be sufficient to allow for the total arc of motion (internal + external rotation ROM) to approximate total arc of motion values for the uninvolved shoulder.[11]
  - Lower extremity star excursions or step-downs should be equal bilaterally with good pelvic control.
- Successful completion of return to sport interval progression
- Normal mechanics with sport (throwing, swimming, tennis) and confirmation from coach, trainer, and/or sports performance specialist that performance is optimized for return to competitive play

Multiple-Choice Questions

QUESTION 1. The rehabilitation for nonoperative management of SLAP tears is focused on:

A. Rotator cuff strengthening
B. Core stability
C. Posterior shoulder flexibility
D. Impairments identified from a comprehensive examination

QUESTION 2. The following is true of Phase I rehabilitation of SLAP tears **EXCEPT:**

A. Include normalizing glenohumeral AROM in all planes
B. Is necessary to complete for at least 4 weeks in all athletes
C. Includes modalities and cryotherapy as needed to improve pain
D. Includes strengthening at terminal ranges of motion

QUESTION 3. Common to most overhead athletes with SLAP tears, posterior shoulder flexibility should be addressed with:

A. Sleeper stretch
B. Horizontal adduction self-stretching
C. Glenohumeral joint mobilizations and soft tissue techniques
D. All of the above

QUESTION 4. Plyometrics for the involved shoulder and upper extremity should be initiated:

A. In positions of stability with the arm in neutral and below shoulder height
B. In simulated positions of throwing/serving/swimming
C. In closed chain behind the plane of the body
D. Rarely

QUESTION 5. The final decision for return to play following rehabilitation of a SLAP tear should be based on testing from:

A. Successful completion of interval return to sport program
B. Clearance from the rehabilitation specialist and physician that milestones have been met
C. Approval from the coach, trainer/strength and conditioning specialist
D. All the above

Answer Key

QUESTION 1. Correct answer: **D** (see key points)

QUESTION 2. Correct answer: **B** (see key points)

QUESTION 3. Correct answer: **A** (see Phase II)

QUESTION 4. Correct answer: **A** (see Phase III)

QUESTION 5. Correct answer: **D** (see Phase IV)

POSTOPERATIVE REHABILITATION AFTER TREATMENT OF SLAP TEARS

Amee L. Seitz, PT, PhD, DPT, OCS, and Thomas J. Gill IV, MD

Indications for Surgical Treatment

Indications for surgical treatment of a superior labrum anterior to posterior (SLAP) tear are persistent symptoms with loss of function and sports performance despite conservative treatment. Symptoms can include:

- Pain, usually with overhead activities
- Loss of strength
- Catching, locking, popping, or grinding
- Occasional night pain or pain with daily activities
- A sense of instability in the shoulder
- Decreased range of motion

Brief Summary of Surgical Treatment

Major Surgical Steps

- General anesthesia and shoulder arthroscopy
- Beach chair position
- Arthroscopic portals
  - A posterior viewing portal placed 2 cm inferior to the posterolateral corner of the acromion
  - A standard anterior portal placed under direct visualization anterior and 1 cm lateral to the coracoid, with the cannula inserted just inferior to the biceps in the rotator interval
- Arthroscopic evaluation to determine type of SLAP, evaluation of the entire glenoid labrum, biceps tendon, articular surface of the glenoid and humeral head, glenohumeral ligaments, subscapularis tendon, and rotator cuff
- A lateral portal is made under direct visualization just posterior to the biceps tendon at the anterior margin of the supraspinatus in the rotator interval
- The superior glenoid was abraded down to a gently bleeding bony bed posterior to the biceps anchor footprint with a 4.2 mm bone cutting shaver
- Single loaded 3.5 mm suture anchors are placed posterior to the biceps footprint.
- The sutures are passed using a suture passing device. The sutures are tied using an arthroscopic sliding knot (Duncan loop) followed by half hitches.
- A probe is used to evaluate the repair integrity

Factors That May Affect Rehabilitation

Surgical

- The type of SLAP repair strongly dictates rehabilitation progression. A type II and IV involving the biceps anchor have precautions regarding early biceps use and graded return of ROM
- Type I and III SLAP repairs typically require arthroscopic debridement of the labrum and not an anatomic repair. Thus rehabilitation progression may be more aggressive to restore range of motion in early phase

Other Surgical Techniques and Options

- If the patient has involvement that necessitates surgical repair of other structures (rotator cuff tendons) the postoperative rehabilitation course will deviate from SLAP to rotator cuff repair guidelines.

Before Surgery: Overview of Goals, Milestones, and Guidelines[1]

GUIDING PRINCIPLES OF POSTOPERATIVE REHABILITATION

- A thorough understanding regarding the type of SLAP repair and other procedures is essential to rehabilitation success (concomitant rotator cuff repair should follow rotator cuff rehabilitation guidelines)
- Adequate protection of repair including biceps when applicable while minimizing postoperative morbidities
- Understanding of positions and activities that stress repair and time frames for healing
- Restoration of normal arthrokinematics and dynamic neuromuscular control of the shoulder complex is critical to successful recovery

Phase I: Immediate Postoperative Period (days 0 to 14)

Clinical Pearls

- In the week or so immediately following surgery, comfort and pain control is important.
- The patient should be educated in positions to maximize comfort including the use of pillows to prop the shoulder in a "loose pack" position (slight abduction, flexion and neutral rotation) and may be encouraged to sleep in a recliner for the first few days following surgery to achieve this. When the patient lies supine without support behind the elbow, there is tension on the repair and/or superior shoulder joint soft tissues.
- Additionally, the patient would benefit from instruction in strategies to put on a shirt and wash under the arm of the involved shoulder by bending at the waist, similar to a Codman's pendulum exercise.

Goals

- Control pain and swelling
- Protect the repair and promote healing
- Minimize side effects of immobilization including stiffness and muscular atrophy

[1]*Prehabilitation, if appropriate, is described in the Nonoperative Rehabilitation section of this chapter.*

Protection

- The use of a sling at all times is necessary except during ROM exercises and bathing. Patients instructed to avoid active biceps contraction, but use of hand and wrist in front of body while in the sling is permitted within pain tolerance.
- No lifting or carrying objects with the involved hand is instructed.

Management of Pain and Swelling

- Patient education regarding proper positioning to reduce tensile loads on repair and surrounding soft tissue using pillows and/or recliner when resting.
- Ice intermittently, 4 to 5 times per day 15 to 20 minutes at a time
- Oral pain medications as instructed by the surgeon
- TENS unit may be used
- Use of Cryo Cuff or ice packs to minimize pain and inflammation
- Modalities including electrical stimulation

Techniques for Progressive Increase in Range of Motion

Guidelines for progressive increase in ROM (Table 4-1) are based on tissue healing and have been adapted from published literature.[1-3]

- Initial ROM HEP before postoperative surgeon's visit consists of Codman's pendulum exercises for the shoulder or modified version of table forward bow (Figure 4-31) which does not differ in the amount of electrical muscle activity of the shoulder from the pendulum exercise.[1]
- Wrist and hand active ROM exercises are encouraged 4 to 5 times per day
- Postural scapular squeezes with arm supported in the sling 4 to 5 times per day

Manual Therapy Techniques

- Type II, IV SLAP Repair ROM Precautions: ER <15° with the arm in scapular plane, humeral elevation in scapular plane 60° to 75° (precautions adjusted for other concurrent surgical repairs such as rotator cuff involvement)
- PROM: Manual range of glenohumeral joint (per precautions) as well as affected elbow, wrist, and scapula. Muscular guarding should be considered and manual therapy adjusted as necessary to facilitate relaxation of the biceps.
- Type I, III SLAP Repair ROM Precautions: ROM to progress within pain tolerance with elevation in scapular plane to 110°, ER at the side, and AAROM behind the back

Stretching and Flexibility Techniques for the Musculotendinous Unit

- Type II, IV SLAP Repair: Stretching not performed during this stage with the exception of the wrist and hand (elbow bent) as needed

Table 4-1 Postoperative ROM Guidelines

Postop Timeframe	Type SLAP Repair	Range of Motion	Scaption (degrees)	Flexion (degrees)	External Rotation (degrees)	Internal Rotation (degrees)	Abduction (degrees)	Adduction (degrees)	Extension (degrees)	Elbow AROM
0–14 d	Type II, IV	PROM	60	60	15 (in 30 scaption)	45 (in 30 scaption)	N/a	0	0	No active flexion
	Type I, III	P/AAROM/ AROM	120	120	60 (in 30 &45 abduction)	60 (in 45 Abduction)	90	0	20	No active flexion
2–4 wk	Type II, IV	P/AAROM	90	90	30 (in 30 scaption)	60 (in 30 scaption)	80	0	0	No active flexion
	Type I, III	P/AAROM→ AROM	Full	Full	Full (in 90 abduction)	Full in 90 Abduction	Full	Full	Full	Active/ resisted
4–6 wk	Type II, IV	P/AAROM→ AROM	145	145	60 (in 45 abduction)	60 (in 45 Abduction)	90	0	20	AROM flexion
6–10 wk	Type II, IV	AAROM/ AROM	Full	Full	90 (in 90 abduction)	75 (in 90 Abduction)	Full	H Add to 90	Full	Full
10–14 wk	Type II, IV	AROM	Full	Full		Full (in 90 Abduction)	Full	Full H Add	Full	Resisted

- Type I, III SLAP Repair: Gentle stretching of the glenohumeral joint within pain tolerance to normalize PROM in all planes

Other Therapeutic Exercises

Activation of Primary Muscles Involved in Injury Area or Surgical Structures

- Active contraction of the biceps, elbow flexion and resisted supination, is contraindicated during this phase in patients with type IV SLAP repairs.

Neuromuscular Dynamic Stability Exercises

- Scapular active ROM including elevation and retraction while in the sling is encouraged every 2 to 3 hours to minimize alterations in scapular position and initiate dynamic scapular control. (Figure 4-32)

Milestones for Progression to the Next Phase

- Successful postoperative follow-up visit with surgeon's office
- No signs of infection and adequate wound healing
- Successful pain control
- Understanding of surgical type of SLAP repair and appropriate rehabilitation plan

FIGURE 4-31. Table forward bows for passive range of motion. (**A**) Start position and (**B**) end position.

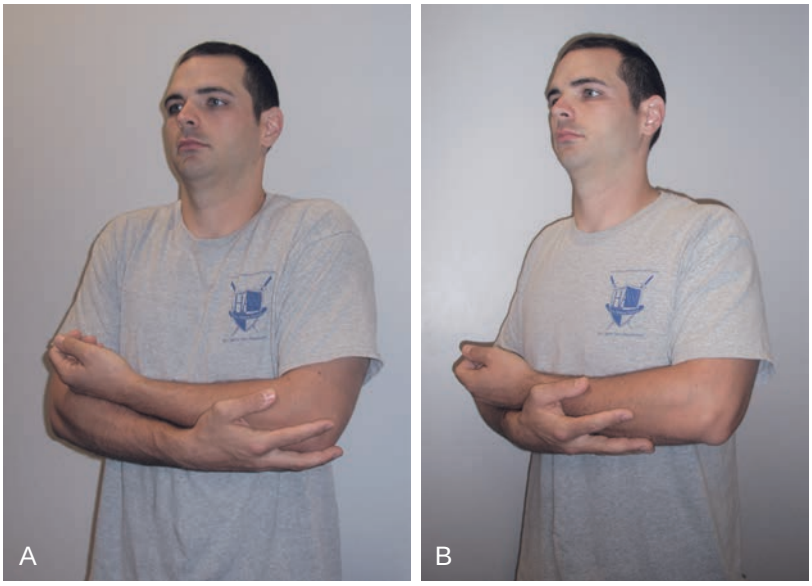

FIGURE 4-32. Scapular ROM in elevation (**A**) and retraction (**B**) which can be performed in the sling.

Phase II (weeks 2 to 6) : Early post-operative phase

Clinical Pearls

- The type of SLAP repair dictates the activities and goals for this phase of rehabilitation.
- The ROM gains should be gradual and well within pain tolerance following ROM Guidelines (Table 4-1).
- Rehabilitation of type II and IV SLAP repairs should focus on protected ROM progressions (Table 4-1) and submaximal rotator cuff and scapular stability exercises.
- Rehabilitation of type I, and III SLAP repairs should wean from sling immediately and focus on normalizing ROM, strength, and dynamic glenohumeral and scapulothoracic control, and core stability.

Goals

- Protection of surgical repair (particularly type II, IV with biceps involvement)
- Gradual restoration of normal glenohumeral range of motion within guidelines
- Decrease pain
- Improve dynamic neuromuscular control rotator cuff, scapular stabilizers, core

TIMELINE 4-2: **Postoperative Rehabilitation after SLAP II and IV Repair**

PHASE I (weeks 1 to 2)	PHASE II (weeks 3 to 6)	PHASE III (weeks 6 to 10)
• Sling • PT modalities • P/AAROM-scapular plane elevation to 60°, ER to 15° and IR to 45° in scapular plane • Active-assistive Codman's exercises and forward bow • Elbow ROM-no active biceps • Wrist and hand ROM exercises	• DC sling between 4 and 6 wk • PT modalities • P/AAROM—wk 3–4 flexion & scapular plane elevation to 90°, ABD to 80°, ER to 30° and IR to 60° in scapular plane; wk 5–6 flexion & scapular plane elevation to 145°, ABD to 90°, ER and IR to 60° in scapular plane & abduction 45° • No active elevation, extension, abduction and biceps up to 4 wk • Elbow stretching at 4 wk • Mobilizations GH joint grade II as needed • TBS/TLS activities as recommended & tolerated • OKC submaximal rhythmic stabilization with short moment arms and proximal perturbation • Rotator cuff exercises—submaximal pain free isometrics at 4 wk • Scapular clock and standing trunk/thoracic spine PNF AROM	• PT modalities as needed • P/AAROM—full ROM in flexion, abduction & scapular plane elevation, ER to 90° and IR to 75° at 90° ABD • End range GH and posterior shoulder stretching in horizontal adduction to 90° • Mobilizations GH joint grade III, IV emphasis on posterior and inferior as needed • TBS/TLS activities as recommended and tolerated • Scapular exercises—PREs • Rotator cuff exercises—PREs • PNF exercises • OKC rhythmic stabilization short moment arms and proximal perturbation • CKC exercises in quadruple progressing to knee plank positions

Protection

Type II, IV SLAP Repair ROM Precautions
- Continued use of sling until postop week 4 to 6 depending on surgeon preference and patient compliance with ROM restrictions
- No active elevation, extension, or abduction until 4 weeks
- No resisted biceps activities (shoulder and elbow flexion, supination)

Type I, III SLAP Repair ROM Precautions
- Gradually wean from sling based on pain tolerance

Management of Pain and Swelling

- Use of Cryo Cuff or ice packs as necessary
- Oral pain medications as needed
- Modalities including interferential electrical stimulation or TENS

Techniques for Progressive Increase in Range of Motion

Increase ROM guidelines for progressive increase in ROM in this phase are outlined in Table 4-1.

Manual Therapy Techniques

Type II, IV SLAP Repair
- Incremental increase in passive glenohumeral ROM per guidelines (Table 4-1): ER to 30° (weeks 3 to 4) and 60° (weeks 5 to 6) with the arm in scapular plane (Figure 4-33), flexion and scapular plane elevation to 90° (weeks 3 to 4) then 145° (weeks 5 to 6), extension to tolerance and IR in scapular plane to 45° initiated in week 4
- Initiate glenohumeral posterior inferior mobilizations grade II for pain progressing to grade III at 6 weeks postop to restore abnormal arthrokinematics as indicated within ROM limitations

FIGURE 4-33. Scapular plane IR and ER passive GH ROM.

- Initiate scapular mobilizations elevation, retraction, depression and posterior tilt

Type I, III SLAP Repair
- Normalize to full passive glenohumeral ROM within pain tolerance in all planes starting ER in neutral progressing to 45° and 90° of abduction
- Grade II, III mobilizations inferior and posterior as needed to reduce anterior superior stress to the capsule in flexion and abduction with external rotation

Soft Tissue Techniques

- Pectoralis minor active release or preferred soft tissue technique as needed to normalize muscle length to restore adequate scapular posterior tilt.[4] Minimum length can be determined by supine assessment of acromion distance from bed should be equal bilaterally.
- Scar mobilization as needed

Additionally type I, III SLAP repair can initiate:
- Normalize posterior shoulder ROM within pain tolerance with horizontal adduction to 90° and internal rotation at 90° of abduction

TIMELINE 4-2 Postoperative Rehabilitation after SLAP II and IV Repair (Continued)

PHASE IV (weeks 10 to 14)	PHASE V (weeks 14 to 24)	PHASE VI (weeks 24+)
• PROM—maintain full motion • Mobilizations as needed • TBS/TAS initiating bicep specific/TLS activities as recommended & tolerated • Scapular exercises—PREs progressed • Rotator cuff exercises—PREs • Thrower's Ten full program • PNF exercises • OKC rhythmic stabilization and manual perturbation exercises • CKC exercises—long moment arm positions stable to unstable surfaces • CKC manual perturbation exercises • Plyometrics—2 arm below shoulder height progressing to 1 arm • Sport-specific exercises begin • Overhead athletes can initiate an interval program (throwing, swimming, tennis) once ROM, strength, and pain goals are met	• PROM—maintain full motion • Mobilizations as needed • TBS/TAS/TLS activities as recommended & tolerated • Scapular exercises—PREs • TAS—biceps/triceps PREs • Rotator cuff exercises—PREs • Thrower's Ten progress intensity • PNF exercises • OKC rhythmic stabilization exercises • CKC exercises • CKC manual perturbation exercises • Plyometrics—overhead acceleration/deceleration progressing to 90/90 1 arm • Overhead strengthening exercises • Sport-specific exercises progressed • Overhead athletes complete an interval program (throwing, swimming, tennis) • Various types of pitches from mound/hits/serves/strokes without restrictions are initiated	• PROM—maintain full motion as needed • Mobilizations as needed • TBS/TAS/TLS activities as recommended & tolerated • Scapular exercises—PREs • TAS—biceps/triceps PREs • Rotator cuff exercises—PREs • Thrower's Ten progress intensity • PNF exercises • OKC rhythmic stabilization exercises • CKC exercises • CKC manual perturbation exercises • Plyometrics—overhead acceleration/deceleration progressing to 90/90 1 arm • Overhead strengthening exercises • Sport-specific exercises progressed • Overhead athletes complete an interval program (throwing, swimming, tennis) • Various types of pitches from mound/hits/serves/strokes without restrictions

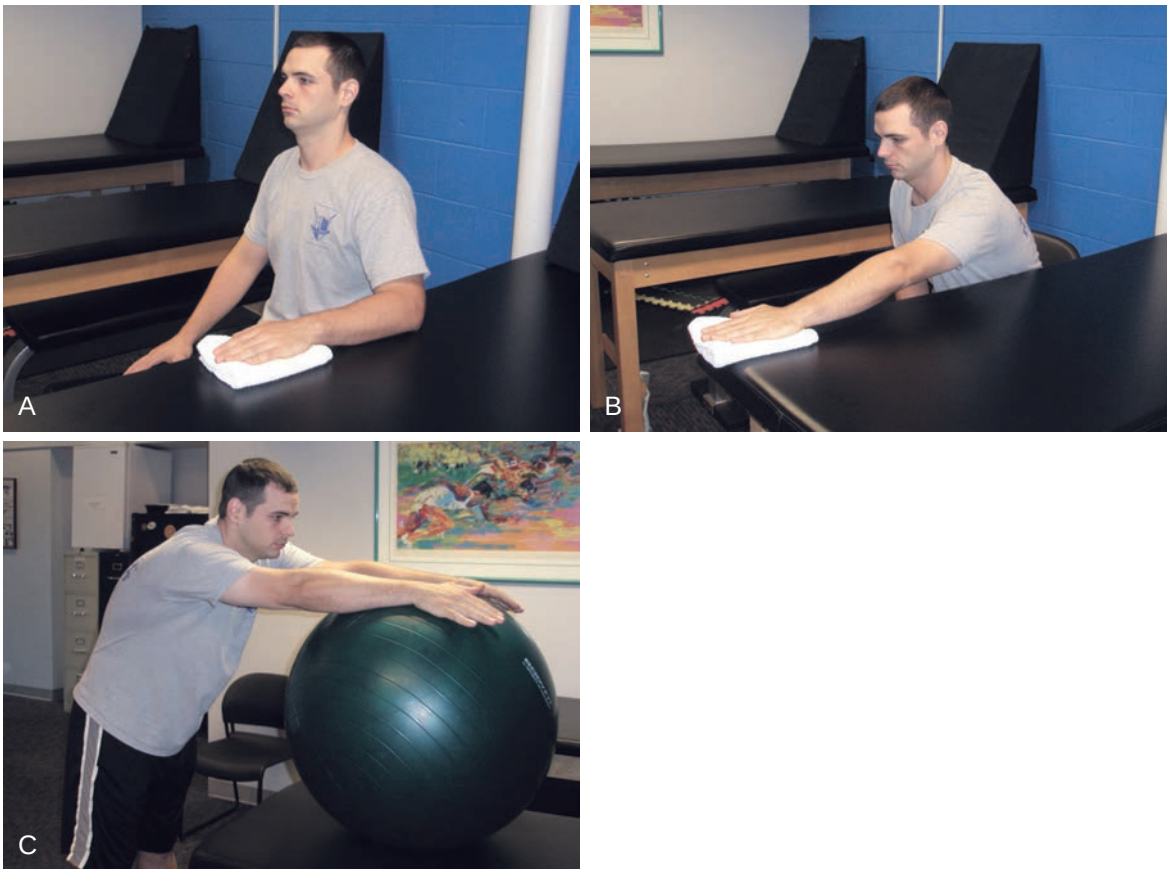

FIGURE 4-34. Stretching elevation with table slides (**A, B**) and ball walks (**C**).

Stretching and Flexibility Techniques for the Musculotendinous Unit

- Closed chain upper extremity table slides progressing to flexed trunk position, ball walks (Figure 4-34) and wall slides within ROM precautions
- T-bar/cane exercises for AAROM within ROM precautions performed supine
- Elbow and wrist ROM stretching until normalized
- Behind the back internal rotation stretching using a towel to gently assist

Additionally type I, III SLAP repair can initiate:

- End range terminal stretching in all planes within pain tolerance until full ROM is achieved
- Posterior shoulder stretching with horizontal adduction to normal progressing to sleeper stretch[4]

TIMELINE 4-3: **Postoperative Rehabilitation after SLAP I and III Repair**

PHASE I (weeks 1 to 2)	PHASE II (weeks 3 to 6)	PHASE III (weeks 6 to 10)
• Sling • PT modalities • A/AAROM-scapular plane elevation to 120°, ER/IR to 60° in 45° ABD • Active-assistive Codman's exercises and forward bow • Submaximal isometrics • Elbow ROM—no active biceps • Wrist and hand ROM exercises	• DC sling • PT modalities • ROM full active and passive • End range GH and posterior shoulder stretching • Mobilizations II, III, IV as needed • TBS/TAS/TLS activities as recommended and tolerated • Scapular exercises—PREs • TAS—biceps/triceps PREs • Rotator cuff exercises—TheraBand and PREs • CKC exercises—Standing and quadruped	• PT modalities as needed • End range GH and posterior shoulder stretching • Mobilizations III, IV emphasis posterior and inferior as needed • TBS/TAS/TLS activities as recommended and tolerated • Thrower's Ten • PNF exercises • OKC rhythmic stabilization and short arc manual perturbation exercises • CKC exercises in plank positions from knees to toes • Plyometrics—2 arm below 45° abduction • Overhead strengthening exercises

FIGURE 4-35. Unilateral lower extremity lateral slides (**A**) and anterior reaches (**B**).

Other Therapeutic Exercises

- Return to nonimpact light aerobic activity (bike, elliptical, StairMaster) within pain tolerance once sling is discharged
- Lower extremity resistance training is initiated
- Core stability is initiated as able with seated ball exercises and unilateral stance lower extremity reaches and lateral slides (Figure 4-35) on stable surface progressed as technique allows

Activation of Primary Muscles Involved in Injury Area or Surgical Structures

Type II, IV SLAP repair:

- Initiate rotator cuff internal/external rotation isometrics within pain tolerance at 4 weeks
- Rhythmic stabilization drills open chain within pain tolerance and ROM guidelines (Table 4-1)

Additionally type I, III SLAP repair can initiate:

- Isometrics for rotator cuff and shoulder in abduction, flexion, extension and adduction initiated immediately
- Active ROM in elevation scapular plane with emphasis on normal scapulohumeral rhythm
- Progress rotator cuff and scapular prone exercises to light isotonic and/or elastic resistance as ROM is normalized without scapular substitution patterns
  - Resisted IR/ER in neutral with elastic resistance
  - Sideling ER and forward punches
  - Side-lying scaption
  - Prone horizontal abduction, rowing

Sensorimotor Exercises

- Scapular clock
- Active elevation in scapular plane with mirror and verbal feedback to normalize dynamic motor control

TIMELINE 4-3 **Postoperative Rehabilitation after SLAP I and III Repair** (Continued)

PHASE IV (weeks 10 to 14)	PHASE V (weeks 14 to 24)
• PROM—maintain full motion • Mobilizations as needed • TBS/TAS/TLS activities as recommended and tolerated • Scapular exercises—PREs • Rotator cuff exercises—PREs • Thrower's Ten progress intensity • PNF exercises • OKC rhythmic stabilization and long arc manual perturbation exercises • CKC exercises plank and long arc positions • CKC manual perturbation exercises • Plyometrics—2 arm progressing to 1 arm overhead • Sport-specific exercises begin • Overhead throwing athletes can begin an interval program (throwing, swimming, tennis)	• PROM—maintain full motion • Mobilizations as needed • TBS/TAS/TLS activities as recommended & tolerated • Scapular exercises—PREs • TAS—biceps/triceps PREs • Rotator cuff exercises—PREs • IR/ER exercises at 90° • Thrower's Ten progress intensity • PNF exercises • OKC rhythmic stabilization exercises • CKC exercises • CKC manual perturbation exercises • Plyometrics—2 arm chest passes progressing to 90/90 1 arm plyos • Overhead strengthening exercises • Sport-specific exercises progressed • Overhead athletes complete an interval program (throwing, swimming, tennis) • Initiate various types of pitches/hits/serves/strokes without restrictions

FIGURE 4-36. Thoracic spine rotations in quadruped heel sitting.

Open and Closed Kinetic Chain Exercises

- Kneeling thoracic spine rotation once sling is discharged to improve scapular and thoracic mobility (Figure 4-36)

Additionally type I, III SLAP repair:

- Closed chain quadruped bent elbow progressing to elbow straight closed chain proximal stability exercises (plank on knees to toes prone and side)

Techniques to Increase Muscle Strength, Power, and Endurance

- Progression of LE strength training exercises
- Progress to elliptical and stair stepper for cardiovascular conditioning

Additionally type I, III SLAP repair:

- Progress biceps and triceps exercises in standing
- Progression of rotator cuff and scapular strength training exercises as tolerates without substitution

Neuromuscular Dynamic Stability Exercises

Type II, IV SLAP repair:

- Initiate submaximal isometrics for rotator cuff (IR/ER), shoulder (ABD, flex, ext) and scapular musculature (shrugs, retraction)
- Manual rhythmic stabilization within ROM guidelines

Additionally type I, III SLAP repair:

- PNF glenohumeral diagonals with manual proximal and distal resistance
- Manual rhythmic stabilization

Sport-Specific Exercises

- Overhead athletes should initiate core and lower extremity stability drills in unilateral stance (standing balance, excursions anterior lateral and diagonals)

Milestones for Progression to the Next Phase

Type II, IV SLAP repair:

- Active ROM without scapular compensations to 150° elevation, ER 50°, IR behind back to L5
- PROM per ROM guidelines

Type I, III SLAP repair:

- Full pain-free active ROM with elevation, abduction and IR/ER at 90° of abduction (overhead athletes may demonstrate loss of IR compared to contralateral but total arc of motion internal and external rotation should be normalized)
- Normal arthrokinematics glenohumeral joint and posterior shoulder ROM. Arthrokinematics with manual accessory motion testing should be assessed in the posterior and inferior direction. Posterior shoulder range of motion can be evaluated with passive horizontal adduction[5] with the scapula stabilized at an angle greater than 90° or beyond the vertical position towards the chest. Internal rotation should be sufficient to allow for the total arc of motion (internal + external rotation ROM) to approximate total arc of motion values for the uninvolved shoulder.[6]
- Normalized scapulohumeral motion during elevation as determined by the scapular dyskinesis test.[7] With this test, the athlete should demonstrate no dysrhythmia or winging during five repetitions of full flexion and abduction holding 5-lb hand weights.

Phase III (weeks 6 to 10)

Clinical Pearls

It is critical that ROM gains are made gradually in positions of stability (scapular plane at side) progressing to positions that challenge stability or integrity of SLAP repair (combined abduction and ER to 90°). Patients with type II and IV SLAP repairs should understand ROM progression and limitations for this phase of rehabilitation. Strengthening and dynamic control exercises should be progressed in the same progressive ROM manner with emphasis on proper form, free of scapular substitution patterns and pain. Proper technique and endurance is favored over increasing resistance.

Goals

- Gradually restore normal A/PROM in all planes
- Improve rotator cuff, scapular muscle strength and neuromuscular control
- Normalize dynamic trunk and kinetic chain strength and motor control

Protection

- Use of sling is no longer indicated

Management of Pain and Swelling

- Oral analgesic use is continued as needed
- NSAID therapy may be prescribed for persistent pain
- Modalities ice and electrical stimulation for pain control PRN
- Cryotherapy is used posttherapy to mitigate postexercise inflammation and soreness

Techniques for Progressive Increase in Range of Motion

Manual Therapy Techniques

- Continue glenohumeral mobilizations grade III with emphasis on posterior and inferior portion of the capsule to restore abnormal arthrokinematics as indicated

Type II, IV SLAP repair:

- Incremental increase in glenohumeral ROM motion to FULL: ER to 90° and IR to 75° with the arm in 90° progressing to full abduction, flexion and scapular plane elevation (Table 4-1).

Soft Tissue Techniques

- Pectoralis doorway stretching as needed to normalize scapular ROM. Doorway stretch should be performed unilateral with emphasis of movement on scapular retraction not glenohumeral horizontal abduction. Caution should be taken to avoid hyperabduction of the humerus as the humerus should remain in the plane of the scapula during this exercise with longer duration holds up to 30 seconds.

Stretching and Flexibility Techniques for the Musculotendinous Unit

- End range stretching in all planes including hands behind the head and reaching up behind back as indicated to achieve normal motion
- Posterior shoulder ROM in cross chest stretch and internal rotation at 90° of abduction (sleeper stretch)

Other Therapeutic Exercises

- Return to all aerobic activity
- Lower extremity resistance training is progressed
- Core stability exercises are progressed to sport-specific positions and conditions

Additionally type I, III SLAP repair:

- Total arm strengthening initiated

Activation of Primary Muscles Involved in Injury Area or Surgical Structures

Type II, IV SLAP repair:

- Initiate rotator cuff and scapular prone exercises to light isotonic and/or elastic resistance as ROM is normalized without scapular substitution patterns
- Resisted IR/ER in neutral
- Side-lying ER and forward punches
- Shoulder retractions
- Standing "W"s (Figure 4-37)
- Prone horizontal abduction "T"s, rowing, extension
- No resistance isolated to biceps

Type I, III SLAP repair:

- Progress shoulder and rotator cuff strengthening to a Thrower's Ten program[8]
  1. Diagonal pattern (D2) flexion
  2. Diagonal pattern (D2) extension
  3. Humeral ER at 0° abduction
  4. Humeral IR at 0° abduction
  5. Humeral ER at 90° abduction
  6. Humeral IR at 90° abduction
  7. Shoulder flexion to 90°
  8. Shoulder scaption
  9. Prone horizontal abduction at neutral
  10. Prone horizontal abduction with full ER at 100°
  11. Prone row
  12. Press-ups
  13. Pushups
  14. Bicep curls/elbow flexion
  15. Triceps extension/elbow extension
  16. Wrist extension/wrist flexion
  17. Wrist supination/wrist pronation

FIGURE 4-37. Standing "W"s with elastic resistance.

Sensorimotor Exercises

- Rhythmic stabilization and manual strengthening of the UE with short moment arms/proximal resistance
- The Bodyblade at 0° abduction as well as 90° scapular elevation
- Core stability exercises with manual resistance on stable progressing to unstable surfaces

Open and Closed Kinetic Chain Exercises

- PNF in D1–2 with manual resistance to scapula and humerus with slow reversals
- Closed chain PNF in quadruped (Figure 4-38)

Additionally type I, III SLAP repair:

- Closed chain quadruped to plank, bent elbow progressing to elbow straight closed chain proximal stability exercises (plank on knees to toes prone and side) Figure 4-39

Techniques to Increase Muscle Strength, Power, and Endurance

- Progression of LE strength training exercises
- Progress to elliptical and stair stepper for cardiovascular conditioning

Plyometrics

ONLY type I, III SLAP repair:

- Light plyometrics with side-lying ball drops (Figure 4-40)
- Two arm rebounder shoulder internal and external rotation with arms at the side (Figure 4-41), chest passes with shoulder ROM below 45° elevation
- Wall dribbles light resistance overhead

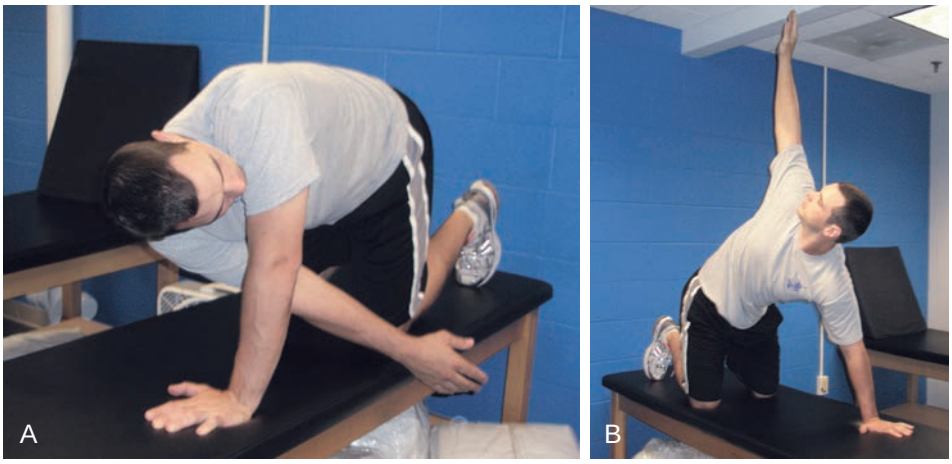

FIGURE 4-38. Closed chain PNF in quadruped.

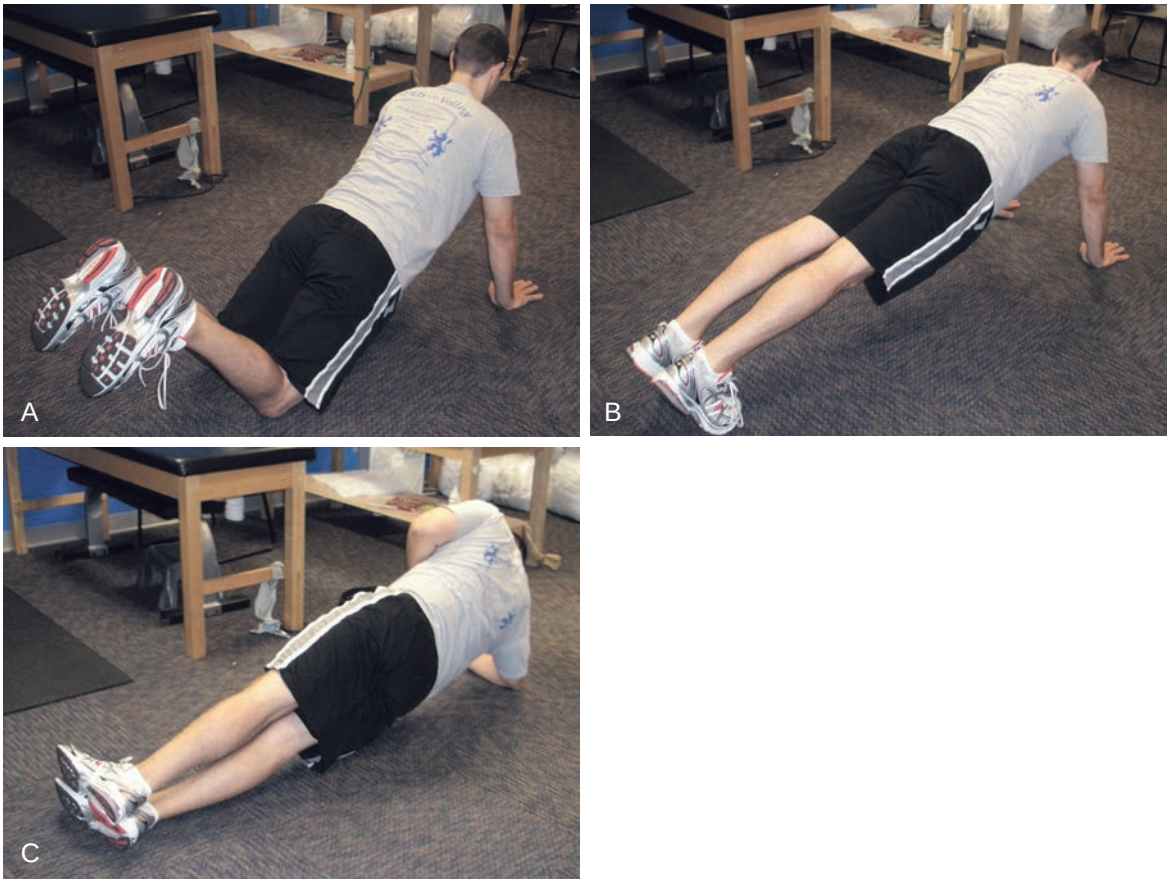

FIGURE 4-39. Plank position prone from knees (**A**), toes (**B**) and side-lying (**C**).

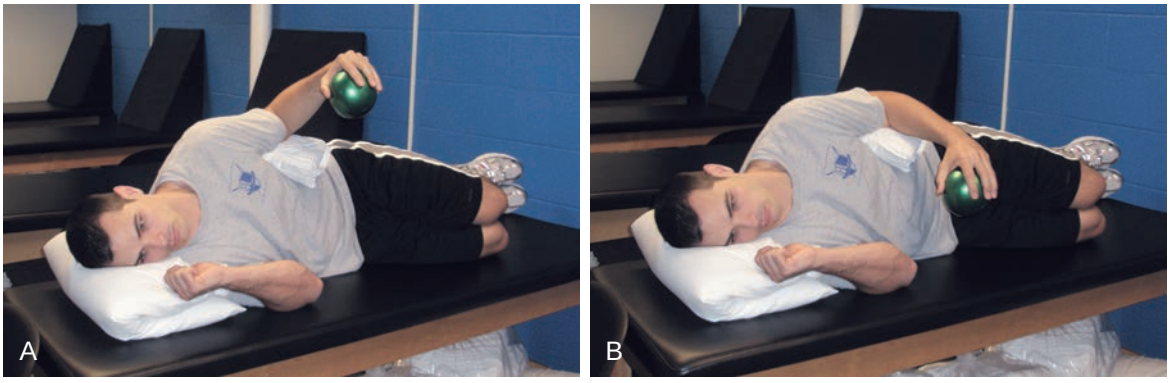

FIGURE 4-40. Eccentric ball drops (A) and catch B

FIGURE 4-41. Plyometrics using rebounder below chest height in IR/ER.

Sport-Specific Exercises

- Initiate exercises and sport-specific drills with arm at the side such as fielding, glove work, and lower extremity footwork drills.

Milestones for Progression to the Next Phase

Type II, IV SLAP repair:
- Full pain-free active ROM with elevation, abduction and IR/ER at 90° of abduction (the dominant shoulder in overhead, particularly throwing athletes may demonstrate loss of IR compared to contralateral due to osseous changes[9] but total arc of internal and external rotation motion should be normalized)

Type I, III SLAP repair:
- Normal arthrokinematics of the glenohumeral joint and posterior shoulder ROM. Arthrokinematics with manual accessory motion testing should be assessed in the posterior and inferior direction. Posterior shoulder range of motion can be evaluated with passive horizontal adduction[5] with the scapula stabilized at an angle greater than 90° or beyond the vertical position towards the chest. Internal rotation should be sufficient to allow for the total arc of motion (internal + external rotation ROM) to approximate total arc of motion values for the uninvolved shoulder.[6]
- Normalized scapulohumeral motion during active ROM in all planes with the scapular dyskinesis test[7] previously described in this chapter.
- Strength 75% to 80% of uninvolved side below shoulder height can be performed with the arm at 0° and 45° of abduction through range of motion with manual resistance of the examiner, but isometrically in multiple ranges using an hand-held dynamometer because an objective measure is more sensitive to detect apparent weakness up to 20% when manual resistance is deemed normal.[10] Isokinetic testing should be deferred until the end of the next phase.

Phase IV (weeks 10 to 14)

Clinical Pearls

- Posterior shoulder flexibility is paramount for successful outcome of all SLAP repairs due to the undue stress a tight posterior capsule can have on the superior-anterior glenohumeral joint structures.
- Horizontal adduction ROM should be achieved with assistance of the therapist manually stabilizing the scapula and at varying angles of elevation 70° to 100° and IR stretching (Figure 4-42) to appropriately address varying shoulder soft tissue restrictions that may be posterior–superior or posterior–inferior.[11]
- Sleeper stretches are an additional cornerstone to restoring normal posterior shoulder tissue length.[4] Rehabilitation in this stage of patients with type II and IV repairs focuses on restoring terminal ROM and progressing strengthening in protected planes of motion.
- Patients with type I and III SLAP repairs rehabilitation progress more quickly with the focus in this phase of rehabilitation to include restoring full strength, and endurance to prepare for return to sport progressions.

Goals

- Full shoulder range of motion in all planes without substitution or pain
- Restore shoulder strength to 80% contralateral side
- Improve muscular strength, power, and endurance
- Improve neuromuscular control and dynamic stability
- Enhance proprioception and kinesthesia

Management of Pain and Swelling

- Ice after exercise

Techniques for Progressive Increase in Range of Motion

Progressive increase in ROM to full per ROM guidelines Table 4-1.

Manual Therapy Techniques

- Glenohumeral mobilizations grade III with emphasis on posterior and inferior portion of the capsule to restore abnormal arthrokinematics in full GH ROM as needed

Stretching and Flexibility Techniques for the Musculotendinous Unit

- Posterior shoulder stretching in horizontal adduction and sleeper stretch

Other Therapeutic Exercises

- Progress aerobic activity
- Lower extremity resistance training is progressed

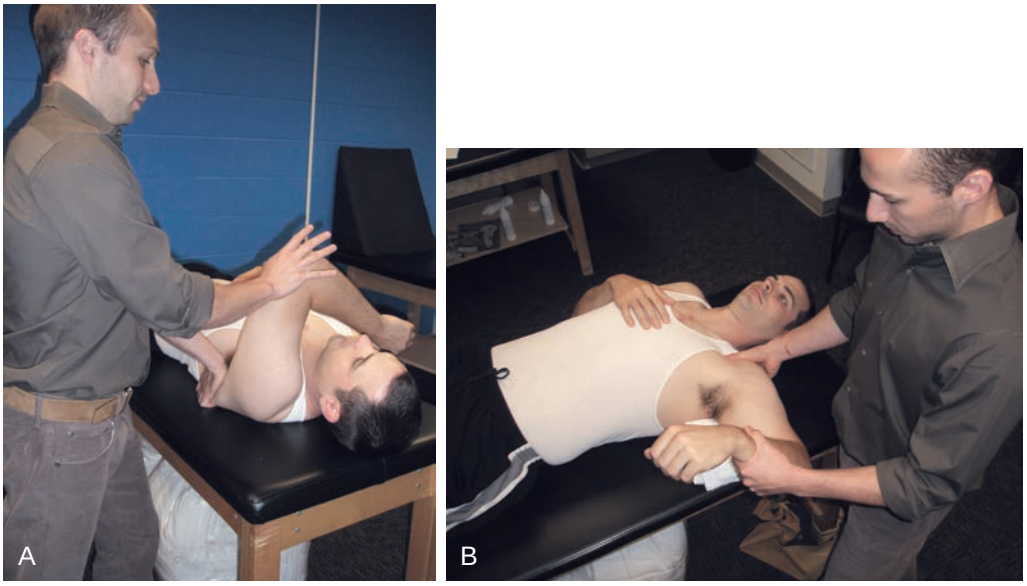

FIGURE 4-42. Manually assisted horizontal adduction (**A**), and IR (**B**) posterior shoulder stretching.

- Core stability exercises are progressed to sport-specific positions and conditions

Additionally type II, IV SLAP repair:

- Total arm strengthening initiated

Activation of Primary Muscles Involved in Injury Area or Surgical Structures

Type II, IV SLAP repair:

- Dynamic hug added to target subscapularis muscle strength.[12] Exercise is performed with the technique of supine dumbbell flys but with TheraBand in standing.
- Prone "Y"s added
- Initiate bicep strengthening
- Thrower's Ten program initiated

Type I, III SLAP repair:

- No restrictions/limitations
- Begin sport-specific return to sport progressions (i.e., interval throwing program)

Sensorimotor Exercises

Type I, III SLAP repair:

- Rhythmic stabilization and manual strengthening of the UE progressed to long moment arms in scapular plane elevation and flexion (Figure 4-43)
- The Bodyblade progressed to 90° abduction and external rotation
- Core stability exercises with manual resistance on stable progressing to unstable surfaces

Open and Closed Kinetic Chain Exercises

Type I, III SLAP repair:

- PNF in D1–2 with manual resistance to scapula and humerus with fast reversals
- Closed chain PNF in plank and long arc positions progressing to unstable surfaces

Techniques to Increase Muscle Strength, Power, and Endurance

- Progression of LE strength training exercises.
- Sport-specific exercises and drills

Plyometrics

Type II, IV SLAP repair:

- Light plyometrics with side-lying and prone ball drops below 45° elevation
- Two-arm rebounder shoulder internal external rotation with arms at the side, chest passes with ROM below 45° elevation

FIGURE 4-43. Rhythmic stabilization in scapular plane (**A**) and flexion (**B**).

- Wall dribbles light resistance overhead

Additionally type I, III SLAP repair:

- Progress plyometrics to unilateral and overhead positions
- Heavy full kinetic chain plyometrics
- One arm rebounder shoulder internal external rotation in abducted position

Sport-Specific Exercises

Additionally type I, III SLAP repair:

- Return to sport-specific interval progressions (throwing, swimming, tennis, etc.) performed on an every other day basis

Milestones for Progression to the Next Phase

Type II, IV SLAP repair:

- Normal arthrokinematics glenohumeral joint and posterior shoulder ROM
- Normalized scapulohumeral motion during active ROM in all planes
- Strength 75% to 80% uninvolved below shoulder height

Type I, III SLAP repair:

- No pain with unrestricted activity
- Successful completion/progress with return to sport interval progressions
- Return to sport testing (goals below)

Phase V (weeks 14 to 24)

Clinical Pearls

- Caution should be taken to avoid progressing the patient too quickly while core stability, proximal scapulothoracic dynamic control and/or adequate rotator cuff strength has yet to be achieved.
- Use of dynamic tests such as the closed kinetic chain upper extremity stability test[13], timed modified pull-up, timed pushup, or single arm shot put tests are helpful to train athletes while monitoring for normal scapular motion with absence of winging or hiking is important.[14]
- Skilled rehabilitation focuses on technique, proper neuromuscular control, and the entire kinetic chain to maximize success in this phase of rehabilitation.
- Rehabilitation professionals who are not familiar working with athletic populations should collaborate with those who have experience and/or consult a strength and conditioning specialist.

Goals

- Progressive increase in functional activities to prepare for unrestricted activity
- No complaints of symptoms/pain with exercise
- Full pain-free uncompensated AROM
- Excellent core and proximal stability of hips and lower extremity with functional tests such as single leg squat or step-down with demonstration of neutral varus or valgus alignment of the knee avoidance of pelvic drop and good balance/control
- Strength of rotator cuff, shoulder and scapular stabilizers at least 80% to 90% uninvolved with isokinetic testing, or if unavailable, hand held dynamometry at multiple arm angles in external rotation, internal rotation and abduction to 90°. Isokinetic testing is preferred.
- Self-report outcome scores >80% such as the Kerlan-Jobe Orthopaedic Clinic[15,16] shoulder and elbow score are more sensitive than regional outcome tools such as the Disability of the Shoulder Arm and Hand.[17]

Management of Pain and Swelling

- Ice after exercise

Techniques for Progressive Increase in Range of Motion

Manual Therapy Techniques

- Glenohumeral mobilizations grade III with emphasis on posterior & inferior portion of the capsule to restore abnormal arthrokinematics in full GH ROM as needed

Stretching and Flexibility Techniques for the Musculotendinous Unit

- Posterior shoulder stretching in horizontal adduction and sleeper stretch to attain and maintain normal flexibility

Other Therapeutic Exercises

- Progress aerobic activity
- Lower extremity resistance training is progressed
- Core stability exercises are progressed to sport-specific positions and conditions
- Total arm strengthening

Activation of Primary Muscles Involved in Injury Area or Surgical Structures

- No restrictions/limitations
- Begin sport-specific return to sport progressions (i.e., interval throwing, swimming, tennis programs) once strength, self-report outcome and full uncompensated active and passive ROM goals of this phase are achieved

Sensorimotor Exercises

- Initiate or progress rhythmic stabilization and manual strengthening of the UE progressed to long moment arms and distal points of resistance
- Initiate or progress The Bodyblade at 90° abduction and external rotation
- Initiate or progress core stability exercises with manual resistance on stable progressing to unstable surfaces

Open and Closed Kinetic Chain Exercises

- PNF in D1–2 with manual resistance with fast reversals and terminal holds with perturbations. (Figure 4-44)
- Closed chain PNF in plank and long arc positions progressing to unstable surfaces

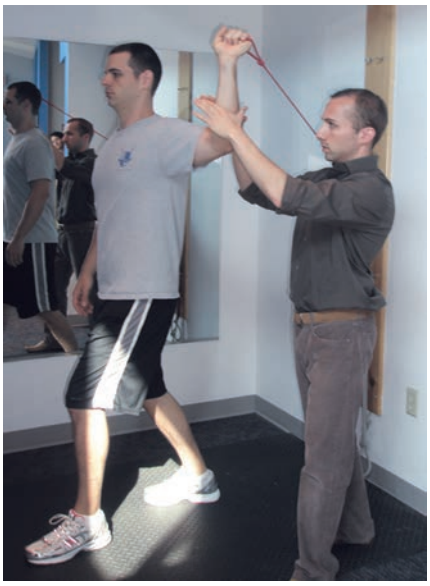

FIGURE 4-44. PNF D2 with terminal holds and manual perturbations.

Techniques to Increase Muscle Strength, Power, and Endurance

- Progression of LE strength training exercises
- Sport-specific exercises and drills

Plyometrics

- Progress plyometrics to unilateral and overhead positions
- Supine IR/ER ball catch and toss with the therapist
- Heavy full kinetic chain plyometrics such as ball slams, medicine ball overhead and sidebody throws
- One arm rebounder shoulder internal external rotation in abducted position

Sport-Specific Exercises

- Initiate or continue return to sport-specific interval progressions (throwing, swimming, tennis, etc.) performed on an every other day basis once strength, ROM and self-report outcome goals are met
- Athletes should work closely with coaches and trainers to insure proper technique with sport activity, particularly when the athlete is fatiguing
- Pitchers should work with coaches to insure proper mechanics with fastball progressing slowly to other types of pitches
- Swimmers should work with coaches to insure proper mechanics with freestyle progressing to other types of swimming strokes
- Tennis players work with coaches to insure proper mechanics with ground strokes progressing to all types of overhead hits and serves

Milestones for Progression Advanced Sport-Specific Training and Conditioning

- No pain with unrestricted activity
- Successful completion/progress with return to sport interval progressions with normal mechanics
- Return to sport testing (goals below)

Criteria for Return to Sport

General

- Normal uncompensated scapulothoracic and glenohumeral motion under fast and resisted conditions using the scapular dyskinesis test[7] as previously described in this chapter
- No symptoms of pain or discomfort during or following exercise
- Functional closed kinetic chain tests, such as such as the closed kinetic chain upper extremity stability test,[13] timed modified pull up, timed pushup, or single arm shot put tests, are >90% uninvolved or considered normal with good control and accuracy
- Strength >90% uninvolved with isokinetic testing or at minimum hand-held dynamometry specific to internal, external, and abduction in multiple arm angles.
- Successful completion of return to sport interval progression

Sport-Specific

- Throwing includes normal mechanics and attention to maintaining form for duration of expected outing and ability to independently maintain posterior shoulder length and rotator cuff strength with home program
- Swimming mechanics are normalized for all types of strokes required for training and competition
- Tennis stroke mechanics are normalized for overhead serve and all types of hitting

After Return to Sport

Continuing Fitness or Rehabilitation Exercises

- Core and total body strengthening conditioning is critical to success in athletic play following SLAP repair

Exercises and Other Techniques for Prevention of Recurrent Injury

- Posterior shoulder flexibility exercises with emphasis on horizontal adduction and sleeper stretch should be included in routine postplay maintenance.
- Thrower's Ten program
- Adequate rest, and periodization of sport-specific training following each competitive season is essential to injury prevention

Multiple-Choice Questions

QUESTION 1. Why is the rehabilitation progression slower with type II, IV SLAP repairs?

A. The labrum has been debrided.
B. The rotator cuff tendons are involved.
C. The labrum and biceps long head tendon anchor has been repaired.
D. The labrum without the biceps tendon has been repaired.

QUESTION 2. What postoperative week is full A/PROM is expected for type I, III SLAP repairs?

A. Week 2
B. Week 6
C. Week 12
D. Week 16

QUESTION 3. Critical to full return of overhead sport activities are normal arthrokinematics at the glenohumeral joint. How do you assess the length of the posterior shoulder tissues?

A. External rotation ROM
B. IR ROM
C. Horizontal adduction
D. All the above

QUESTION 4. To protect the repair, ROM and strengthening progressions start in which plane of motion?

A. Coronal
B. Sagittal
C. Transverse
D. Scapular plane

QUESTION 5. What BEST describes when patients following type II, IV SLAP repair can be progressed from Phase III to Phase IV rehabilitation?

A. At 10 weeks postoperative time frame
B. As long as the goals of Phase III rehabilitation has been achieved
C. Strength >80% uninvolved
D. None of the above

Answer Key

QUESTION 1. Correct answer: **C** (see Phase II)

QUESTION 2. Correct answer: **B** (see Phase II)

QUESTION 3. Correct answer: **D** (see Phase III and Phase IV)

QUESTION 4. Correct answer: **D** (see Phase II and Table 4-1)

QUESTION 5. Correct answer: **B** (see Phase III)

BEYOND BASIC REHABILITATION: RETURN TO PITCHING AND THROWING AFTER SLAP TEAR REPAIR

Thomas J. Gill IV, MD, Joseph J. Van Allen, MSPT, SCS, ATC, CSCS, and Jeremiah Randall, PT, DPT, ATC, CSCS

Introduction

ASPECTS OF PITCHING AND THROWING THAT REQUIRE SPECIAL ATTENTION IN REHABILITATION

- Full glenohumeral range of motion with special emphasis place on shoulder abduction and external rotation
- Adequate glenohumeral strength
- Adequate periscapular strength
- Completion of an upper extremity medicine ball plyometric progression
- Return of proper throwing mechanics
- Completion of an interval throwing program (Boxes 4-1, 4-2) with no pain and minimal muscle soreness

SLAP Labrum Repair in the Pitcher and Thrower: Key Aspects

- Injuries to the superior and posterosuperior labrum are commonly seen in overhead athletes, especially throwers. This is caused by the extreme forces placed on the glenohumeral joint during the late cocking and early acceleration phases of throwing. These forces result in the "peel-back phenomenon," which can lead to unstable biceps anchors (type II SLAP tear).[1]
- In addition, the extreme degree of external rotation in abduction can lead to "internal impingement," as the articular surface of the infraspinatus tendon impacts the posterosuperior labrum.[2]
- The deceleration phase of throwing requires eccentric contraction of the biceps, which has been hypothesized to lead to superior labral tearing.[3]
- Returning to a high level of throwing is challenging after surgical repair of a SLAP tear, especially if full and complete strength and external rotation/abduction is not restored during the rehabilitation process.
- Several studies have reported on returning to previous level of competition following a SLAP repair in the overhead athlete/baseball population:
  - Neri et al.[4] reported that 13 of 23 (57%) overhead athletes who underwent a type II SLAP repair had returned to the preinjury level of competition at a 1-year follow-up.
  - A study conducted by Cohen et al. in 2011[5] reported that 7 of 22 (32%) professional baseball players who underwent a labral repair returned to previous or higher level of competition.

BOX 4-1 Return to Throwing Program Summary

Criteria to Initiate Interval Throwing Program

- Full glenohumeral range of motion
- Adequate glenohumeral strength
- Adequate dynamic stabilization
- Completion of an upper extremity medicine ball plyometric progression
- Physician clearance

Definitions

- Fastball: Two seam or four seam fastball that, in which stress on the joints (glenohumeral, elbow, or wrist) involved, is minimal compared to other pitches.
- Change up: Off-speed pitch with a similar arm action to the fastball and similar stress placed across the joints of the upper extremity
- Breaking pitches: Type of off-speed pitch that places increased stress on the joints (glenohumeral, elbow, or wrist) involved. (e.g., slider, breaking ball)
- Flat ground: Pitching performed on flat ground (not mound) at a distance of 60 feet with a catcher down.
- Slope work: Initiation of throwing off the mound by gradually increasing the angle from the horizontal ground to the height of the mound.
  - Mound is 10 inches above the playing field. Starting 6 inches in front of the pitcher's rubber, the mound slopes downward to playing field at a rate of 1 inches per foot over a span of 6 feet.
  - Bullpen sessions: Throwing session completed off the mound in the bullpen at a distance of 60 feet in a controlled setting with no batter present
  - Live batting practice: Sport-specific setting with the pitcher throwing to a batter with the pitch selection predetermined.
  - Simulated game: Sport-specific setting with the pitcher throwing to a batter with the pitch selection based on a game situation.

Basic Principles

- Max number of throws at each distance per day is 25 throws
- Initiate each new distance with 15 throws
- Maximum distance is 120 feet
- Off-days from throwing are incorporated based on pathology, time off from throwing, position, muscle soreness experienced, and other individual factors
  - Early stages of an interval throwing program incorporate an alternating throwing routine.
    - Day 1: Throw
    - Day 2: Off
    - Day 3: Throw
    - Day 4 : Off
    - Day 5 Throw
  - As the interval throwing program progresses, throwing on consecutive days is incorporated.
    - Day 1: Throw
    - Day 2: Throw
    - Day 3: Off
    - Day 4: Throw
    - Day 5: Throw
    - Day 6: Off
    - Day 7: Throw
    - Day 8: Throw
    - Day 9: Throw
    - Day 10: Off
- Pitch progression (flat ground and sides)
  - Fastball → Change up→ Breaking balls
- Bullpen session progression
  - 25 Fastball → 30 Fastball/Change up → 35 All
- Game progression
  - 1 inning/25 pitches → 2 innings/35 pitches
- Incorporate a crow hop at 90 feet and beyond
- Concentrate on using proper throwing mechanics during all steps of the throwing progression
- Pitching coach should be present at all times during the interval throwing program

Criteria to Progress to Next Step

- Able to complete full throwing program with no pain or exacerbation of symptoms reported
- Able to complete throwing program with minimal muscle fatigue
- Able to complete throwing program with ball on a straight line (no "rainbows")
- No muscle soreness reported the following day.

Continued on following page

BOX 4-1 Return to Throwing Program Summary *(Continued)*

Individual Differences

- Each athlete will progress at their own rate through the interval throwing program
- Individuals may need additional days when throwing is initiated on flat ground and each time a new variable is added to the throwing program—throwing breaking balls, mound work, etc.

Warm-Up Principles Prior to Interval Throwing Program

- Increase core body temperature through any mode of cardiovascular exercise
- Static/dynamic stretching of the glenohumeral joint with emphasis on the posterior rotator cuff
- Glenohumeral joint therapeutic exercise prethrowing routine to increase local muscle temperature of involved upper extremity

BOX 4-2 Return to Throwing Program

Step 16

- Side × 35—All pitches

Step 17

- Live batting practice (BP): 1 inning/25 pitches

Step 18

- Live BP: 2 innings/40 pitches (20/20)
  - 10′ rest between sets to simulate time between innings

Step 19

- Simulated game 1 inning/25 pitches

Step 20

- Simulated game 2 innings/35 pitches (20/15)
  - 10′ rest between sets to simulate time between innings

Step 21

- Game: 2 innings/35 pitches

Phase I: Advanced Strength and Conditioning Programs

Periodization

- **Linear Model:** A model that typically separates a training program into cycles and primarily manipulates the variables of intensity and training volume. May be separated into specific cycles depending on the athlete's needs and ultimate goals.
- **Microcycles:** A model in which training periods during this phase that would last 2 to 4 weeks depending on the goals of the athlete. The actual time period would be based primarily on the athlete's pathology and time period since last throwing.
  - Within the microcycles a preparatory period would be included to prepare the athlete for an interval throwing program. Within that preparatory period a hypertrophy/strength phase in which intensity and training volume would be manipulated with the intensity at a moderate level and training volume at a high level. As the athlete progresses to the end of this phase, the intensity would increase and the training volume would decrease accordingly.

Program Design/Performance Training Program

Sport-Specific Concepts of Integrated Training

- **Flexibility/Joint Mobility for Joint Stability:** It is important to address areas of muscle tightness that can impact muscle performance and ultimately sports performance. Various approaches to improve flexibility can be used including static stretching, dynamic stretching, preparatory warm-ups, and proprioceptive neuromuscular facilitation (PNF) techniques.
- Joint mobility is an important area to address during the rehabilitation process and is essential to maintain an appropriate balance between joint stability and mobility to allow the extremity to function properly.
- Various joint mobilization methods are incorporated through each rehabilitation phase to maintain an appropriate amount of joint mobility.
- Joint stability is defined as the ability to maintain joint congruity while undergoing unconscious perturbations to allow the extremity to perform an optimal movement pattern (throwing). This can be incorporated through the use of proprioception and perturbation drills in both a closed and open kinetic chain environment. As the rehabilitation program is advanced, flexibility continues to be incorporated but is no longer of primary importance.
- **Training with Optimum Posture:** Corrective exercise to address postural faults should be emphasized in the early stages of rehabilitation and continued through the advanced phases as exercises become more complex.
- **Sensorimotor and Balance Training:** Joint mechanoreceptors responsible for sensorimotor integration are often primary impairments following labral surgery. Proprioception training incorporated in the early stages of rehabilitation is hypothesized to reestablish sensitivity of the joint mechanoreceptors and increase dynamic stabilization of the shoulder joint allowing for coordinated muscle activity during functional movements. These exercises are advanced in the remaining phases to be incorporated with functional movements. During this phase, joint repositioning drills are the primary means used to stimulate the joint mechanoreceptors while allowing the appropriate healing to occur. In addition, proprioception training (Bodyblade drills, etc.) for the uninvolved extremity has been indicated to demonstrate gains for the surgical extremity.
- **Core Training:** A training technique incorporated throughout the entire rehabilitation process and advanced as appropriate to include open or closed kinetic chain exercises. In this phase, basic core training is continued with respect to the healing structures of the glenohumeral joint. The core training movements would include glute bridge progression, bird dog progression, and static plank series.
- **Cardiorespiratory Training:** In addition to specific rehabilitation techniques to the glenohumeral joint, there are benefits to training the cardiorespiratory system.[6] Certain hormones are released by endocrine glands during this type of training that aid in the recovery process and assist in maintaining a level of fitness for the entire body. Examples of these hormones include epinephrine, released by the adrenal gland, and growth hormone, released by the pituitary gland. In this phase, basic cardiorespiratory training is included to build a base level of fitness for the athlete.
- **Multi-planar Training Exercises:** During this phase, exercises are primarily uniplanar movements to maximize strength gains for specific muscles. As the athlete progresses to the end of Phase I and into Phase II the exercises progress to multiplanar movements (see Figure 4-52).
- **Training for Optimum Muscle Balance:** Muscle balance, specific to the strength and flexibility of the agonist and antagonist muscles should be addressed in the earlier phases of rehabilitation and continue to be emphasized as the athlete is progressed to functional movements. In this phase, basic strengthening of the rotator cuff and parascapular muscles is indicated based on the strength impairments of the individual (Figure 4-45).[7] The strengthening movements indicated for each postsurgical case will vary and depend on the impairments identified by the rehab specialist. Examples of exercises that may be indicated during this phase balance include full can (Figure 4-46)[8] and SL ER (Figure 4-47).[9]
- **Training for Optimum Muscle Functional Strength:** Targeting muscles and movement patterns that closely resemble the desired movement to improve maximal force at a specific velocity. The strengthening movements during this phase are nonfunctional and designed to build basic strength based on previously identified strength impairments. Examples of exercises that may be indicated during this phase balance include full can (Figure 4-46) and SL ER (Figure 4-47).
- **Neuromuscular Dynamic Stability Exercises:** A concept that is a key component of any shoulder rehabilitation

FIGURE 4-45. Prone scapular retraction with 90° shoulder abduction with external rotation.

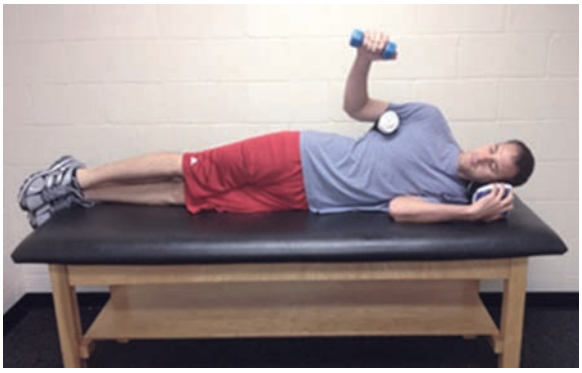

FIGURE 4-47. Side-lying external rotation exercise.

FIGURE 4-46. Standing full can exercise.

caused by the inherent instability of the glenohumeral joint. Trained by using proprioception techniques in an open or closed kinetic chain environment that challenge the joint mechanoreceptors in response to planned or unplanned perturbations of the extremity. Important to establish this type of stability in a controlled fashion during the early stages of rehab and progress as appropriate. During this phase, stability is accomplished through joint repositioning drills and incorporating manual proprioception drills as appropriate with respect to the healing tissues.

Olympic Lifts Used in the Training Program

- **Snatch:** This technique is not commonly used in the rehabilitation or training of the overheard throwing athlete caused by the stress applied to the shoulder and elbow joints. This specific lift offers little benefit and not does resemble functional movements of the overhead athlete.

TIMELINE 4-4: **Postoperative Rehabilitation After Shoulder SLAP Labral Repair**

PHASE I (weeks 1 to 4)

week 0–2

- Sling
- PT modalities
- PROM/gentle AAROM
  - Flexion to 60° (wk 2: flexion to 75°)
  - Elevation in scapular plane to 60°
  - ER/IR with arm in scapular plane
    - ER to 10°–15°
    - IR to 45°
- No active ER, extension, abduction, or elevation
- Submaximal isometrics for shoulder musculature
- Elbow/hand ROM
- Hand gripping movements
- No isolated biceps contractions

weeks 3–4

- Sling
- PT modalities
- PROM/AAROM
  - Flexion to 90°
  - Abduction to 75°–85°
  - ER in scapular plane and 35° abduction to 25°–30°
  - IR in scapular plane and 35° abduction to 55°–60°
- No active extension, abduction, or elevation
- Initiate rhythmic stabilization drills
- ER/IR tubing at 0° abduction
- Continue submaximal isometrics
- Discontinue use of sling at 4 wk

PHASE II (weeks 5 to 9)

weeks 5–6

- Continue to progress ROM
  - Flexion to 145°
  - ER at 45° abduction: 45°–50°
  - IR at 45° abduction: 55°–60°
  - At 6 wk begin light and gradual ER at 90° abduction—progress to 30°–40° ER
  - Initiate stretching exercises
  - Initiate light (easy) ROM at 90° abduction
  - ER/IR tubing at 0° abduction
  - Initiate PNF manual resistance
  - Initiate active shoulder abduction (without resistance)
  - Initiate "full can" exercise (weight of arm)
  - Initiate prone rowing, prone horizontal abduction
  - No isolated biceps contractions

weeks 7–9

- Continue to progress ROM
  - Flexion to 180°
  - ER at 90° abduction: 90°–95°
  - IR at 90° abduction: 70°–75°
- Continue all stretching exercises
- Progress rotator cuff/parascapular strengthening exercises

- **Clean and Jerk:** This technique is not commonly used with the overheard throwing athlete caused by the stress applied to the shoulder and elbow joints. This specific lift offers little benefit and not does resemble functional movements of the overhead athlete.
- **Power Clean:** This technique is not commonly used with the overheard throwing athlete caused by the stress applied to the shoulder and elbow joints. This specific lift offers little benefit and does not resemble functional movements of the overhead athlete.

Training Principles Used in the Design of the Program

- **Principle of Progression**: The ability to advance an athlete from basic movements (single joint, uniplanar, primary muscle group activation) to complex movements (multijoint, multiplane, multimuscle group involvement).
- Natural progression during the rehabilitation process is moving from simple movements to complex functional movements that mirror the throwing motion and incorporate the same muscle groups. In this phase, basic rotator cuff and scapular strengthening exercises should be used to provide a base level of strength for the athlete.
  - Example: Prone scapular retraction with shoulder abduction at 90° with an external load (cuff weight) with emphasis on controlled eccentric movement of the posterior rotator musculature (Figure 4-45). This is a single plane exercise involving multiple joints that target the primary muscles used during the throwing motion. However, this is not considered a functional movement caused by the body position and nonfunctional movement of the upper extremity.
- **Principle of Overload**: The progression of an athlete to a higher volume or intensity training session than accustomed to advance their functional status. To apply this principle appropriately, the total volume (sets, reps, resistance) must be progressed in a timely manner to maximize strength gains while avoiding the negative effects of overtraining.
- **Principle of Variation**: Each rehabilitation program should include options of exercises that target the same muscle groups to avoid stagnation or a plateau in gains. Exercises that target the primary external rotators of the rotator cuff (infraspinatus and teres minor) are of primary importance in a postsurgical overheard thrower. There are several different variations of this exercise that can be included to maximize strength gains.
  - Examples of movements that target the external rotators:
    - Prone scapular retraction with 90° shoulder abduction with external rotation (Figure 4-45).
    - Side-lying external rotation (Figure 4-47).
    - Wall slides (Figure 4-48)
  - The rehab specialist must keep in mind that each one of these movements provides differing levels of infraspintus/teres minor muscle activity and must take that into account when determining when each movement is appropriate.
- **Principle of Individualization**: Each rehabilitation program should be tailored to fit each athlete according to their specific needs. Multiple factors should be taken into account; body composition, age, position, injury history.

TIMELINE 4-4 **Postoperative Rehabilitation After Shoulder SLAP Labral Repair** (Continued)

PHASE III (weeks 10 to 14)	PHASE VI (weeks 14 to 16+)
weeks 10–12	**weeks 14–16**

• Continue to progress ROM
  • ER at 90° abduction: 110°–115°
  • IR at 90° abduction: 70°–75°
• Continue all stretching exercises
• Progress rotator cuff/parascapular strengthening exercises
• Initiate modified upper body program in weight room
	• Continue to progress ROM to functional demands of throwing
	• Progress isolated biceps strengthening
	• Progress bilateral medicine ball drills
	• Initiate unilateral medicine ball drills
	• Continue all stretching exercises
	• Progress rotator cuff/parascapular strengthening exercises

weeks 12–14	**weeks 16+**
• Continue to progress ROM to functional demands of throwing • Initiate isolated biceps strengthening • Initiate bilateral medicine ball drills • Continue all stretching exercises • Progress rotator cuff/parascapular strengthening exercises	• Initiate return to throwing program • progress through throwing program as appropriate • Mound/slope work • Live BPs/simulated games • Game competition • Continue all stretching exercises • Progress rotator cuff/parascapular strengthening exercises

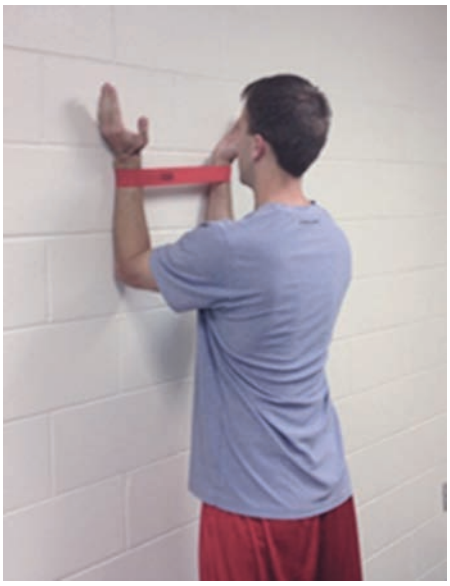

FIGURE 4-48. Wall slides exercise.

- **Principles of Specificity**: The principle of specific adaptation to imposed demands (SAID) is often used in the design of rehabilitation programs. The type of rehabilitation principles that are implemented is the driving force behind the types of adaptations that the body will undergo during the rehabilitation process.
- In this case, the movements should closely resemble the motion of throwing to retrain the primary muscles involved. This concept is primarily applied during the second phase to prepare the athlete for the interval throwing program to follow.

Application of Acute Training Variables

- **Repetitions:** Each set of a specific exercise should be 15 to 25 repetitions during this phase
- **Sets:** Each exercise should be performed for three sets during this phase
- **Rest Interval:** Primarily the fast glycolysis and oxidative energy system is used during the rehabilitation training sessions. A work to rest ratio of 1:3 is used to maximize training effects [6]
- **Intensity:** During this phase, the intensity of the rehabilitation is moderate to high
- **Training Frequency:** Strength training during this phase would be performed 3 to 4 times per week, and every other day for the principle of rest and recovery of the muscles
- **Training Duration:** An appropriate training program during this phase would be 45 to 60 minutes in duration.
- **Training Volume**: The training volume during this phase would be high to prepare the athlete for the stresses applied during throwing. At the end of this phase, the training volume would begin to decrease.
- **Exercises Specificity:** Figures 4-46 through 4-49 are examples of specific exercises that should incorporated during Phase I; however, the entire program should not be limited to these four exercises.

Phase II: Performance Enhancement Training Techniques

Periodization

- During this phase, a linear periodization model is continued to maximize the rehabilitation process. During this microcycle, the preparatory period is used to continue to prepare the athlete for an interval throwing program.
- The power phase of the microcycle is introduced to prepare the appropriate tissues for the stresses during throwing. As in the previous phase, the variables of intensity and training volume would be manipulated and an inversely proportional concept would be applied. The intensity would increase as the phase progresses with the training volume decreasing at a subsequent rate. At the end of this phase, the intensity would be at a high level with the training volume low.

Program Design/Performance Training Program

- **Core Training:** In the advanced stages of rehabilitation, integrated core training with upper extremity movements is essential to maximize the optimum rehabilitation outcome. Open or closed kinetic chain upper extremity exercises may be incorporated with basic core stability training to maximize the rehabilitation outcome.
  - Example: Performing a full can exercise on an unstable surface with an altered base of support. This incorporates a basic shoulder movement with a core stability exercise (Figure 4-50).
- **Cardiorespiratory Training:** The same basic principles apply as in the previous phase. The cardiorespiratory training will begin to become more sport-specific at this point to prepare the athlete for returning to a game-like setting.

FIGURE 4-49. Standing internal rotation exercise.

FIGURE 4-50. Physioball full can exercise.

- **Multi-Planar Training Activities:** Exercises involving multiple planes of movement are continued in this phase in preparation for throwing.
- **Training for Optimum Muscle Functional Power:** Movement patterns that closely resemble the desired movement to improve maximal force and completed in the shortest amount of time possible are introduced in this phase.
  - An upper extremity medicine ball plyometric progression is introduced during this phase to improve the power of the upper extremity. This progression is explained in more detail later in this chapter.
- **Plyometric Training:** Underused training technique in the upper extremity is an excellent progression to bridge the gap between basic rotator cuff and scapular strengthening movements to an interval throwing program. This type of training uses the stretch shortening cycle to increase the power of specific movement patterns similar to throwing.
  - Example: Bilateral medicine ball chest pass (Figure 4-51)

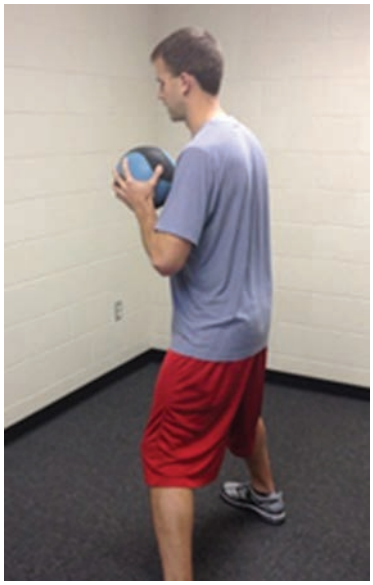

FIGURE 4-51. Bilateral medicine ball chest pass.

- **Functional Training:** Movement patterns that closely resemble the throwing motion.

Olympic Lifts Used in the Training Program

- **Snatch:** This technique is not commonly used in the rehab or training of the overheard throwing athlete caused by the stress applied to the shoulder and elbow joints. This specific lift offers little benefit and not does resemble functional movements of the overhead athlete.
- **Clean and Jerk:** This technique is not commonly used with the overheard throwing athlete caused by the stress applied to the shoulder and elbow joints. This specific lift offers little benefit and not does resemble functional movements of the overhead athlete.
- **Power Clean:** This technique is not commonly used with the overheard throwing athlete caused by the stress applied to the shoulder and elbow joints. This specific lift offers little benefit and not does resemble functional movements of the overhead athlete.

Training Principles Used in the Design of the Program

- **Principle of Progression:** The basic exercise presented in Phase I (see Figure 4-45) is progressed to a proprioceptive neuromuscular facilitation (PNF) D2 movement involving an eccentric contraction of the posterior rotator cuff using the throwing motion in a functional base of support (left half kneeling). (Figure 4-52).

Application of Acute Training Variables

- Repetitions: The repetitions of each exercise decreases to 12 to 15 for each exercise.
- Sets: Each exercise should be performed for two sets during this phase.
- Intensity: During this phase the intensity level is high
- Training frequency: Training would be performed 3 times a week during this phase.

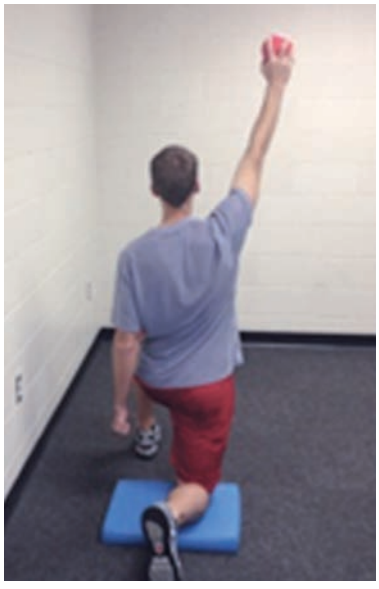

FIGURE 4-52. Left half kneeling PNF D2 eccentric medicine ball catches.

- Training duration: An appropriate training program during this phase would be 30 to 45 minutes in duration.
- Training volume: The training volume decreases compared to the previous phase.
- Specific exercises used in the training: Examples of exercises to be implanted during this phase have been presented prior to this section. These examples are intended to be examples and progressed accordingly.

Phase III: Sport-Specific Training

Program Design/Performance Training Program

- **Core Training:** In this phase, the core training continues to be integrated with shoulder exercises.
- **Cardiorespiratory Training:** This aspect of the training becomes position-specific during this phase of training.
- **Multi-planar Training Activities:** The multi-planar exercises performed in the previous two phases are now progressed to a sport-specific movement (throwing).

Sport-Specific Concepts of Integrated Training

- Training that involves a specific sport movement within a controlled environment. Examples of this training would include live batting practice and simulated games.

Olympic Lifts Used in the Training Program

- **Snatch:** This technique is not commonly used in the rehab or training of the overheard throwing athlete caused by the stress applied to the shoulder and elbow joints. This specific lift offers little benefit and not does resemble functional movements of the overhead athlete.
- **Clean and Jerk:** This technique is not commonly used with the overheard throwing athlete caused by the stress applied to the shoulder and elbow joints. This specific lift offers little benefit and not does resemble functional movements of the overhead athlete.
- **Power Clean:** This technique is not commonly used with the overheard throwing athlete caused by the stress applied to the shoulder and elbow joints. This specific lift offers little benefit and not does resemble functional movements of the overhead athlete.

Sports Performance Testing

General Information

- **General History:**
  - A through medical examination by a medical doctor should be obtained prior to the initiation of any training program.
  - A past medical history questionnaire should be filled out and reviewed with the athlete to identify family history of pathology, genetic disorders, and nutritional tendencies.
- **Subjective Questionnaires:** A variety of questionnaires are used to identify potential areas of concerns.
- **Medical History:** A previous medical history should be obtained.
- **Sports Injury History:** A previous sports injury history should be obtained.
- **Surgical History:** Surgical history of the athlete should be obtained and taken into consideration when designing a rehabilitation program.
- **Chronic Conditions/Medication:** Chronic conditions and past/current medications should be obtained.

Specific Criteria for Progression to the Next Stage to Determine Readiness for Pitching and Throwing

Objective Tests

- **Body Composition Tests:** Tests to measure body fat percentage are commonly used to assess the training effects of the entire body. Techniques used are skinfold measurements, underwater and hydrostatic weighing.
- **Movement Performance Testing:** Numerous performance-testing methods can be used to measure specific movements and functional movements. The functional movement screen (FMS) is often used as a part of the preparticipation physical assessment. Additional functional tests specific to the upper extremity are presented below.

Range of Motion (Phase I)

- The primary impairment in the early stages of rehabilitation must be normalized before addressing additional impairments. Preinjury ranges of motion measurements are obtained prior to the injury to have a baseline specific to the individual.
- The minimum goal is to obtain the preinjury range of motion and progress to normalize impairments when compared to the uninvolved extremity. Clinical research has examined glenohumeral range of motion. Specific research has focused on range of motion changes in pitchers and the effect that throwing has on it.[10,11] Additionally, range of motion and its correlation to pathology has also been studied.[12-14]

Strength (Phase II)

- The impairment that becomes the primary focus once the range of motion goals have been achieved.
- Traditionally, strength is measured using subjective manual muscle testing but this method has poor reliability and is not the preferred method from a research standpoint.[15]
- A hand-held dynamometer is a measuring device that can be used to objectively measure strength gains during the rehab progression.[16]
- Isokinetic testing can also be used as an objective measurement. This type of testing is explained in detail in the following section.

Upper Extremity Plyometric Progression (Phase II)

- To prepare the athlete for the stresses placed on the involved extremity during throwing, an upper extremity plyometric medicine ball progression is implemented. The progression for this activity would follow the model below:
  - Bilateral medicine ball concentric movements
  - Bilateral medicine ball eccentric movements
  - Bilateral medicine ball functional movements
  - Unilateral medicine ball concentric movements
  - Unilateral medicine ball eccentric movements
  - Unilateral medicine ball functional movements
- This progression should be completed over the course of several weeks taking into account the athlete's pathology, etc. The ability to complete the progression pain-free and with minimal muscle soreness following would indicate the athlete is ready to initiate an interval throwing program.

Functional Testing

- Limited clinical research exists involving upper extremity functional testing. Specific tests and outcomes are presented in the following section.
- The objective tests that are currently used are specific to the stability of the shoulder complex rather than the functional movement of throwing. Ideally, the overhead athlete would pass certain functional tests before initiating a throwing program but the lack of researched methods in this area makes it difficult. Although not specific to the overhead thrower, the following are upper extremity objective tests that can be used.
  - Isokinetic strength testing
    - Several prominent research studies have used isokinetic testing of the external and internal rotators of the shoulder to quantify muscle strength. Using this data, a ratio of 66% has been developed between the two muscle groups to indicate a minimum strength level for a healthy population. This has been studied in both baseball and non-baseball populations.[16-19]
  - Davies closed kinetic chain stability tests[20]
    - The athlete's body is placed in a push-up position with tape 36″ apart. The object is to move both hands back and from between tape marks counting each repetition completing within 15 seconds. A test retest study of this test produced a reliability coefficient of 0.927 indicating it to be highly reliable.[21] Additional testing by Rousch[22] determined reference values for this test.
    - Insert table with reference values here.
  - One arm hop test[23]
    - The athlete is placed in a unilateral push-up position with a 10.2 cm step-up box directly lateral to the involved extremity. The subject performs a one arm hop onto the step-up box and returns to the starting position. A total of five repetitions are performed with the time taken to complete recorded.

Outcome Scales used for Patient's Progression and Status

- American shoulder and elbow surgeons shoulder form (ASES). A self-administered questionnaire used to assess pain and ADL function in patients with shoulder pathology. This questionnaire is based on a 100-point scale and can be administered through the rehabilitation process to track a patient's progress.[24]
- Disabilities of the arm, shoulder, and hand (DASH). The DASH is a self-administered questionnaire to assess pain of function of the upper extremity. A 100-point scale is used in which the higher the score, the higher the disability of the patient.

Criteria to Release an Athlete to Complete Participation in Pitching without Further Supervision

- Typically following a SLAP repair, the athlete will return to throwing at approximately 4 months postsurgery. The athlete is not released to return to game competition until successful completion of an interval throwing program. Specific criteria used to progress through a throwing program is outlined in the Return to Throwing Program Summary. In addition to successfully progressing through this throwing program, the athlete must demonstrate preinjury velocity and accuracy to access if he is ready to return to game competition.

Evidence

Burkhart SS, Morgan C: SLAP lesions in the overhead athlete. *Orthop Clin North Am* 32:431–441, viii, 2001.

This study reported on a case series of 54 baseball players and their rate of return to preinjury performance level after the repair of a type II SLAP lesion. Eighty-seven percent of players were able to return to their preinjury level of throwing and 84 were able to return to their prior level of performance. (Case Series, Level IV evidence)

Gorantla K, Gill C, Wright RW: The outcome of type II SLAP repair: a systematic review. *Arthroscopy* 26:537–545, 2010.

A systematic review of the results of type II SLAP lesions in studies with a minimum of 2-year follow-up and level IV evidence or higher published in English peer-reviewed journals. This review found that the arthroscopic repair of type II SLAP tears had excellent results in individuals who did not participate in throwing or overhead sports, and those that participated in these activities had varying results. (Systemic review of Level III and IV studies, Level IV evidence)

Neri BR, ElAttrache NS, Owsley KC, et al: Outcome of type II superior labral anterior posterior repairs in elite overhead athletes: Effect of concomitant partial-thickness rotator cuff tears. *Am J Sports Med* 39:114–120, 2011.

A retrospective case series on 23 elite (college or professional) overhead athletes who had a minimum 1-year follow-up after an arthroscopic repair of type II SLAP lesions compared to a healthy cohort of athletes. Only 57 % of athletes were able

to return to their preinjury level of competition. (Cohort study, Level III evidence)

Neuman BJ, Boisvert CB, Reiter B, et al: Results of arthroscopic repair of type II superior labral anterior posterior lesions in overhead athletes: assessment of return to preinjury playing level and satisfaction. *Am J Sports Med* 39:1883–1888, 2011.

A retrospective review of 30 overhead athletes who underwent arthroscopic surgery for repair of a type II SLAP tear. Arthroscopic results based on the American Shoulder and Elbow Society (ASES) and the Kerlan-Jobe Orthopaedic Clinic shoulder and elbow (KJOC) score had excellent results, however, these scores were not reliable for throwers. (Case series, Level IV evidence)

Sayde WM, Cohen SB, Ciccotti MG, et al: Return to play after Type II superior labral anterior-posterior lesion repairs in athletes: a systematic review. *Clin Orthop Relat Res* 470:1595–1600, 2012.

A literature review of English peer reviewed journals from 1950 to 2010 reporting on 506 patients with type II SLAP repairs and a minimum of a 2-year follow-up from 14 different studies. Most individuals were able to return to their previous level of play, however overhead athletes were less likely to return to their previous level of play. (Level III evidence)

Multiple-Choice Questions

QUESTION 1. What is the key range of motion that requires special attention when returning an athlete to this sport?

A. Abduction
B. Internal rotation
C. External rotation
D. Both A and C.

QUESTION 2. What Olympic lift is NOT included in this rehabilitation?

A. Dips
B. Clean and jerk
C. Power clean
D. Snatch

QUESTION 3. What exercises should athletes continue indefinitely?

A. Biceps strength
B. Periscapular training
C. Postural exercise
D. Sleeper stretch

QUESTION 4. What are the important considerations for return to throwing?

A. Time from surgery
B. Range of motion
C. Return to full strength
D. All of the above

QUESTION 5. Athletes with SLAP tears are most commonly symptomatic during which phase of throwing?

A. Deceleration
B. Early cocking
C. Late cocking
D. Follow-through

Answer Key

QUESTION 1. Correct answer: **D** (see Introduction)

QUESTION 2. Correct answer: **A** (see Phase I)

QUESTION 3. Correct answer: **B** (see Sports Performance training)

QUESTION 4. Correct answer: **D** (see Sports Performance Testing)

QUESTION 5. Correct answer: **C** (see Introduction)

BEYOND BASIC REHABILITATION: RETURN TO VOLLEYBALL AFTER LABRAL SURGERY (SLAP REPAIR OR DEBRIDEMENT AND DECOMPRESSION OF SPINOGLENOID NOTCH CYST)

Aaron Brock, MS, ATC, CSCS, PES, Alexander K. Meininger, MD, and Sherwin S.W. Ho, MD

Introduction

- Overuse injuries of the glenohumeral joint are common in overhead athletes.
- Volleyball athletes are particularly at risk and up to 60% of intramural competitive volleyball athletes note shoulder dysfunction.[1]
- It has been estimated that a competitive volleyball athlete practices 20 hours and performs over 1000 overhead spikes weekly.
- Infraspinatus loss of strength has been shown to be up to 22% in volleyball players with suprascapular neuropathy.
- Power loss up to 40% by Cybex testing has been documented.[2]
- Thirty percent of professional male volleyball players have evidence of infraspinatus atrophy (Figure 4-53), diminished external rotation strength, or fatty infiltration.[3]
- Subclinical suprascapular neuropathy can be found in an additional 12% of volleyball athletes.[2,4,5]
- Electrophysiologic and clinical evidence of suprascapular denervation has been found in 33% to 45% of competitive volleyball players.[4,6]
- The natural history of suprascapular neuropathy in volleyball players suggests 8% fail to respond to conservative treatments.[7]
- Both conservative and surgical therapies have shown a successful return to sport.[7]
- Surgical repair of type II SLAP tears has been associated with 74% return to sport in overhead athletes.

FIGURE 4-53. A,B: Suprascapular nerve injuries showing atrophy.

- Any athlete recovering from SLAP tears or infraspinatus syndrome must undergo a phased upper extremity return to play program (UERPP).

Seven Goals of Advanced Therapy

- Progress rotator cuff strength and endurance, placing emphasis on external rotation.
- Progress scapular stabilizer strength and endurance.
- Progress dynamic stability and neuromuscular control.
- Manage and modify upper body strength and conditioning.
- Progress the kinetic chain and core training.
- Address hypertonic tissue e.g., manual therapy (myofascial release, active release technique [ART] for tightness typical of volleyball athletes: posterior rotator cuff/capsule, pectoralis minor, latissimus dorsi, upper trapezius, and levator scapulae).
- Initiate return-to-play program with appropriate technique.

Table 4-2 Exercise Ranking

Muscle	Exercise	Notes
Supraspinatus	1. Full can to 120° 2. Prone Y 3. Pushup plus (+) 4. Prone W (ER at 90°)	1. Better than empty can 2. Also good exercise for lower trap 3. Also good for serratus anterior 4. Also good for external rotators
Infraspinatus & teres minor	1. Side-lying ER 2. Standing ER at 0° 3. Prone W (ER at 90°) 4. Prone Y	1. Highest EMG activity and safe (with towel roll) 2. Allows for proper form without compensation 3. Increased capsular strain but high EMG 4. Good activation of ER group
Subscapularis	1. IR at 90° 2. IR at 0° 3. Pushup plus (+) 4. Scapular hug	1. Decreased large muscle activation compared to 0° 2. More large muscle group activation 3. Also good for serratus anterior 4. Also good for serratus anterior

Phase I: Advanced Strength and Conditioning Programs

Periodization

- SLAP rehabilitation is functionally divided into:
  - Microcycles: Progression through each phase (weekly most common)
  - Mesocycles:
    - Strengthening
    - Sport-specific exercise
    - Upper extremity return to play program
- Stepwise and undulating periodizations are both important aspects of SLAP rehabilitation.

Program Design/Performance Training Program: Advanced SLAP Therapy

Despite the many differences between sport-specific demands, goals in the early phase of any SLAP rehabilitation program is to:[8]

- Restore full range of motion
- Control pain and inflammation
- Provide maximum protection to the shoulder complex

Once the acute and intermediate phases of therapy have been successfully completed, it is time to move beyond basic rehabilitation and introduce more dynamic loads to the shoulder complex and prepare the patient's shoulder for volleyball activity. Researchers using indwelling electromyography have identified the exercises included below that maximize muscular activity in the rotator cuff and scapular stabilizers.[9-12]

Rotator Cuff Strength and Endurance[10] (Table 4-2)

- Degrees of abduction/flexion: Advanced rehabilitation begins to include exercises replicating normal patterns of motion, such as proprioceptive neuromuscular facilitation (PNF), trunk muscle activation and core strengthening. Appropriate SLAP rehabilitation focuses on those exercises exceeding 90° of abduction/flexion.
  - Scaption
  - Diagonal pulls: low resistance PNF movements such as a low-to-high cross-body pull
  - 90°/90° external rotation (ER)/internal rotation (IR)
  - Retract and rotate (Figure 4-54)
  - Bodyblade vibration core training: Two-handed Bodyblade controlled oscillations positioned at 160° of shoulder flexion
  - Wall bounces
  - Point of contact (see progress dynamic stability and improve neuromuscular control, below, for explanation)
- Resistance/reps: Undulating periodization of resistance and repetition is employed to focus on strength and endurance.
  - Increasing resistance and lower repetitions can be used to induce muscle hypertrophy and strength goals
  - Lower resistance is combined with higher repetitions to achieve endurance goals. Examples:
    - 4 × 8 to failure each set versus 3 × 30 with intense lactate burn
    - Dumbbell and pulley machines best for strength
    - Bands and body blade good for endurance
- Type of exercises: With a strength-base established, eccentric exercises can be introduced to further strengthen the deceleration (negative) component of the rotator cuff. Common exercises are:
  - 90/90 ball catches
  - Scaption ball catches
  - Wall bounces
  - Plyometric back rebounds

FIGURE 4-54. Retract and rotate/scapular punch.

- Speed: The volleyball spike requires incredibly high torque throughout the shoulder girdle. Safe introduction of fast twitch movements can begin to get the athlete comfortable with quick accelerations. Start with comfortable, short arcs of motion. Caution should be taken when getting into the fully cocked position.
  - Diagonal pulls with Thera-Band
  - Hitting pull backs: Thera-Band or SportCord
  - Exercise in the cocking phase of the volleyball spike is performed by attaching resistance to the wrist allowing the hand to be free

Rokito et al.[13] review the five phases of a volleyball spike:

- Windup: Begins with shoulder extension as the player swings the arms behind the body to create momentum and ends with flexion and abduction as the player initiates external rotation.
- Cocking: Begins with the initiation of external rotation and ends with maximal external rotation and scapular retraction.
- Acceleration: Begins with forceful internal rotation and elbow extension ending with ball impact
- Deceleration: Begins with ball impact at ~1 o'clock position and ends with arm perpendicular to the trunk as it is extended
- Follow-through: Begins with upper arm perpendicular to the trunk and ends when shoulder extension is complete.

A. Suprapsinatus

- During a volleyball spike supraspinatus activity was highest (71%) during the windup phase.[13]
- Therefore, it's important to evaluate which exercises would best activate and strengthen this muscle.

Supraspinatus activity is similar in both the empty and full can exercise; although the full can may be preferred because:

- IR does not allow the greater tuberosity to clear from under the acromion during humeral elevation, which decreases the mechanical advantage of the supraspinatus thus increasing tensile stresses to the tendon.[14] This may also create more pain and therefore a compensatory shoulder shrug.[14]
- IR creates scapular protraction or winging and anterior tilt to the scapula, decreasing the subacromial space and therefore increasing subacromial impingement.[15]

Supraspinatus strengthening exercises include:

- Prone full can (prone horizontal abduction 100° thumbs up)
- Pushup plus
- Overhead press in scapular plane
- Prone ER at 90° abduction
- Standing ER at 90° abduction
- PNF flexion/extension patterns

B. Infraspinatus (IF)/teres minor (TM)

- Infraspinatus activity approaches 60% during windup. Teres minor activity was at 39% upon windup and increased to 51% during cocking and acceleration.
- SLAP lesions are often found associated with weakness of the external rotators in overhead athletes.
- The IF is prone to be atrophied in volleyball attackers caused by suprascapular nerve injury.
- IF/TM exercises include:
  - Prone horizontal abduction at 100° with ER
  - Side-lying abduction, flexion
  - Full can
  - D1/D2 flexion patterns.

C. Subscapularis (SS)

Subscapularis activation is highest in acceleration (65%) and lowest during follow-through (16%). Simultaneous SS and IF activation during humeral elevation resists superior humeral head translation and neutralizes the IR and ER torques they generate to help enhance joint stability.[16]

The SS is highly active in several shoulder exercises:

- Pushup plus
- Scapular dynamic hugs (Figure 4-55)
- Scapular rows
- Side-lying abduction
- D2 flexion and extension patterns
- ER exercises to help stabilize the GH joint

Scapular Stabilizer Strengthening[9] (Table 4-3)

- Serratus anterior (SA)
  - SA is most active in:
    - Pushup plus
    - Dynamic hug
    - Serratus punches
  - Significant SA activity was also demonstrated with:
    - D1 and D2 diagonal pattern flexion
    - D2 diagonal pattern extension

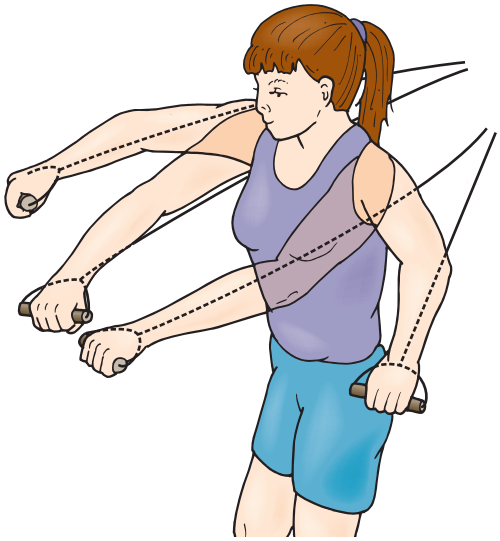

FIGURE 4-55. The dynamic hug exercise horizontally flexes the humerus at a constant 60° of humeral elevation while the hands follow an imaginary arc until maximum protraction is attained. *(Redrawn from Decker MJ, Hintermeister RA, Faber KJ, Hawkins RJ: Serratus anterior muscle activity during selected rehabilitation exercises. Am J Sports Med 27:784-791, 1999.)*

  - Supine upward scapular punch
  - IR and ER at 90° abduction, flexion.
- Trapezius muscle controls scapular upward rotation and elevation through the upper trapezius (UT), retraction by the middle trapezius (MT), and upward rotation and depression for the lower trapezius (LT).

Table 4-3 Scapular Stabilization Exercises

Muscle	Exercise	Notes
Serratus anterior	1. Pushup plus 2. Dynamic hug 3. Serratus punch at 120° 4. Scaption at 120°	1. Also good for IS and TM. 2. Performed below 90° 3. Also adds upward rotation 4. Also good for SS
Lower trapezius	1. Prone Y 2. Prone W (ER at 90°) 3. Prone T thumbup 4. ER Pull aparts	1. High EMG, also good for supraspinatus 2. High EMG, also good for IS and TM 3. Good ratio of upper lower to upper trapezius 4. Good ratio and good for IS and TM
Middle trapezius	1. Prone row 2. Prone Y 3. Prone T thumbup 4. Prone W (ER at 90°)	1. High EMG, good ratio of trapezius activation 2. High EMG 3. High EMG, good for lower trapezius 4. High EMG, also good for IS and TM
Upper trapezius	1. Shrug 2. Prone row 3. Prone T thumbup	1. High EMG 2. Good ratio for upper, middle, and lower trapezius 3. Also good for lower and middle trapezius
Rhomboids	1. Prone row 2. Prone T thumbup 3. Prone I (extension)	1. Also good for trapezius 2. Also good for trapezius 3. High EMG

  - High UT activity occurs with:
    - Shoulder shrug
    - Prone rowing
    - Prone horizontal abduction at 90° and 135°
    - D1 pattern flexion and most other exercises with humeral elevation above 120°.
  - High LT activity occurs in:
    - Prone rowing
    - Prone horizontal abduction at 90° and above
    - D2 PNF flexion and extension
    - High scapular rows, along with abduction and flexion
  - Four exercises to improve balance between typically overactive UT and typically underactive LT:[17]
    - Side-lying ER
    - Side-lying forward flexion
    - Prone horizontal abduction with ER
    - Prone extension
- Rhomboids and levator scapulae function as scapular retractors, downward rotators, and elevators. Exercises used to strengthen the RC and scapular stabilizers are also effective in strengthening the rhomboids and LS.

Progress Dynamic Stability and Improve Neuromuscular Control

- The goal of dynamic coordination of the rotator cuff and scapular stabilizers is accomplished by coactivation and force coupling between the shoulder girdle musculature.
- As the athlete's shoulder strength improves, exercises that replicate sport-specific movement patterns should be incorporated. Many of these terminal exercises may involve multijoint, multiplanar functional movement patterns.[18]

When prescribing exercises to enhance this neuromuscular control and maximize force couple action, we always consider the following:

1. Proprioceptive Neuromuscular Facilitation (PNF)/diagonal patterns. PNF has moderate support for its effectiveness in promoting functional progression.[19-21] We prefer D1 extension, D2 extension, and D2 flexion and typically avoid D1 flexion caused by impingement concerns. I also prefer manual resistance with PNF but diagonal patterns with a band or cable system are adequate alternatives.
2. Rhythmic Stabilization (RS): Reflexive muscular responses are produced via isometric contractions in various ROM. I perform RS in two volleyball specific joint positions, end cocking phase (abduction, ER) and at point of contact (POC) (~10 to 11 o'clock in scapular plane). The POC position is a loose packed position and therefore elicits less proprioceptive feedback.[22,23] Therefore focusing RS in the POC, sport-specific position may create more dynamic stability during the volleyball spike.
3. Closed kinetic chain (CKC) exercise: Upper extremity CKC or weight bearing exercises produce humeral head compression within the glenoid thereby enhancing muscular cocontraction.[24-26] The dynamic stabilizing system is even further stressed when adding RS and unstable surfaces to CKC exercises (i.e., front

planks, side planks, front hand step-ups, lateral hand step-ups, weight shifts, pushup plus (+), etc.).

Manage Upper Body Strength and Conditioning

Upper body modifications include:

Bench Press: The bench press stresses the humeral head stabilizers and long head of biceps brachii.

- Eliminate straight bar bench and use only dumbbells. Dumbbell bench press is more difficult than straight bar bench and therefore less weight is needed to get the desired effect. Dumbbells also allow for easier modification of hand spacing, grip selection, and GH motion.
- Stay narrow and keep abduction at less than 45° (keep elbows in). This minimizes peak shoulder torque and reduces cuff and biceps requirements for humeral head stabilization.[27]
- Recruit serratus anterior by adding a reach or plus (+) to the press whether it is a bench press or pushup.

Pushups: Use the same modification principles as the bench press:

- Narrow hand positioning (less than 1.5 shoulder width).
- Limit abduction by keeping the elbows in next to the trunk.
- Limit ROM (place medicine ball under the sternum).
- Recruit serratus anterior by adding a plus (+) at the end range.
- Volume of chest exercise needs to be monitored since tightness in the pectoralis muscles possibly creates an undesirable postural effect of rounded shoulders.

Shoulder press:

- Avoid barbell and use dumbbell instead.
- Begin the shoulder press with a neutral grip and in the scapular plane.
- Extra attention needs to be placed on the scapular retractors during the press
- Avoid behind the head shoulder press caused by the high five position (GH-abduction in ER) creating anterior shear stress and labral stress.
- Proceed with caution to the full overhead position where dynamic stability is challenged and impingement is likely.
- The explosive push press can be added when the athlete has completed controlled shoulder press exercises with no symptoms.

Biceps:

- The bicep needs to be protected with SLAP injuries. However, as the biceps is an important shoulder stabilizer, it should be included in a comprehensive strength-training program. Scapular retraction should be emphasized while performing biceps exercises and resistance should be mild to moderate.

Triceps:

- With concern for impingement, overhead triceps extension should not be performed. Lying triceps extensions or standing triceps pushdowns are alternatives; or add a triceps kick back to a single arm row.

Pullups:

- Chin-ups create more activate of the biceps and therefore need to be limited with SLAP recovery. Traditional pullups are less taxing to the biceps and therefore are safer.[28] Latissimus pulldowns should not be done behind the head. Instead, recline the body 30° and pull the bar to the chest just above the xiphoid process.

Power/hang cleans:

- Can possibly be stressful to the shoulder complex as the weight is "racked" after being pulled from the floor. The deceleration phase of a power clean creates an eccentric contraction of the biceps and therefore is undesirable for athletes with a SLAP lesion. It's important to use bumper plates so the athlete can drop the bar to the platform without having to decelerate the bar.[27]

Squats:

- Squats require the athlete to support the bar in the high five position which may be undesirable. Therefore, front squats may be an appropriate substitute. Front squats allow for a bar position that is much safer for injured shoulders.[27]

Kinetic Chain Involvement and Core Training

Some examples of kinetic chain exercises include:

1. Rotational squat press: Holding a plate, dumbbell or cable, squat and reach down. Then squat up and rotate while pressing the arms upward.
2. Front lunge punches: Lunge forward and punch forward or upward at the same time.
3. Lawnmowers: Squat down, reach low, and pull diagonally upward.
4. Lateral lunge punches: Squat in the frontal plane and add a diagonal or front punch.
5. Single leg cable reach and pull: begin in a single Romanian dead lift (RDL) stance reaching forward, then mid row while performing a single leg RDL movement.

Examples of core stability exercises ("train from the inside out"):[29]

1. McGill's Big 3: 1. Curl up: Lie on your back with one leg flat and one knee bent (foot flat on the floor). Curl your trunk up without flexing your cervical spine.
2. McGill's Big 3: 2. Side plank: Brace yourself on your elbow and lift your hips off the ground keeping a straight solid posture. Add weight to increase demand.
3. McGill's Big 3: 3. Bird dog: Start on hands and knees. Extend one hip while reaching (flexing) with the opposite arm.
4. Stir the pot: Assume the elbow front plank position on a physioball and rotate the ball clockwise and counterclockwise while maintaining a straight solid position.
5. Dying bugs: Lie on your back with hips and knees flexed and arms straight up to the ceiling, set your core, and extend one knee while reaching back with the opposite arm

Examples of traditional core strength exercises:

1. Hanging knee to elbows: Hang from a pullup bar and flex the hips and touch the knees to elbows with a slow return to the hanging position.
2. Weighted toe touches: Lie on your back with knees extended and hips flexed to ~45°. Set the core and perform an abdominal crunch as you touch a bar to your toes.
3. Windshield wipers: Lie on your back on the floor and hold a bar up in the beginning bench press position, then swing both legs side to side with straight knees.
4. Barbell roll outs: Assume the quadruped position and grasp a bar or an abdominal wheel. Roll the bar/wheel out in front until chest is parallel to the ground (or earlier if the low back neutral position is lost).
5. Weighted side bends: Grasp a dumbbell in one hand and hold at the side. Side bend towards the weighted side and then side bend back to the upright position.

Examples of functional core strength exercises:

1. Pallov press with rotation: Stand facing perpendicular to a cable machine grasping the handle with both hands and starting with hands touching the sternum. Extend the arms in front of the body and then rotate the trunk 90° both directions.
2. Downward chop: Split stance or kneeling facing the cable machine, reach high and grasp the handle with both hands. Pull the cable down with the abdominal muscles in a chopping motion. Swinging a sledgehammer into a tractor tire can also accomplish this.
3. Medicine ball rotational downward slam: Similar in motion to the downward chop, hold a medicine ball over the shoulder, load by rotating to that side then quickly rotate the trunk and slam the ball downward.
4. Figure-8 plates: Hold a 25-lb plate out in front of your sternum. Initiate movement with the trunk as you trace figure-8s with the plate.
5. Medicine ball tosses into wall: Stand either facing the wall or perpendicular. Initiate rotational movement as you toss the ball into the wall.

Address Hypertonic Tissue

Continue to address any hypertonic tissue typical of volleyball athletes through manual therapy, myofascial release, active release techniques (ART) and joint mobilization including posterior rotator cuff/capsule, pectoralis minor, latissimus dorsi, upper trapezius, and levator scapulae.

- Individualized therapy is critical. Each athlete's needs are determined with a thorough evaluation.
- However, Janda's upper crossed syndrome (UCS) can be found in many volleyball athletes. Rounded, protracted shoulders and a forward leaning head posture characterize this syndrome. The pattern is common in athletes working in one-dimensional training protocols and is theorized to contribute to shoulder girdle injury patterns.[17,30]
  - Dorsal: Tight upper trapezius and levator scapula.
  - Ventral: Tight pectoralis major and minor.
  - Weak Rhomboids, lower trapezius, and serratus anterior.
  - Tight scalenes, subscapularis, latissimus dorsi, and teres major.
  - Weak teres minor, infraspinatus, and posterior deltoid.
  - These muscular imbalances potentially lead to the following postural disturbances: Thoracic kyphosis, forward head posture, elevated and protracted scapulae, and rounded shoulders.
  - UCS and postural disturbances are resolved through a number of therapeutic interventions.
  - The primary goal is to restore muscle balance by lengthening the hypertonic tissue and strengthening the weakened muscles.
  - Lengthening the tight tissue is accomplished through a variety of techniques such as stretching and manual therapy. Several stretching techniques are at the therapist's disposal including static, dynamic, PNF, and post-facilitation stretching.
  - Manual therapy options include myofascial release, trigger point therapy, strain counterstrain, mobilization, manipulation, instrument assisted therapy, and more. Myofascial self release with foam rollers and STICKS are options as it is low cost and can be done by the athletes themselves.[31]
- Commercially available self-massage tools, such as TheStick, or 12″ foam rollers are often recommended, portable and commonplace among elite athletes prescribed manual therapy techniques.
  - A variety of taping techniques have been described for postural correction.
- Kinesio Tape is therapeutic elastic tape for sports injury. High-level exposure during the 2008 Olympic Games in Beijing, China lead to a resurgence of 1970s' techniques.
  - Case reports document improved function with low risk and anecdotal athlete satisfaction; despite the paucity of Level I data to support routine use of Kinesio Tape.[32-34]
- Postural clothing, such as the Intelliskin shirt, provides proprioceptive feedback and enhances scapular control in overhead athletes.[35,36] We commonly incorporate Intelliskin into the scapular rehabilitation of overhead athletes (See Bonus Exercise, Figures 4-56).
- Lastly, we routinely employ a three-part "perfect posture" exercise to encourage postural correction, enhance scapular kinematics, and avoid upper crossed syndrome in our athletes.
  - Start with the midback, head, and low back pressed into the wall, heels 6 inches from the wall, with arms at the sides.
    - Part 1 involves the head pressed into the wall without lifting the chin, scapular retraction, and arms pushing into the wall (elbow extended).
    - Part 2 involves abducting the arms to 90° and pushing the elbows into the wall (while also

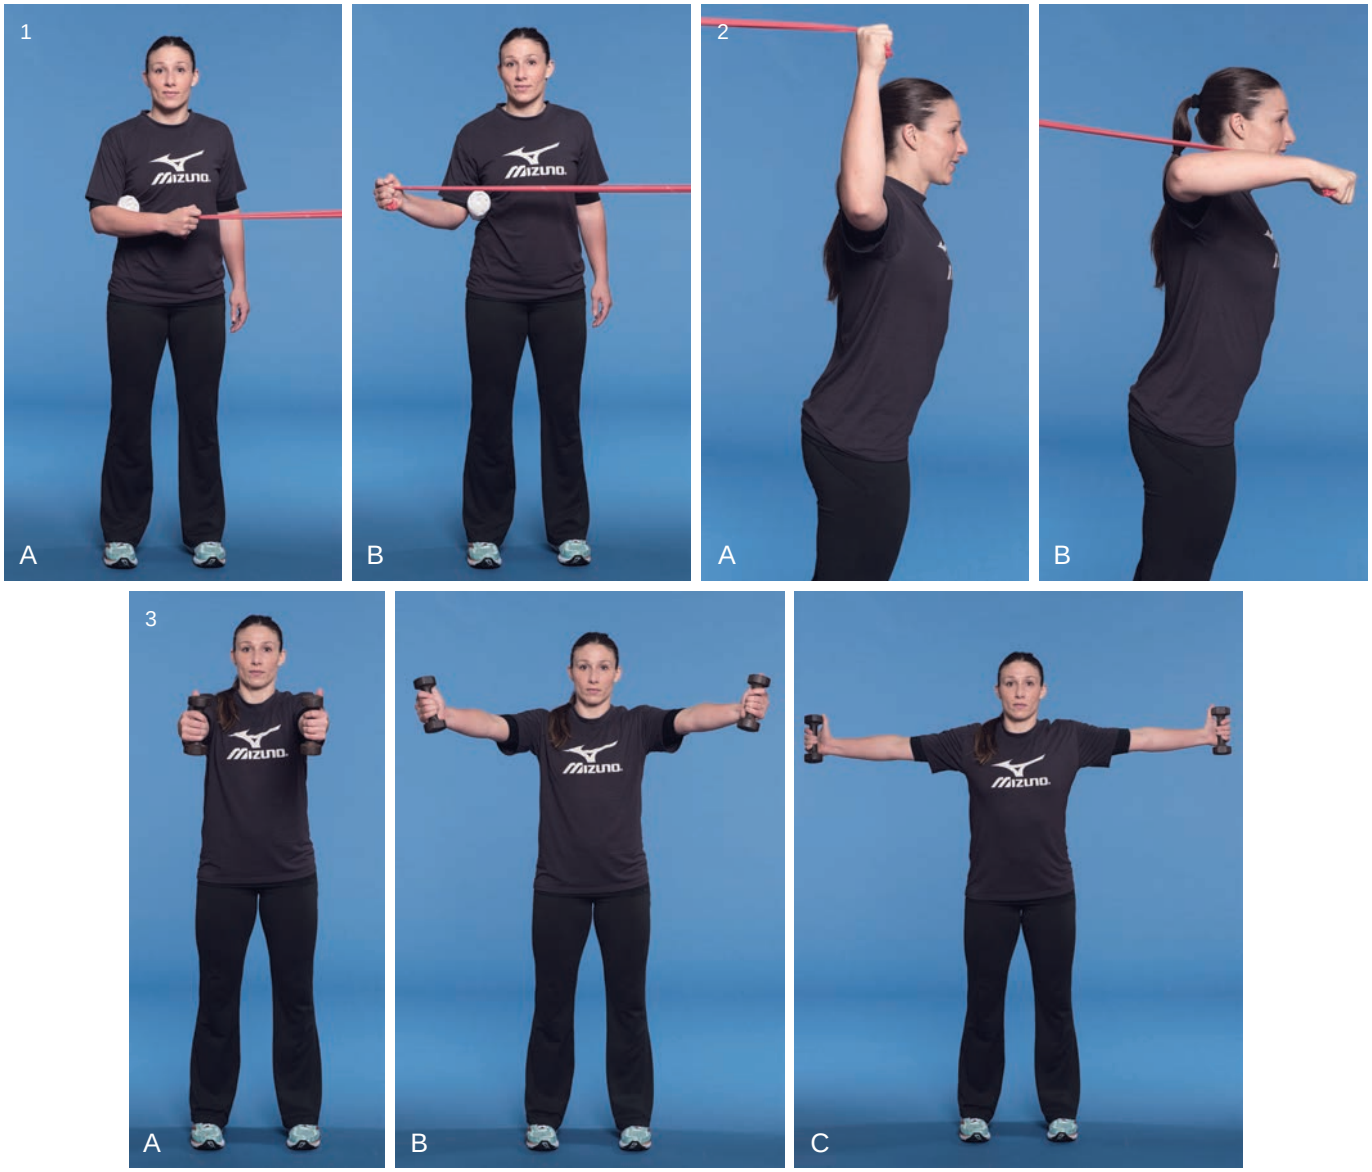

FIGURE 4-56. Hitter's Ten exercises. **Exercise 1:** External Rotation (ER) at side. Elbow bent at 90°, start in a fully internally rotated position and externally rotate with a rolled towel squeezed between the side and elbow.
Exercise 2: IR at 90. Face away from the band, elbow bent at 90°, shoulder raised to 90°, start in fully externally rotated position and internally rotate.
Exercise 3: Three-way raise. Standing with knees slightly bent, raise the dumbbell directly in front of your body, directly to the side of your body and also in between those two positions.

Continued

"setting the core" and continuing to push the back of the head into the wall).
- Part 3 progresses to external rotation and pressing the back of the hands into the wall.

Phase II: Performance Enhancement Training Techniques

Sport-Specific/Position-Specific Court Work

- Upper extremity return to play program (UERPP, Box 4-3).
- Position-specific work.
- Technique: Footwork (feet to ball), central axis rotation, hip/trunk driven spike.
- Serve receive (careful with defense—diving and quick GH flexion).
- Mental training/imagery.
- Any well-organized physical therapy plan assesses the individual and adjusts the plan accordingly.
- The Hitter's Ten (see Box 4-4, and Figures 4-56 and 4-57) is simply a guideline to appropriate exercises as determined by EMG studies and clinical experience.
- Many other valuable exercises are available to the rehabilitation specialist during each stage of the rehabilitation process but the Hitter's Ten provides safe, comprehensive, and practical options for strengthening exercises.

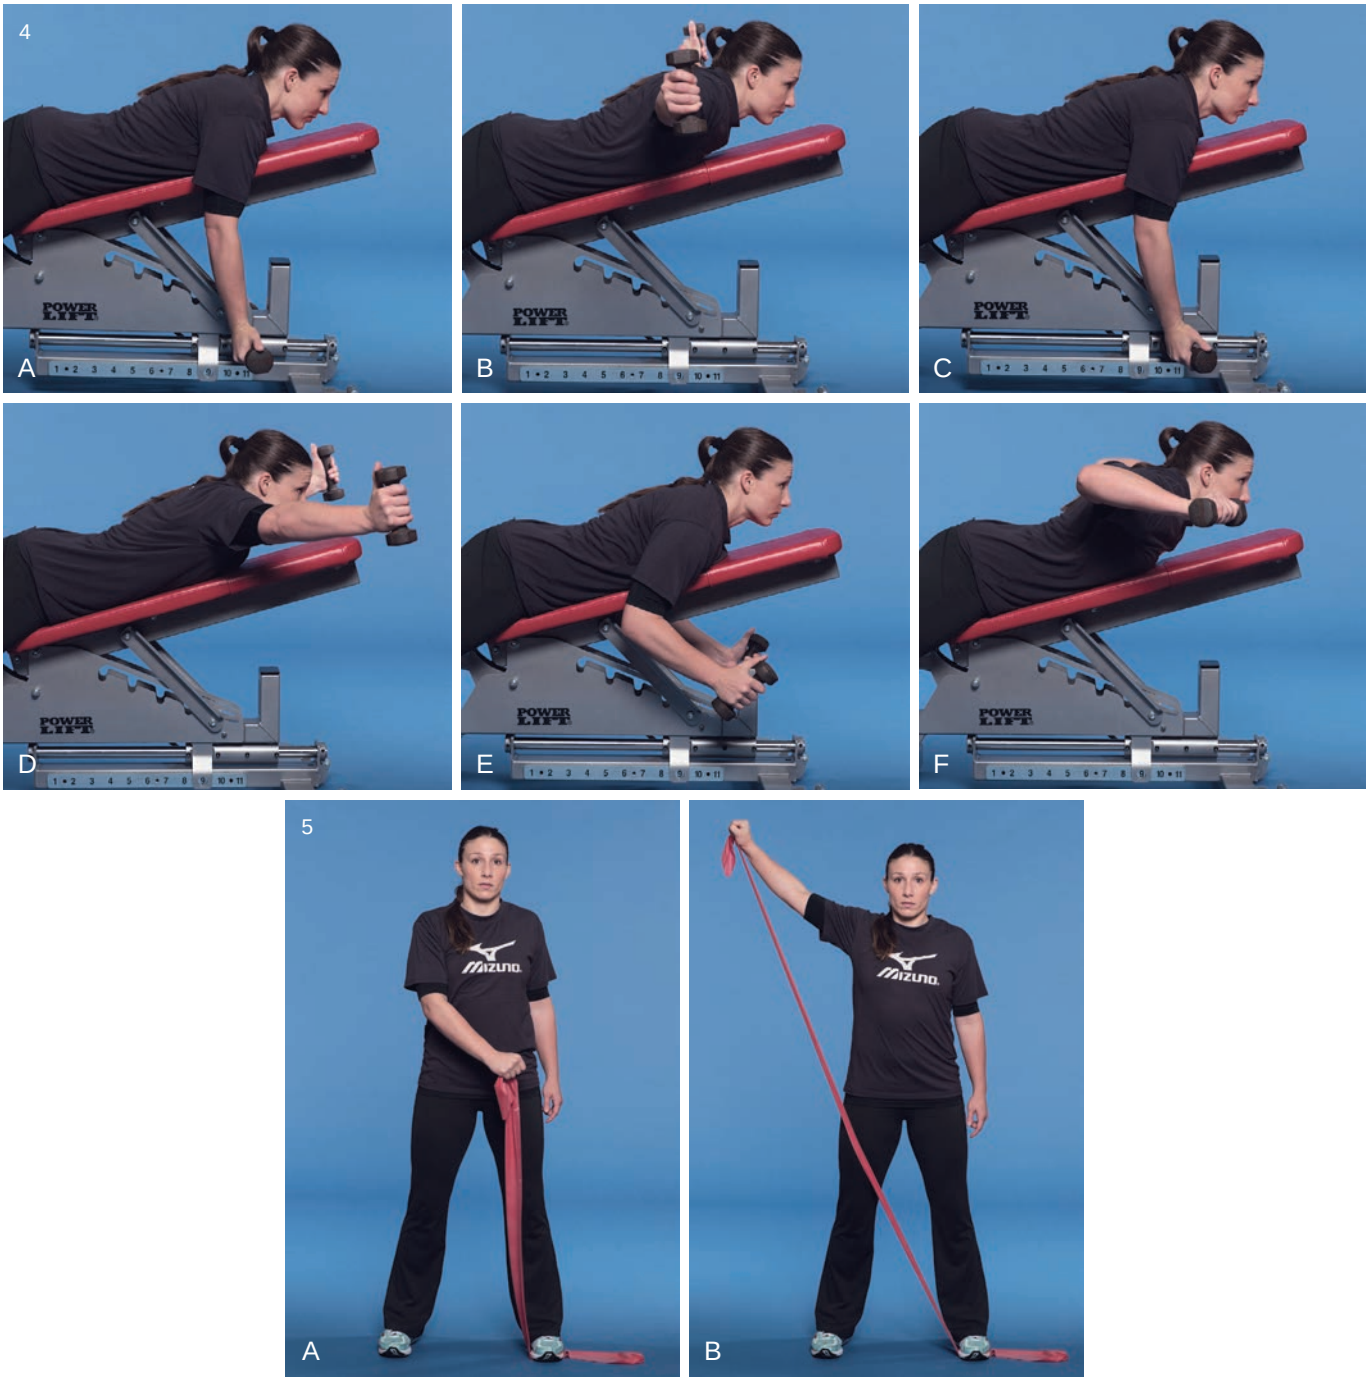

FIGURE 4-56. cont'd. Exercise 4: Three-way scap pinch on bench. Face down on slightly inclined bench, raise the arms up/pinch scaps with bent elbows (W), straight elbows (T) and in the Y position with elbows straight.
Exercise 5: Diagonal pull, low to high. Step on band with opposite foot, start with arm in front of your body and finish by pulling diagonally across your body like pulling a sword from its sheath.

Phase III: Sport-Specific Training

- UERPP provides athletes, coaches, and medical providers with specific guidelines that may facilitate a safe return to play from an upper extremity injury.
- The program is designed to induce appropriate, progressive stresses to the involved tissues thereby minimizing the risk of reinjury upon return to overhead activity.

Parameters:

- Initiation of UERPP is determined by tissue healing time and the successful completion of acute and intermediate phases of rehabilitation.
- UERPP must be accompanied by comprehensive rehabilitation and strength training programs.
- Due to individual variability, there is no set time line for progressing through the stages and ultimate completion of the program.

FIGURE 4-56. cont'd. Exercise 6: Diagonal pull, high to low (6 A, B). Anchor the band high, grasp the band with arm across your body and pull down and away from your body, ending low.
Exercise 7: Push up plus. Begin in the push-up position, keep elbows straight as you allow the scapulae to come together, then push into the ground pressing the scapulae away from each other outwardly.
Exercise 8: POC ABC (extension and flexion). Face pole, position body as if to spike, raise arm into point of contact position (where you contact the ball when spiking; ideally, 1 or 2 o'clock), and trace the ABCs in the air. Flexion is accomplished by the same technique—only facing away from the pole.
Exercise 9: Mid row. Face the band, grasp the band with elbows extended reaching out in front of you. Bend your elbows as you pull your elbows back.
Exercise 10: Pull-aparts. Grasp both ends of a short band. Pinch your scaps as you pull the ends of the band away from each other.

FIGURE 4-56. cont'd. Bonus Exercise: "Perfect posture holds." The forward head, rounded shoulders and hunched back posture places increased stress on your shoulder. Perform this exercise by standing with your back and head against the wall with your heels 6 inches away from the wall. Press your lower back into the wall, pinch your shoulder blades together, and push the back of your head into the wall. You can also raise up your arms, press your elbows into the wall, then externally rotate and press the back of your hands into the wall. Also, many of our athletes wear an Intelliskin posture shirt to help with proper positioning. *(From Brock A: Staying on the court: The complete guide to shoulder maintenance, Part I. VolleyBall USA, Anaheim, CA. Digital Issue at usavolleyball.org/mag.)*

BOX 4-3 Upper Extremity Return to Play Program

Stage 1: Advanced rehabilitation

1. Overhead rehabilitation exercises
   - Point of contact (POC) flexion, extension, stabilization
   - Bodyblade blocking
   - Wall bounces
   - Eccentric ball catches
   - Eccentric swing decelerations
   - Proprioceptive neuromuscular facilitation (PNF) past 90
2. Depending on the injury, 1 to 3 pain-free overhead rehabilitation sessions before Stage 2
3. Can perform controlled passing and setting drills

Stage 2: Remember how to swing (plus block and dig)

1. Shadow swinging
   - 15 to 20 straight on, line of approach (LOA) swings in front of mirror with no ball
   - Focus on core contraction, trunk rotation, and proper arm mechanics
2. Kneeling swinging
   - 15 to 20 swings in front of mirror with no ball
   - Focus on core contraction, trunk rotation, and proper arm mechanics
   - Possible to include the first Stage 2 workout on the same day as late Stage 1 activities
   - Increase volume to 20 to 30 swings for the second Stage 2 workout
   - Usually give day off between Stage 2 workouts
3. Resisted swinging
   - 15 to 20 swings with cord (varying intensity)
   - Focus on core contraction, trunk rotation, and proper arm mechanics
   - Induce shoulder complex fatigue
   - Increase speed of arm swing for fast twitch fiber activation
   - Can use throughout all stages as desired
     - Blocking
     - 10 to 15 controlled light roll shots into the block
     - 10 to 15 controlled 50% swing into the block
     - Digging
     - Lay prone on ground with arm outstretched
     - Start kneeling and slowly move into prone outstretched arm position x5
     - Start kneeling and quickly move into prone outstretched arm position x5

BOX 4-3 Upper Extremity Return to Play Program *(Continued)*

Stage 3: Swing with ball contact

1. 50% hitting off wall or to a partner over the net
   - Start with 15 to 20 swings (all three types of swings: cross body, wrist away, line of approach)
   - Possible to include the first Stage 3 workout on the same day as late Stage 2 activities
2. 75% hitting off wall or to a partner
   - Begin to increase the intensity and volume during the second workout in Stage 3
   - Begin to reach for a high ball contact point and make contact at 10 to 11 o'clock … not low at 9 o'clock
3. 100% hitting off wall or to a partner
   - 30 to 40 swings at progressive intensities
   - Depending on the injury, nonswinging days may need to be included for rest
   - Technique must be perfect before moving into a less controlled environment
   - Stages 2 and 3 become part of the warm up for the future stages
     - Blocking
     - 15 to 20 controlled 75% spikes into block
     - Digging
     - Defensive position controlled diving with outstretched arm x10

Stage 4: Pepper

In this routine, Player 1 and Player 2 face one another.
- Player 1 introduces the ball via a toss or hit
- Player 2 passes the ball back
- Player 1 sets the ball
- Player 2 spikes the ball
- Player 1 digs the ball
- Player 2 then sets the ball
- Player 1 spikes
- Player 2 digs, etc.

1. 50% pepper
   - Could be introduced before 100% hitting off the wall
   - Possible to include the first Stage 4 workout on the same day as late Stage 3 activities
   - Adjust body position to game simulation environment
2. 75% pepper
   - Begin to increase the intensity and volume during the second Stage 4 workout
3. 100% pepper
   - Possibly able to complete in the same day as 50% and 75% since 100% swings have already been attained while hitting off wall
     - Blocking
     - 15 to 20 controlled 100% spikes into block
     - 15 to 20 live 100% spikes into block
     - Digging
     - Defensive position diving during pepper (10 times)

Stage 5: Spike

1. 50% controlled spiking no block
   - 15 to 20 swings for first workout
   - Most likely can be introduced before 100% pepper is attained
   - Focus on footwork and hitting mechanics
   - Stay straight ahead with location
   - Stay on the left if you're an outside hitter; stay on the right if you're an opposite
2. 75% controlled spiking
   - Begin to increase the intensity and volume during the second Stage 5 workout
   - Begin to fan location with slight cross body and wrist away
   - Begin to work against a block
   - OH introduce back row and R side attack
   - The athlete should be able to participate in some controlled team drills
3. 100% controlled spiking
   - 10 to 15 reps at 100% intensity the first workout
   - Access to all the shots
   - 100% velocity
   - Continue to be disciplined on footwork and hitting mechanics
     - Blocking
     - No limitations
     - Digging
     - Diving with outstretched arm during live drills (20 times)

Continued on following page

BOX 4-3 Upper Extremity Return to Play Program *(Continued)*

Stage 6: Serve

1. 50% serving
   - Can be introduced during stage 5, especially if float serve
   - Work on controlled toss
   - 10 to 15 reps the first day
2. 75% serving
   - Begin to increase the intensity and volume during the second Stage 6 workout
3. 100% serving
   - Serving intensity is easier to control
   - Don't hit 100% if the toss isn't good
   - Focus on getting the toss out in front of the body
     - Digging
     - No limitations

Stage 7: Play Volleyball

1. 100% live competition
   - All controlled stages have been cleared
   - The chaotic nature of live play needs to be reintroduced
   - Limit the volume of live swings to 15 to 20 during first Stage 7 workout and increase volume in subsequent workouts
   - Limit the volume of live play … day ON day OFF for first week, 2 days ON 1 day OFF 2 days ON for second week, and possibly 5 days straight in third week.

BOX 4-4 Hitter's Ten Program

Part 1: Early-Stage Rehabilitation

1. Side-lying external rotation
2. Prone Y (120° to 135°of abduction)
3. Prone T (90° of abduction)
4. Prone W (bent elbow 90° of abduction)
5. Prone M (GH extension elbows straight)
6. Prone row (scapular retraction and then bent elbow row)
7. Subscapularis lift off (isolated subscapularis exercise)
8. Ceiling punch
9. Standing shoulder flexion
10. Standing shoulder full can

Note: Exercises in Part I are applicable not only to postoperative SLAP rehabilitation patients but also to maintenance therapy in the overhead athlete.

Part 2: Late-Stage Rehabilitation

1. Three-way raise
   - Abduction
   - Scaption (full can)
   - Flexion
2. Point of contact (POC) extension
3. Point of contact (POC) flexion
4. Diagonal pulls high to low
5. Diagonal pulls low to high
6. IR at 90/90
7. Retract and rotate at 90/90
8. Pushup plus (+)
9. Bent over dumbbell Ys and Ts
10. Body blade
    - Hitting
    - Blocking
    - At side IR/ER
    - Scaption

Note: Many mid/late stage exercises are not mentioned in Part 2 of the Hitter's Ten program. If a rehabilitation specialist is available, many manual exercises could be excellent options at this stage. Also, other exercises are valuable if additional equipment/devices are available. As always, a skilled clinician needs to continually assess the athlete's progress to determine what is most appropriate.

BOX 4-4 Hitter's Ten Program *(Continued)*

Part 3: Maintenance on the Court with Thera-Band Exercises
1. ER at side with bolster under arm
2. IR at side with bolster under arm
3. Mid row to overhead press
4. ER pull aparts with arms adducted, elbows bent and shoulder rotation against resistance
5. Scapular pull-aparts with shoulders forward flexed, elbows straight and scapular retraction against resistance
6. Full can exercises
7. D2 extension diagonal pattern (throwing acceleration)
8. "High/low" (alternating 135° and 45° scapular pinch)
9. Hitting pull backs
10. Dynamic bear hug

Note: Specific exercises can be added if there is access to a medical professional for assisted exercise: Manual PNF patterns, eccentric over the shoulder ball catch and rhythmic stabilization.

Part 4: Hitter's Ten: Maintenance Program
1. External rotation at side with towel roll
2. Internal rotation at 90°
3. Three-way raise: front, scaption to 120, lateral
4. Three-way scap pinch on bench: W, T, Y
5. Diagonal pull low to high
6. Diagonal pull high to low
7. Pushup plus
8. Point of contact (POC) ABCs (flexion and extension)
9. Midrow
10. Pull aparts

Bonus: Perfect posture holds.
Specific exercises can be added to these lists if there is access to a medical professional for assisted exercise: Manual PNF patterns, eccentric over the shoulder ball catch, rhythmic stabilization, etc.

- This program should be performed under supervision of the athlete's physician and rehabilitation team to ensure appropriate progression.
- General muscle stiffness or soreness is acceptable. However, if the athlete experiences sharp pain or pain at the point of injury, take 1 day off and repeat the workout or drop down to the previous stage.
- Volume, intensity, and environment need to be evaluated and monitored.

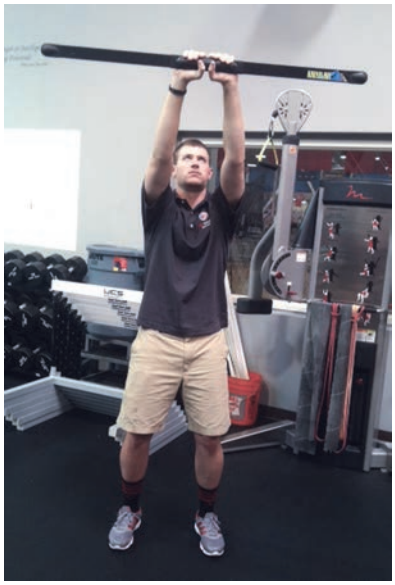

FIGURE 4-57. Blocking position with Bodyblade.

- Be creative on involving the athlete into partial practice depending on limitations.

Daily prep prior to volleyball activity: (see Box 4-5)
- Tissue warming: Heat, US, core temperature increase
- Tissue preparation: Manual therapy, self myofascial release stretches
- Shoulder activation series: Rotator cuff, scapular stabilizers, proprioception
- Full body warm up: Core temperature increases, active stretching, movement preparation, neuronal activation
- Upper extremity return to play program (see Box 4-3)

Sports Performance Testing

General Information

- General history
- Subjective questionnaires
- Medical history
- Sports injury history
- Surgical history
- Chronic conditions/medication

Specific Tests

- Static/dynamic postural assessments
- Dynamic muscle performance testing
- Movement performance testing
- Sport-specific testing

BOX 4-5 Sample Progression for SLAP Nonoperative Return to Play

Week 0-10: Acute and intermediate rehabilitation

WEEK 10:

Day 1—Stage 1 advanced rehab
Day 2—No overhead activity
Day 3—Stage 1 advanced rehab
Day 4—No overhead activity
Day 5—Stage 1 advanced rehab + early Stage 2 activity (15 shadow + 15 kneeling swings)
Day 6—No overhead activity
Day 7—Off

WEEK 11:

Day 1—Daily prep series. Mid Stage 2 workout (20 shadow + 20 kneeling swings plus 10 to 20 resisted swings). Stage 2 blocking and digging activity.
Day 2—No overhead activity
Day 3—Repeat Day 1 plus first Stage 3 workout (15 to 20 swings off the wall, up to 50% intensity)
Day 4—No overhead activity
Day 5—Repeat Day 1 plus second Stage 3 workout (20 to 30 swings up to 75% intensity)
Day 6—No overhead activity
Day 7—Off

WEEK 12:

Day 1—Daily prep series and hitting warm up (20 shadow, 10 resisted). Third Stage 3 workout (30 to 40 swings up to 100% intensity … 20 to 30 swings up to 75% plus 10 @ 100%). Stage 3 blocking and digging activity
Day 2—No overhead activity
Day 3—Repeat Day 1 plus first Stage 4 workout (~10′ 50% pepper—no diving)
Day 4—No overhead activity
Day 5—Repeat Day 1 plus second Stage 4 workout (10′ 75% pepper—no diving)
Day 6—No overhead activity
Day 7—Off

WEEK 13:

Day 1—Daily prep series and hitting warm up (20 shadow, 10 resisted, 20 swings off wall) plus third Stage 4 workout (ten 100% pepper with diving) plus first Stage 5 workout (15 to 20 spikes up to 50%) plus Stage 4 blocking and digging activity
Day 2—No overhead activity
Day 3—Daily prep series, hitting warm up, pepper plus second Stage 5 workout (20 to 25 spikes up to 75%).
Day 4—No overhead activity
Day 5—Daily prep series, hitting warm up, pepper plus third Stage 5 workout (25 to 30 spikes up to 100%) plus first Stage 6 workout (10 to 15 serves up to 50%)
Day 6—No overhead activity
Day 7—Off

WEEK 14:

Day 1—Prep, hit, pepper, spike (30 to 40 spikes up to 100%) plus second Stage 6 workout (15 to 20 serves up to 75%) plus Stage 5 blocking and digging activity. Can begin to get these spikes in a semi-controlled team drill.
Day 2—No overhead activity
Day 3—Prep, hit, pepper, warm up spike (15 to 20 spikes up to 100%) plus third Stage 6 workout (10 to 15 serves up to 100%) plus first Stage 7 workout (15 to 20 spikes in live activity)
Day 4—No overhead activity. Participate in practice but no swinging.
Day 5—Prep, hit, pepper, warm up spike plus second Stage 7 workout (20 to 25 spikes in live activity)
Day 6—Repeat day 5
Day 7—Off

WEEK 15:

Day 1—Warm up + third Stage 7 workout (1/2 of live practice activity)
Day 2—warm up + fourth Stage 7 workout (3/4 of live practice activity)
Day 3—No swinging
Day 4—Warm up + fifth Stage 7 workout (3/4 of live practice activity)
Day 5—Warm up + sixth Stage 7 workout (full practice)
Day 6—Repeat day 5
Day 7—Off

WEEK 16:

Repeat week 15

WEEK 17:

Full practice daily

. Used with permission from USA Volleyball, Anaheim, Ca

Specific Criteria for Release to Unsupervised Complete Participation in Volleyball

- Near full range of motion (80%+)
  - Scapulothoracic
  - Glenohumeral
- Strength testing
  - 4/5 minimum manual muscle testing versus contralateral extremity
- No substitution patterns
- No subjective exacerbation with increasing activity

Evidence

Shepard MF, Dugas JR, Zeng N, et al: Differences in the ultimate strength of the biceps anchor and the generation of type II superior labral anterior posterior lesions in a cadaveric model. *Am J Sports Med* 32:1197–2201, 2004.

Shepard et al. conducted a biomechanical experiment of 16 cadaveric shoulders. They found that the superior labrum and biceps anchor was significantly weaker when loaded with a posterior vector. This finding suggests that the superior labrum may be most vulnerable to injury in late cocking. (Level II evidence)

Multiple-Choice Questions

QUESTION 1. Suprascapular nerve entrapment at the spinoglenoid notch may be associated with atrophy of the:

A. Subscapularis
B. Supraspinatus
C. Infraspinatus
D. A and B
E. B and C

QUESTION 2. A 21-year-old right handed volleyball player undergoes arthroscopic repair of a right shoulder type II SLAP tear with two labral anchors in the 11 and 1 o'clock positions. Postoperative rehabilitation for this SLAP repair should include:

A. Immediate full active range of motion that simulates sport-specific activities.
B. Full-time sling wear with no active nor passive motion for at least 6 weeks until labral tissues heal.
C. Rotator cuff strengthening by postoperative week two to prevent disuse atrophy and shoulder instability.
D. Limited passive motion for 4 weeks then progressive active motion until 8 weeks followed by sport-specific strengthening until at least 12 to 16 weeks postoperatively.
E. Eccentric open-chain biceps contraction exercises beginning at postoperative week 2 to retrain the biceps muscle and stimulate SLAP healing at the biceps anchor on the glenoid.

QUESTION 3. Which one of the following rehabilitation techniques should be avoided in the patient who is 2 weeks postoperative from the surgical repair of a SLAP lesion?

A. Active assisted elevation in the scapular plane.
B. Passive forearm pronation.
C. Passive external rotation at 90° of abduction
D. Open chain passive elbow flexion
E. Passive assisted elevation in the scapular plane

QUESTION 4. Which of the following rehabilitation exercises is most appropriate immediately following the repair of a SLAP repair?

A. Passive external rotation at 90° of abduction
B. Isotonic rotator cuff strengthening
C. Isokinetic resistive elbow flexion
D. Passive and active assisted flexion in scapular plane
E. Concentric latissimus pull down exercises

QUESTION 5. The goal of sport-specific, Phase III training after SLAP repair is:

A. On-time and in-season return to competition.
B. Progresses through a generic exercise program applicable to every athlete.
C. Induces appropriate, progressive stresses to the tissue minimizing the risk of reinjury.
D. The single most important rehabilitation tool, regardless of progress through prior rehab stages.

Answer Key

QUESTION 1. Correct answer: **C** (see Introduction)

QUESTION 2. Correct answer: **D** (see Part I: Program Design).

QUESTION 3. Correct answer: **C** (see Part I: Rotator Cuff Strength)

QUESTION 4. Correct answer: **D** (see Part I: Program Design).

QUESTION 5. Correct answer: **C** (see Sport-Specific Training)

Chapter 5

Biceps Tendon Disorders

INTRODUCTION

Brian Armstrong, MPT, and Eric C. Hall, MS, ATC, CSCS

Epidemiology

- The proximal biceps tendon is a primary source of anterior shoulder pain.
- Proximal biceps tendon injuries are more often present in the older population in conjunction with rotator cuff disease, anterior impingement, or glenohumeral instability.
- Isolated proximal biceps tendon injuries are more common in patients 18 to 35 years of age involved in specific sports.
- Proximal biceps tendon injuries are more prevalent in males due to the nature of male sports and the general manual labor requirements in the working population.
- Tendon rupture is most common in males in their sixth and seventh decades of life.
- Several studies demonstrate a low incidence of isolated bicep tendon injuries.
- Primary biceps tendinitis accounts for only 5% of all biceps tendon injuries.
- The injury typically occurs in sports such as tennis, gymnastics, badminton, squash, volleyball, weight lifting, canoeing, fencing, golfing, boxing, and all sports that require repetitive overhead throwing.
- Specific positions in which the injury occurs are pitchers in baseball and softball, quarterbacks in football, javelin throwers, outside hitters in volleyball.

Pathophysiology

- The long head of the biceps tendon (LHBT) originates from the superior glenoid rim and the superior labrum. It then exits the glenohumeral joint and passes through the rotator interval, arches over the humeral head and passes through the intertubercular groove (Figure5-1).
- The proximal tendon is richly innervated with sensory nerve fibers containing substance P and calcitonin, thus a major reason for a primary source of anterior shoulder pain.
- The tendon is stabilized by a tendinoligamentous sling consisting of the coracohumeral ligament, superior glenohumeral ligament, fibers from the supraspinatus, and fibers from the subscapularis (Figure 5-2).
- Once in the bicipital groove, the tendon passes under the transverse humeral ligament. The bicipital groove will vary in depth, width, and angle of the walls. A shallow groove may be present in those with LHBT instability.
- The function of the proximal biceps tendon is not completely understood and is somewhat controversial. Neer proposed that the tendon depresses the humeral head with contraction. Andrews et al. noted that contraction of the biceps leads to compression of the glenohumeral (GH) joint. Others feel that the tendon may provide passive stability to the joint by acting as a physical block against certain motions.
- Neer first described anterior impingement syndrome where subacromial spurs were shown to cause degenerative wear on both the rotator cuff and the biceps tendon.
- Proximal biceps tendon injuries can be classified into three different categories:

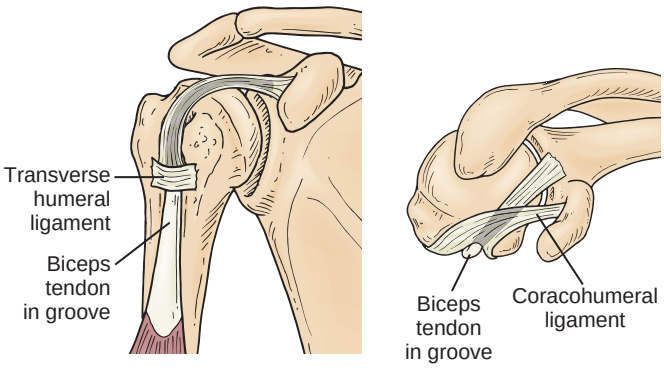

FIGURE 5-1. Anatomy of the proximal biceps tendon. *(Redrawn from Krishnan S, Hawkins R, Warren R: The shoulder and the overhead athlete, Philadelphia, 2004, Lippincott Williams & Wilkins.)*

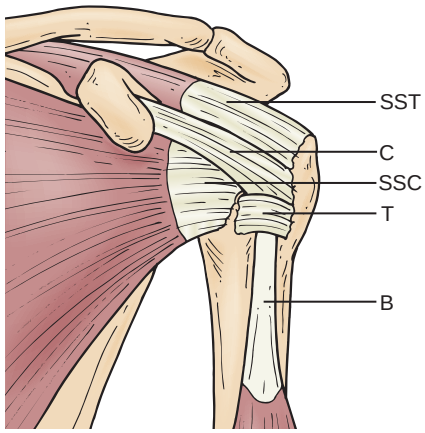

FIGURE 5-2. Anatomy of the tendinoligamentous sling. *B,* long head of biceps brachii tendon; *C,* coracohumeral ligament; *SSC,* subscapularis tendon; *SST,* supraspinatus tendon; *T,* transverse humeral ligament. *(Redrawn from Morag Y, Jacobson J, Shields G, et al: MR arthrography of rotator interval, long head of the biceps brachii, and biceps pulley of the shoulder. Radiology 235:21-30, 2005. Available at http://radiology.rsna.org/content/235/1/21.full)*

  - Tendinopathy: biceps tendinitis, tenosynovitis, and tendinosis
  - Instability: tendon dislocation and subluxation
  - Rupture: most often occurring within the bicipital groove
- Biceps tendinitis is a common diagnosis but is typically a misnomer because most athletes who are having pain typically have already gone through the inflammation stages and are now experiencing tendon sheath inflammation and tendon degeneration—a tendinosis condition.
- Tendinopathies are typically derived from overuse injuries, impingement syndromes, and glenohumeral instability.
- Instability of the biceps tendon can result from a tear in the tendinoligamentous sling, a tear in the transverse ligament, or a shallow bicipital groove.
- Ruptures of the biceps tendon typically occur with traumatic events or with an excessive eccentric load. Oftentimes a rupture follows a long course of tendon degeneration and shoulder pain. When a tendon ruptures in this way, it often results in relief of pain.

Intrinsic Factors

- Subacromial impingement
- Coracoacromial impingement
- Anterior glenohumeral instability
- Rotator cuff weakness

Extrinsic Factors

- Repetitive anterior shear stresses to the shoulder as with the pitching motion, bowling, volleyball, and the tennis swing can lead to stretching of anterior soft tissues, eventually leading to increased glenohumeral instability causing impingement of anterior structures.
- Furthermore, increased anterior translation can lead to internal impingement of the posterior rotator cuff, causing fraying of the posterior cuff fibers. Once anterior structures are stretched and posterior cuff fibers are compromised, increased loads are placed on the bicep anchor, possibly leading to a SLAP (superior labrum anterior and posterior) tear.
- The term *peel-back mechanism* is often used to describe the forces on the labrum and proximal bicep tendon with overhead throwing motion. This has been compared to the way one might pull a weed out of the ground by tugging at it in different directions.
- With throwing, a large eccentric load is placed through the bicep to decelerate elbow extension speeds of approximately 2200 degrees/second.

Traumatic Factors

- Traumatic rupture of the proximal biceps tendon is rare.
- Rupture incidents are most common in the middle-aged to older active population with underlying biceps and rotator cuff pathologies.
- Mechanisms of injury typically involve high intensity eccentric loads on the biceps muscle and tendon.
- Sports that have been found to have the most incidents of biceps tendon ruptures are gymnastics, wrestling, arm wrestling, boxing, and bodybuilding/weightlifting.

Histopathological Findings

- Systemic diseases that specifically cause deterioration of a tendon are rare.
- Foreign bodies that directly cause tendon deterioration are slightly more common, but represent less than 10% of all tendon injuries.
- Overuse injuries are typically the most frequent cause of tendon injuries.
  - Repetitive intense physical use of a tendon, specifically repetitive eccentric loads, causes continuous microtrauma and does not allow for sufficient rest and recovery between tendon use.
  - Poor circulation in and around a tendon in conjunction with increased tendon activity can lead to poor oxygenation and tendon nutrition. This explains why a more sedentary subject may be predisposed to tendon injury when participating in infrequent intense physical activity.

Clinical Presentation and Examination

History

- Normally there is no specific mechanism of injury, but some sort of repetitive overhead activity will be involved.
- Subjects with tendinopathy typically describe difficulty with warming up, a brief period of pain-free activity, increasing pain late with activity, and then stiffness and/or achiness after activity.

FIGURE 5-3. Popeye deformity. *(From From Wysocki RW, Verma NN: Distal biceps repair. In Cole BJ, Sekiya JK, editors: Surgical techniques of the shoulder, elbow, and knee in sports medicine. Philadelphia: 2008, Saunders, p. 401, with permission.)*

Physical Examination

- Tendon rupture
  - Obvious deformity, called a "Popeye" deformity. When the proximal tendon ruptures, the tendon will typically retract distally causing an obvious bulge of muscle tissue, and bruising anteriorly (Figure 5-3).
  - When a rupture occurs, most patients present with initial acute pain from the trauma of the incident, but soon after notice an overall relief of anterior shoulder pain that may have been present from chronic biceps tendon pathology.
- Tendon instability
  - Often presents with an audible or palpable "snap" in a specific arc of motion, such as with turning the steering wheel of a car or moving from an adducted and internally rotated position to an abducted and externally rotated position.
- Tendinopathy
  - Pain is typically located within the bicipital groove and sometimes radiates toward the deltoid insertion. Since most biceps tendinopathies are accompanied by impingement, glenohumeral instability, and/or rotator cuff disorders, the pain is most often diffuse over the anterior shoulder.
  - Pain is intensified with anterior impingement positions.

Abnormal Findings

- Point tenderness over the proximal biceps tendon should rotate laterally with glenohumeral ER. This technique is helpful in differentiating between other soft tissue structures that should not move with glenohumeral external rotation (ER).
- Positive special tests
  - O'Brien's active compression test
  - Speed's test
  - Yergason's test
  - Ludington's test
  - Lift-off test: test the integrity of the subscapularis
  - Jobe's relocation test: test for anterior GH instability
  - Biceps instability test.

Imaging

- Plain-film radiographs: often read as normal in the instance of proximal biceps tendinitis, but may reveal supporting evidence of anterior impingement, glenohumeral arthritis, or a shallow bicipital groove.
- Ultrasonography: cost effective and easily tolerated. Very useful in detecting abnormalities of the biceps tendon.
- Magnetic resonance imaging: a noninvasive study that is an excellent imaging modality for soft tissue structures. Sometimes used with a contrast dye (invasive) to better evaluate tissue structure.
- Arthroscopy: the best method to visually evaluate the integrity of the tendon in vivo
- Electrodiagnostic testing: In rare situations, neurological disorders may cause pain that mimics that of a biceps tendon disorder.

Differential Diagnosis

- Rotator cuff pathology: specifically with the subscapularis
  - Positive lift-off test reveals possible subscapularis injury
  - Weakness and/or pain with resisted ER/IR at 0 degrees of abduction
- Glenohumeral instability/labral pathology
  - Positive Jobe's relocation test reveals possible glenohumeral instability
  - Possible history of traumatic injury
  - Pain with repetitive activities involving extreme end ranges of motion, as with overhead throwing
- Subacromial impingement syndrome: Positive impingement tests can result in pain at the anterior shoulder.

Treatment

Nonoperative Management

- Conservative treatment
  - Rest, ice, antiinflammatory medication for evidence of an inflamed tendon
  - Once acute pain is resolved, physical therapy should be started.
    - This should involve gradual progressions of ROM exercises, scapular stabilization and movement correction exercises, progressing to posterior rotator cuff stretching and strengthening progressions, general upper body conditioning, then to sport-specific/activity-specific functional progressions.
- Steroid injections: sometimes used to facilitate the prescribed rehabilitation program
- Subacromial injections: often used to treat both primary and secondary tendinitis. Again, only used when there is evidence of tendon inflammation.

Guidelines for Choosing Among the Nonsurgical Treatment Options

- Patient is likely to be compliant with a rehabilitation program.
- Patient generally does not require repetitive overhead activity or other repetitive physical activity requiring use of the biceps. Most often middle-aged and older adults.

Surgical Indications

- Consistent pain and spasms following a consistent course of physical therapy
- Young and physically active patient requiring repetitive elbow flexion, supination, and shoulder flexion activities
- Biceps rupture patient to whom cosmetic appearance is important

Guidelines for Choosing Among the Surgical Treatment Options

- Age
- Physical activity level
- Type of physical activity
- Value of cosmetic appearance
- Compliance probability

Evidence

Ahmad C, ElAttrache N: Arthroscopic biceps tenodesis. *Orthop Clin North Am* 34:499–506, 2003.

The purpose of this article was to study the effects of an arthroscopic biceps tenodesis procedure. The authors found the tenodesis procedure has advantages over tenotomy by maintaining length-tension relationships, elbow flexion and forearm supination strength, maintenance of muscle tone, and prevention of deformity. The authors' note the type of procedures necessary will vary depending on other existing shoulder conditions and that further studies and long term follow up is needed to better evaluate the outcomes of these procedures. (Level III Evidence)

Churgay C: Diagnosis and treatment of biceps tendinitis and tendinosis. *Am Fam Physician* 80:470–476, 2009.

The purpose of this paper was to review the anatomy and physiology, and discuss different diagnosis techniques and treatment options available for biceps tendinopathies. The author concentrates on physical examination findings that help the practitioner perform a differential diagnosis along with the use of diagnostic imaging techniques. (Level V evidence)

Ejnisman B, Monteiro G, Andreolie C: Disorder of the long head of the biceps tendon. *Br J Sports Med* 44:347–354, 2010.

This paper recognizes the continuous debates on the function, diagnosis, and treatment of the long head of the biceps tendon disorders. The purpose of this paper was to review and discuss the anatomy, function, pathology, clinical manifestation, physical examination, imaging, and treatment of disorders of the long head of the biceps tendon. (Level V evidence)

Elser F, Braun S, Dewing C: Anatomy, function, injuries, and treatment of the long head of the biceps brachii tendon. *Arthroscopy* 27:581–592, 2011.

This article offers a current review of anatomy and biomechanical properties of the long head of the biceps tendon and provides an evidence-based approach to present treatment strategies for LHBT disorders. The authors suggest there is poor evidence to explain the exact role of the biceps tendon on the shoulder joint. Until the function of the LHB can be better defined, it is hard to argue cases for all types of surgical interventions. (Level V evidence)

Kelly A, Drakos M, Fealy S: Arthroscopic release of the long head of the biceps tendon. *Am J Sports Med* 33:208–213, 2005.

This study consisted of 40 patients who underwent arthroscopic release of the long head of the biceps tendon as an isolated procedure or part of a concomitant shoulder procedure and were followed for 2 years. Results revealed that 100% of patients had no pain in the biceps tendon at rest, 95% had no pain with palpation in the bicipital groove, and only 38% reported pain with fatigue and discomfort following resisted elbow flexion. Clinical relevance of this study suggests that this procedure may be an acceptable intervention for a specifically selected group of individuals. (Level II evidence)

Krupp R, Kevern M, Gaines M: Long head of the biceps tendon pain: Differential diagnosis and treatment. *J Orthop Sports Phys Ther* 39:55–70, 2009.

The purpose of this manuscript was to review the current anatomical, functional, and clinical information regarding the long head of the biceps tendon, including conservative treatment, surgical treatment, and postsurgical rehabilitation programs. Controversy exists regarding the exact function the LHBT has at the glenohumeral joint, and whether or not to perform tenotomy or tenodesis when surgical intervention is necessary. They conclude that removal of the biceps tendon is beneficial as the loss of its function on the GH joint is much less detrimental than retaining a diseased tendon. (Level V evidence)

Paynter K: Disorders of the long head of the biceps tendon. *Phys Med Rehab Clin N Am* 15:511–528, 2004.

This article reviews the anatomy, pathology, function, clinical evaluation, and treatment of disorders of the long head of the biceps tendon. They stress the importance of proper terminology of tendon disorders to improve dialogue between clinicians, which will help overall care. They suggest conservative care is often the most recommended course of treatment and is often sufficient in gaining acceptable outcomes. However, they also note when conservative care is not successful, surgical intervention is necessary for favorable outcomes. (Level V evidence)

Szabo I, Boileau P, Walch GL: The proximal biceps as a pain generator and results of tenotomy. *Sports Med Arthrosc* 16:180–186, 2008.

This article studies the role the proximal bicep tendon plays as a pain generator with rotator cuff pathologies. In their two studies, the authors found that in cases where rotator cuff repairs are not possible and/or desirable, arthroscopic biceps tenotomy and tenodesis yields favorable clinical results in the treatment of full thickness rotator cuff tears. (Level III evidence)

Multiple-Choice Questions

QUESTION 1. Which choice below is not a tendinopathy disorder?

A. Tendinitis
B. Tendinosis
C. Bicep muscle strain
D. Tenosynovitis

QUESTION 2. What are common intrinsic factors that lead to biceps tendon injuries?

A. Subacromial impingement
B. Rotator cuff weakness
C. Coracoacromial impingement
D. All of the above

QUESTION 3. Which sport below is least likely to play a role in proximal biceps tendon injury?

A. Soccer
B. Baseball
C. Boxing
D. Bowling

QUESTION 4. What is a common differential diagnosis for proximal biceps tendon injuries?

A. AC sprain
B. SLAP tear
C. Humeral stress fracture
D. Stingers

QUESTION 5. Which treatment below is often considered when conservative treatments for primary biceps tendinitis have failed?

A. Sling
B. Postural correction
C. Static stretches
D. Tendon sheath injection

Answer Key

QUESTION 1. Correct answer: **C** (see Pathophysiology)

QUESTION 2. Correct answer: **D** (see Pathophysiology)

QUESTION 3. Correct answer: **A** (see Epidemiology and Extrinsic Factors)

QUESTION 4. Correct answer: **B** (see Differential Diagnosis)

QUESTION 5. Correct answer: **D** (see Nonsurgical Treatment Options)

NONOPERATIVE REHABILITATION OF LONG HEAD OF BICEPS TENDINITIS/TENDINOSIS

Brian Armstrong, MPT, and Eric C. Hall, MS, ATC, CSCS

GUIDING PRINCIPLES OF NONOPERATIVE REHABILITATION

- Nonoperative treatment should be based on the recognition and accurate classification of the biceps pathology.[1,2,3]
- Differential diagnosis is critical to a successful outcome–tendinitis vs. tendinosis[2,4,5]
- Patient should follow an individual criterion-based rehabilitation program with attention placed on response to treatment in terms of changes in pain, swelling, or motion.[6]
- Any comprehensive rehabilitation program following biceps injury should focus on restoring dynamic stability to the shoulder.[3,6]

Phase I (Weeks 1 to 3): Acute Phase

Treatment for Pain/Swelling

- Clinical modalities as needed:
  - Disposable iontophoresis patch (Figure 5-4).[4]
  - Electrotherapy: low-frequency transcutaneous electrical nerve stimulation
  - Ultrasound (biceps tendinosis)
  - Laser
  - Phonophoresis
- Cryotherapy: ice massage
- Oral pain medications as needed
- Subacromial injection[5]
- Heat (biceps tendinosis)
- Rest
- Patient education:
  - Withdrawal from aggravating activities
  - Avoidance of reaching and lifting overhead
  - Proper posture during sitting/sleeping

FIGURE 5-4. Disposable iontophoresis patch. *(Empi Medical, St. Paul, MN).*

Techniques for Progressive Increase in Range of Motion

Manual Therapy Techniques

- Apply glenohumeral, sternoclavicular, and scapulothoracic joint mobilizations to restrictive capsular tissues (grades I/II/III).
- Manual glenohumeral joint range of motion
- Thoracic and cervical spine mobilizations/manipulations

Soft Tissue Techniques for Biceps Tendinosis

- Cross-friction massage

Stretching/Flexibility Techniques for the Musculotendinous Unit

- Rope-and-pulley
- Wand stretching, passive range of motion, flexion and external rotation (Figure 5-5)
- Posterior capsule stretching—cross-arm stretch or sleeper stretch[4]
- Self-stretches-upper trapezius, levator scapulae, and pectoralis minor stretching
- Biceps tendinitis—frequent bouts of light range-of-motion/stretching/flexibility exercises during inflammatory stage[5]

Other Therapeutic Exercises

- Leg strengthening exercises
- Low-intensity cardiovascular conditioning activities such as Stairmaster, stationary bike riding, running in the pool, elliptical (without use of upper extremity), or treadmill walking.
- Core stability exercises

Techniques to Increase Muscle Strength, Power, and Endurance

- Early scapular strengthening, scapular stabilization with emphasis on low/mid trapezius.[7]
- Modified isometrics: arm below 90° and abduction 45°[8]

Neuromuscular Dynamic Stability Exercises

- Utilize biofeedback to increase neuromuscular control of scapular musculature.[9]

Milestones for Progression to the Next Phase

- Restoration of full passive range of motion
- Restoration of normal accessary motion
- Decreased signs of inflammation: no discomfort at rest and no warmth felt upon palpation[9]
- Good tolerance of Phase I program

Phase II (Weeks 4 to 8): Subacute Phase, Active Range of Motion, Early Strengthening

Treatment for Pain/Swelling

- Cryotherapy, ice massage
- Clinical modalities as needed
- Continue activity modification, modification of aggravating activities

Techniques for Progressive Increase in Range of Motion

Manual Therapy Techniques

- Progressive glenohumeral, scapulothoracic, and sternoclavicular joint mobilizations as needed (grades II/III/IV)
- Manual glenohumeral range of motion
- Pectoralis stretching

Soft Tissue Techniques for Biceps Tendinosis

- Transverse friction massage

Stretching/Flexibility Techniques for the Musculotendinous Unit

- Active assisted to active range of motion exercises
  - Flexion, abduction, external rotation and internal rotation

TIMELINE 5-1 **Nonoperative Rehabilitation of Long Head of Biceps Tendinitis/Tendinosis**

PHASE I (weeks 1 to 3)	PHASE II (weeks 4 to 8)
• Cryotherapy: ice massage	• Cryotherapy
• Heat/cross-friction massage (biceps tendinosis)	• PT modalities
• PT modalities	• Activity modification
• Patient education about activity modification	• Progressive GH/ST/SC joint mobilizations (grade II-IV)
• GH/ST/SC joint mobilizations (grade I-III)	• AAROM exercises
• Thoracic and cervical spine mobilizations/manipulations	• Self-stretches: anterior, posterior, inferior capsule
• Active assistive Codman's exercises	• Submaximal biceps curls with dumbbells: eccentric for biceps tendinosis
• Passive ROM/wand/rope-and-pulley exercises	• TBS/TAS/TLS activities as recommended and tolerated
• Posterior capsule stretching	• Scapular exercises with PNF
• Self-stretches: upper trapezius, levator scapulae, pectoralis minor	• PNF diagonals
• Modified isometrics	• Rotator cuff strengthening: R/ER, scaption, prone I/T/Y/W
• Scapular neuromuscular control: biofeedback	

FIGURE 5-5. Wand flexion, wand ER at 0° of abduction, and wand ER in the scapular plane.

- Self-stretches for anterior, posterior, and inferior capsule
- Rhomboid and latissimus dorsi stretching

Muscle Activation of Primary Muscles Involved

- Submaximal bicep curls with dumbbells (eccentric for biceps tendinosis[4])

Techniques to Increase Muscle Strength, Power, and Endurance

- Begin rotator cuff strengthening[6,7]
  - Theraband-internal rotation and external rotation
  - Scaption
  - Prone I,T,Y,W (Figure 5-6)
- Submaximal triceps kickback
- Dumbbell forearm exercises
- Scapular protraction/retraction exercises[10]

TIMELINE 5-1 **Nonoperative Rehabilitation of Long Head of Biceps Tendinitis/Tendinosis** (Continued)

PHASE III (weeks 6 to 12)	PHASE IV (weeks 10 to 16)
• PT modalities as needed • PROM (full) • Mobilizations as needed • TBS/TAS/TLS activities as recommended and tolerated • Scapular exercises: push-up progression and prone rowing • TAS: biceps/triceps PREs • GH joint exercises: PREs • Rotator cuff exercises: isotonic dumbbell strengthening • Thrower's 10 • PNF exercises: bodyblade • OKC rhythmic stabilization exercises • CKC exercises • CKC manual perturbation exercises • Upper-body ergometer	• PROM (full) • Mobilizations as needed • TBS/TAS/TLS activities as recommended and tolerated • Initiate upper-body gym strengthening program (modified) • Scapular exercises: PREs • TAS: biceps/triceps PREs • GH joint exercises: PREs • Rotator cuff exercises: PREs • Thrower's 10: progress intensity • Plyometrics: two-arm progressing to one-arm • PNF exercises • OKC rhythmic stabilization exercises • CKC exercises • CKC manual perturbation exercises • Overhead strengthening exercises • Begin sport-specific exercises • Overhead throwing athletes can begin and progress through an interval program

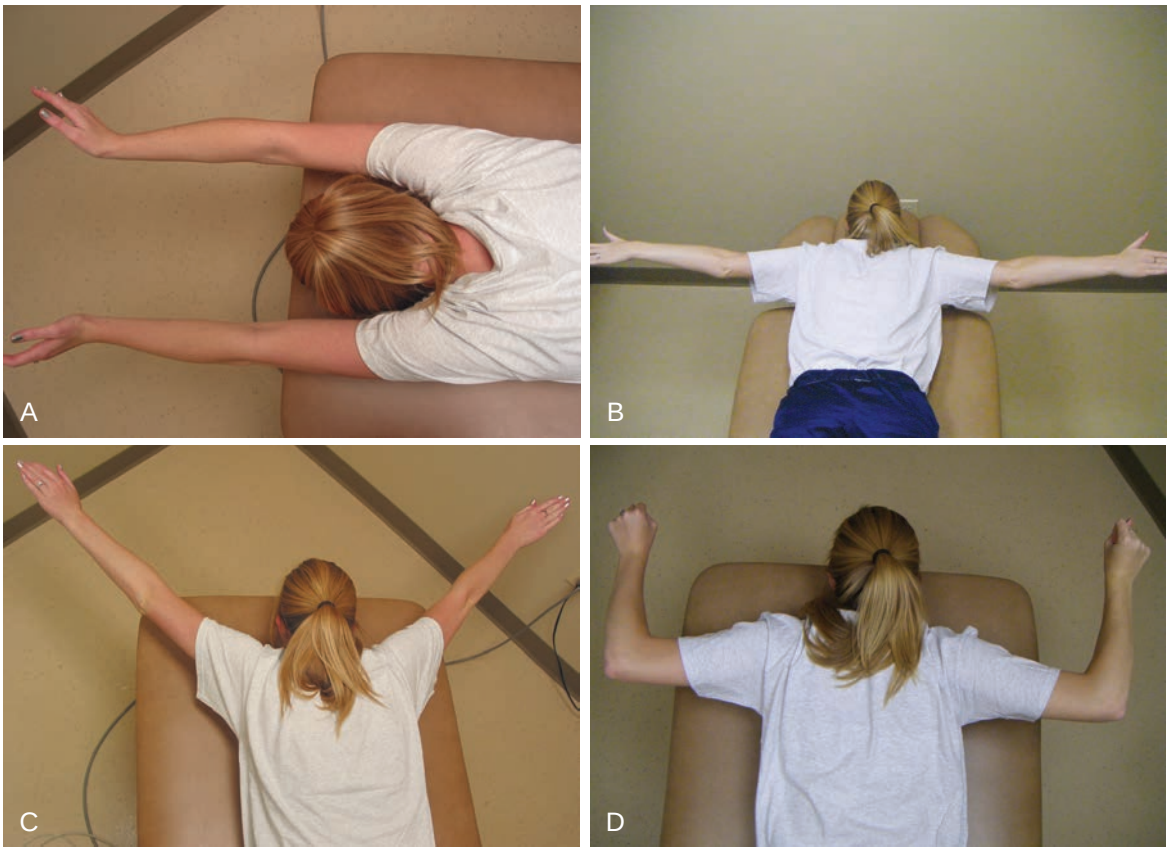

FIGURE 5-6. Prone I/T/Y/W exercise with scapular retraction.

Neuromuscular Dynamic Stability Exercises

- Initiate neuromuscular control exercises:[11]
  - Scapular stabilization with submaximal proprioceptive neuromuscular facilitation (PNF)
  - Diagonal I (DI) and diagonal II (DII) PNF pulley
  - Scapular clock (Figure 5-7)

Milestones for Progression to the Next Phase

- Restoration of normal active assisted range of motion
- No symptoms during activities of daily living
- Improved muscular performance

Phase III (Weeks 6 to 12): Progressive Exercise Stage

Treatment for Pain/Swelling

- Cryotherapy as needed

Techniques for Progressive Increase in Range of Motion

Manual Therapy Techniques

- Aggressive joint mobilizations, if needed

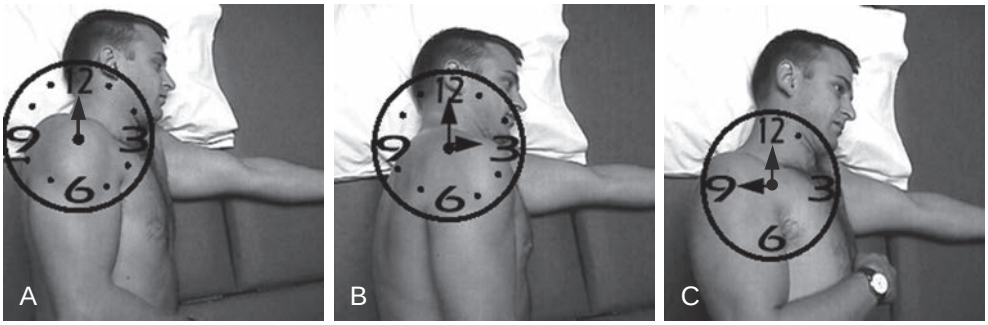

FIGURE 5-7. Scapular clock to promote neuromuscular reeducation (12 o'clock/3 o'clock/9 o'clock).

FIGURE 5-8. Rhythmic stabilizations at 90/120/60° of flexion.

Stretching/Flexibility Techniques for the Musculotendinous Unit

- Continue self-capsular stretching
- Aggressive wand ROM in all planes

Other Therapeutic Exercises

- Initiate upper body ergometer for endurance

Muscle Activation of Primary Muscles Involved in Injury Area or Surgical Structures

- Advance biceps dumbbell strengthening

Techniques to Increase Muscle Strength, Power, and Endurance

- Initiate isotonic dumbbell strengthening program[12]
  - Side-lying external rotation
  - Prone extension and horizontal abduction in external rotation
  - Standing scaption and flexion
- Scapular strength: push-up progression and rowing
- Initiate "Thrower's 10" program[5]

Neuromuscular Dynamic Stability Exercises

- Advance shoulder/scapular PNF
- Initiate shoulder and scapular rhythmic stabilizations (Figure 5-8).[4,11]
  - Isometric to dynamic
  - Slow to fast
  - Multiple direction
- Manual scapular resistance (Figure 5-9)
- Standing body blade (Figure 5-10).[11]
  - Can initiate PNF patterns

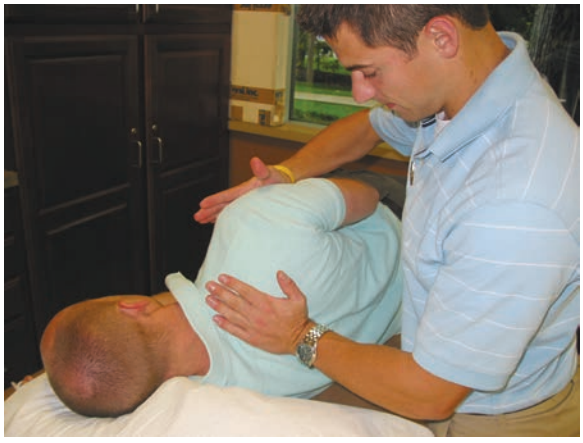

FIGURE 5-9. Manual side-lying scapular resistance.

FIGURE 5-10. Bodyblade at 90° of abduction/adduction and 90° of flexion/extension to promote neuromuscular dynamic stability.

Milestones for Progression to the Next Phase

- Full, nonpainful ROM
- No pain or tenderness
- Continued improved muscular performance

Phase IV (Weeks 10 to 16): Advanced Strengthening/Return to Activity Phase

Treatment for Pain/Swelling

- Cryotherapy as needed

Techniques for Progressive Increase in Range of Motion

Stretching/Flexibility Techniques for the Musculotendinous Unit

- Self-capsular stretching to maintain capsular mobility/ROM

Other Therapeutic Exercises

- Initiate upper body gym strengthening program (modified to avoid positions of impingement).[3,11,13]
  - Minimize overhead activities
  - Keeps hands within eyesight

Muscle Activation of Primary Muscles Involved in Injury Area or Surgical Structures

- Continued advancement of biceps strengthening

Techniques to Increase Muscle Strength, Power, and Endurance

- Advance isotonic rotator cuff dumbbell program
- Push up progression

Neuromuscular Dynamic Stability Exercises

- Advance scapular PNF exercises
- Resisted PNF patterns
- Advance rhythmic stabilization in all planes

Plyometrics

- Initiate plyometric exercises (Figure 5-11)[14]
  - Duplicate the explosive dynamics of overhead athletes
  - Progress from 2-arm to 1-arm

Sport-Specific Exercises

- Initiate Interval Functional Progression Program:[9]
  - Throwing
  - Golf
  - Tennis

Milestones for Progression to Advanced Sport-Specific Training and Conditioning

- Full, nonpainful ROM
- No pain or tenderness

FIGURE 5-11. Plyometric weighted ball toss against wall in 90/90 position.

- Satisfactory clinical exam
- Satisfactory strength evaluation (manual muscle testing and/or isokinetic testing 5% to 10% greater than nondominant side)
- Adequate dynamic stabilization and muscular endurance as measured by isokinetic testing and closed kinetic chain (CKC) functional testing for sport-specific actions to analyze muscle performance and activation characteristics

Criteria for Abandoning Nonoperative Treatment and Proceeding to Surgery or Other More Invasive Intervention

- No improvement after 3 to 6 months of a comprehensive rehabilitation program
- Plateau in recovery at an undesirable level of function

Transition to Performance Enhancement: Tips and Guidelines

Before transitioning to performance enhancement, the patient must have met criteria to return to play during the rehabilitation progression. An interval sport program that progressively applies more forces to the healing structures and gradually returns the athlete to full athletic competition as quickly and safely as possible must be completed. For sport-specific rehabilitation programs to be successful, the entire body must be reeducated in a stepwise fashion to perform the various activities related to the sport.

Performance Enhancement and Beyond Rehab: Training/Trainer and Optimization of Athletic Performance

- Maintenance program
  - Flexibility exercises, self-capsular stretches
  - Isotonic exercises, rotator cuff/total arm strengthening (TAS)
  - Theratubing exercises, IR/ER 90/90 position, D2 PNF pattern
  - Serratus pushups
- Optimize specific sport/occupational biomechanics to performance.
- Continue enhancing strength and conditioning parameters that improve power and performance related to activity.
- Need for a supervised and structured off-season, preseason, and in-season training regime.

Specific Criteria for Return to Sports Participation

- Full, nonpainful ROM
- Satisfactory clinical exam and isokinetic strength test
- Clearance from MD
- Adequate dynamic stabilization and muscular endurance as measured by isokinetic testing and sport-specific CKC testing
- Completion of interval sport program or functional progression to sport/activity

Evidence

Cohen B, Romeo A, Bach B, Jr: Shoulder injuries. In Brotzman S, Wilk K, editors: *Clinical orthopaedic rehabilitation*, ed 2, Philadelphia, 2003, Mosby, pp 125–250.

This chapter gives evidence-based rehabilitation protocols and exercise programs for various shoulder injuries. Included is the rehabilitation protocol for nonoperative management of biceps tendinitis/tendinosis. Throughout the chapter several "tricks" and "pearls" are provided to assist the clinician in the rehabilitation process.

Ellenbecker T, Cools A: Rehabilitation of shoulder impingement syndrome and rotator cuff injuries: an evidence-based review. *Br J Sports Med* 44(5):319–327, 2010.

This article presents an evidence-based review of the key treatment strategies to rehabilitate and restore shoulder function of the athlete with rotator cuff impingement and biceps tendon disorders. (Level V Evidence)

Hsu A, Ghodadra N: Biceps tenotomy versus tenodesis: A review of clinical outcomes and biomechanical results. *J Shoulder Elbow Surg* 20(2):326–332, 2011.

The purpose of this review was to analyze tenotomy vs tenodesis in incidence of cosmetic deformity and load to tendon failure for each technique. The review also provided clinical outcomes and available literature to clarify the evidence-based strength and weaknesses of each procedure to provide general guidelines for when to use each treatment. (Level III Evidence)

Krupp R, Kevern M, Gaines M, et al: Long head of the biceps tendon pain: Differential diagnosis and treatment. *J Orthop Sports Phys Ther* 39(2):55–70, 2009.

The purpose of this manuscript was to review current evidence-based anatomical, functional, and clinical information regarding the long head of biceps tendon, including conservative treatment, surgical treatment, and postsurgical rehabilitation regimens. (Level V evidence)

Ott J, William C, Wilk K: Soft tissue injuries of the shoulder. In Wilk K, Reinold M, Andrews J, editors: *The athlete's shoulder*, ed 2, Philadelphia PA, 2009, Elsevier, pp 283–292.

The purpose of this chapter was to provide the latest evidence-based research regarding soft tissue injuries about the shoulder, including information regarding biceps tendon injuries. An evidence-based nonoperative rehabilitation approach is given based on the diagnosis of biceps tendinitis or tendinosis.

Reinold M, Escamilla R, Wilk K: Current concepts in the scientific and clinical rationale behind exercises for glenohumeral and scapulothoracic musculature. *J Orthop Sports Phys Ther* 39(2):105–117, 2009.

The purpose of this extensive review was to provide the clinician with a thorough overview of the available literature relevant to develop a safe, effective, and appropriate exercise program for injury rehabilitation and prevention of the glenohumeral and scapulothoracic joints. (Level V evidence)

Ryu J, Pedowitz R: Rehabilitation of biceps tendon disorders in athletes. *Clin Sports Med* 29:229–246, 2010.

This article focuses on nonsurgical rehabilitation and postoperative rehabilitation of biceps tendon injuries. The article provides a review of the function, anatomy, and pathology of the biceps. Evidence-based research is provided in guiding a patient though a comprehensive rehabilitation program. (Level V Evidence)

Swanik KA, Lephart SM, Swanik CB, et al: The effects of shoulder plyometric training on proprioception and selected muscle performance characteristics. *J Shoulder Elbow Surg* 11:579–586, 2002.

The purpose of this study was to determine the effect of plyometric training of the shoulder internal rotators on proprioception, kinesthesia, and selected muscle performance characteristics in female swimmers. This study suggests that plyometric activities may facilitate neural adaptations that enhance proprioception, kinesthesia, and muscle performance characteristics. Significant neuromuscular benefits may be attained if they are implemented earlier into shoulder rehabilitation programs. (Level III evidence)

Multiple-Choice Questions

QUESTION 1. During what phase of rehabilitation do you begin active assisted/active range of motion exercises?

A. Phase I
B. Phase II
C. Phase III
D. Phase IV

QUESTION 2. What must be achieved for progression to Phase IV?

A. Full, nonpainful ROM
B. No, pain or tenderness
C. Satisfactory clinical exam
D. All the above

QUESTION 3. When treating biceps tendinosis during what phase of rehabilitation is it appropriate to begin cross-friction massage?

A. Phase I
B. Phase II
C. Phase III
D. Phase IV

QUESTION 4. Which exercise would be inappropriate to perform upper extremity strengthening in the gym during phase IV rehabilitation?

A. Eccentric bicep curls
B. Triceps kick backs
C. Military bench press
D. Scaption

QUESTION 5. During what phase of rehabilitation would it be appropriate to initiate the upper body ergometer for endurance?

A. Phase I
B. Phase II
C. Phase III
D. Phase IV

Answer Key

QUESTION 1. Correct answer: **B** (see Phase II Rehabilitation)

QUESTION 2. Correct answer: **B** (see Phase III Rehabilitation)

QUESTION 3. Correct answer: **A** (see Phase I rehabilitation)

QUESTION 4. Correct answer: **C** (see Phase IV rehabilitation)

QUESTION 5. Correct answer: **C** (see Phase III Rehabilitation)

POSTOPERATIVE REHABILITATION AFTER BICEPS TENOTOMY AND TENODESIS

Brian Armstrong, MPT, Eric C. Hall, MS, ATC, CSCS, and Peter Sallay, MD

Indications for Surgical Treatment

- Failure of nonoperative management for 3 to 6 months that included rest, rehabilitation, antiinflammatory medication, and/or cortisone injection failure[1]
- Failed adequate shoulder decompression and continues to have pure shoulder pain consistent with biceps tendinitis[2-6]
- Significant chronic long head of biceps dysfunction along it length or from its labral attachment[7]
- Cosmetic: patient does not accept "Popeye deformity"
- Indication for biceps tenodesis: greater than 25% to 50% partial-thickness tear of tendon, subluxation, disruption of the bicipital groove or soft tissue stabilizers, chronic atrophy of the tendon[4,8-10]

Brief Summary of Surgical Technique

Major Surgical Steps

- A posterior portal is used for visualization, and routine diagnostic arthroscopic examination is performed. An anterolateral working portal is used for instrumentation (Figure 5-12).
- Biceps tenotomy is performed by sectioning the tendon at its origin at the supraglenoid tubercle and superior labrum. The tendon is allowed to retract out of the glenohumeral joint.[6,11-15]
  - An associated acromioplasty can be performed in patients with an anterior acromial spur.
  - The superior labrum and biceps stump are then examined for further lesions.
  - Unstable flaps at the superior stump that could potentially cause mechanical irritation are debrided with an arthroscopic shaver.
- Biceps tenodesis may be performed open or arthroscopically with interference screw fixation to bone, keyhole fixation to bone, suture anchor fixation, and suture fixation to adjacent tissue.[3,16-22]
  - The biceps proximal attachment on the superior labrum is released. The residual stump on the superior labrum is debrided to a stable and smooth margin.
  - The open method involves a unicortical hole placed approximately 1 cm distal to the proximal aspect of the bicipital groove created in the floor of the groove. The biceps tendon is then inserted into the newly created hole. An interference screw is the inserted and secured until it is flush with the humeral cortex.[17]
    - A similar technique can be done using an interference screw system (Biotenodesis Screw, Arthrex, Naples, FL).[21]
  - A mini-open incision/arthroscopic procedure can be done in the deltopectoral interval by splitting the deltoid. The tendon is released arthroscopically and retrieved at the entry point into the joint. A locking stitch is placed in the free end after excising the intraarticular portion. The anchor is then seated, and the attached sutures are used to secure the biceps tendon. The free ends of the locking suture are then used to reinforce the tenodesis by sewing to the rotator interval capsule or to the tissue overlying the bicipital groove.[17]
    - A soft tissue tenodesis can be performed in the same manner as an anchor technique. The tendon is secured using the locking suture but without anchoring it to bone.[20]
  - When performed arthroscopically a unicortical hole is placed in the proximal portion of the bicipital groove and the transected end of the biceps tendon is inserted into the newly created hole. A screw is introduced and secured until it is flush with the bottom of the groove.[18,19]

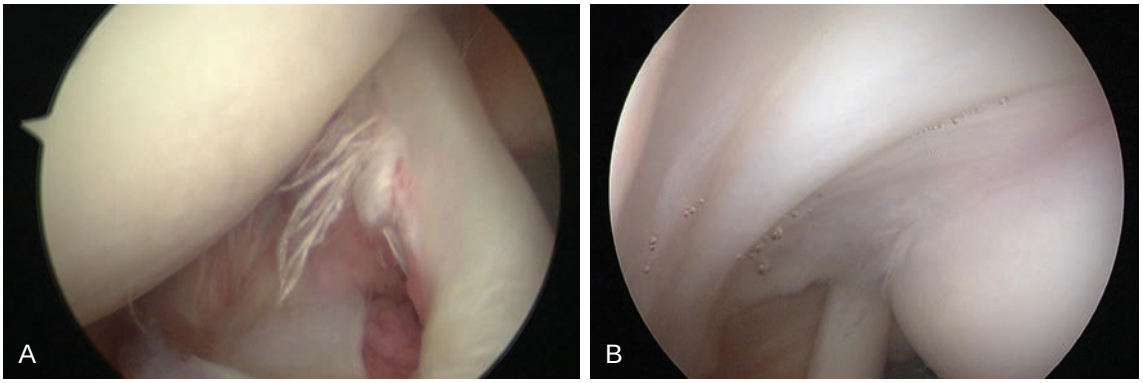

FIGURE 5-12. A, A posterior portal is used for visualization, and routine diagnostic arthroscopic examination is performed. **B,** An anterolateral working portal is used for instrumentation.

- The purpose of this procedure is to anchor the biceps tendon at a new location so that complete rupture and its consequences, that is, deformity and weakness, can be prevented.
- With all of these procedures, it is critical to obtain the correct length-tension relationship of the LHBT to preserve strength, function, and cosmesis.

Factors That May Affect Rehabilitation

- Biceps tenotomy is commonly used in older, low-demand individuals or in those who are unable to comply with immediate postoperative restrictions.
- Advantages of tenotomy are:
  - Technical simplicity
  - Shorter and less complex rehabilitation time
  - Accelerated return to daily activities
- Biceps tenodesis is appropriate in young, athletic, active individuals.
- In relation to tenotomy, the advantages of tenodesis include
  - Minimal to no loss of elbow flexion and supination strength
  - Less risk of postoperative cramping
  - No associated "Popeye" deformity
- Disadvantages include
  - More complex operation
  - A period of postoperative immobilization
  - Lengthier rehabilitation
  - Possible wound problems and rare chance of nerve injury

Other Surgical Techniques and Options

- Arthroscopic debridement of the biceps long head tendon
  - Suggested for partial tears, including delamination and fraying that involves less than 25% of the tendon in young, active patients or less than 50% of the tendon in older, sedentary patients[2,10]
  - Can begin an aggressive rehabilitation program during the first postoperative week
  - Usually accompanied by a decompression of subacromial soft tissue alone in younger patients
- Subacromial decompression
  - May be done arthroscopically or open to address tendinopathy of the biceps secondary to "impingement syndrome."[23,24]
  - Rehabilitation is advanced as rapidly as pain and swelling/inflammation allow
- Type II and IV superior labrum from anterior to posterior (SLAP) tears[2,25-27]
  - Type II SLAP tears have a detached biceps anchor and therefore require stabilization.
  - Type IV SLAP tears include a bucket-handle portion of the labrum that extends into the biceps tendon.
    - If the tendon is not too degenerative and the tear involves less than 30% to 40% of the tendon anchor, the tendon can be simply debrided and the superior labrum either debrided or reattached, provided the flap is large enough.
    - Although controversial and no clear tendon tear size exists for tendon repair, if more than 40% of the tendon is involved, a side-to-side repair is performed along with treatment of the labrum.

TIMELINE 5-2 **Postoperative Rehabilitation After Biceps Tenotomy/Tenodesis**

PHASE I (weeks 0 to 2)	PHASE II (weeks 2 to 6)
• Sling (biceps tenotomy patients will wear for discomfort and be weaned off as symptoms decrease) • PT modalities: IFC stim and TENS • PROM exercises in all planes for shoulder with elbow slightly bent/elbow/forearm • Active assistive Codman's exercises • Cryotherapy • Seated scapular retractions • Cervical ROM exercises • Gripping exercises	• Sling (d/c use as tolerated) • PT modalities: IFC and TENS as needed • Cryotherapy for pain and inflammation • Progress shoulder PROM to AAROM to AROM exercises in all planes as tolerated • Lawn chair progression/wand exercises/table slides in flexion/pulley flexion and scaption/wall climb • Begin posterior capsule stretching as needed: side-lying IR stretch and cross-body adduction stretch • Active elbow flexion and extension • Active forearm supination/pronation • Submaximal isometrics with arm at side • Scapular exercises: prone row/active punches (protraction/retraction)

- In cases in which the biceps origin is more significantly damaged of if there is a great deal of degeneration of the tendon, biceps tenodesis or tenotomy offers a better option to direct repair.
- Postoperative rehabilitation following SLAP repair is determined by the type of SLAP lesion, the surgical procedure performed (debridement vs. repair), and other concomitant pathology.[27]
  - Generally, the patient's shoulder is immobilized for a period of time, followed by emphasis on restoring motion and, lastly, initiating strengthening exercises.
  - In cases in which the biceps is resected, biceps muscular contractions typically begin between 6 and 8 weeks postoperative.
  - In cases in which the biceps is repaired, no resisted biceps activities are allowed for at least 3 months following surgery.

Phase I (first 14 days): Immediate Postoperative Period[1]

Goals

- Decrease pain and inflammation.
- Achieve gradual restoration of passive range of motion (PROM).
- Allow healing of soft tissue.
- Prevent negative effects of immobilization (biceps tenodesis).
- Enhance scapular function.

[1]*The pre-habilitation outline is included in the nonoperative treatment section of this chapter.*

Clinical Pearl

During Phase I rehabilitation there are differences in the management of biceps tenotomy compared with tenodesis; therefore patient education is critical. Biceps tenotomy rehabilitation is more aggressive and advances at a quicker pace, whereas rehabilitation following biceps tenodesis progresses more slowly to protect the biceps tendon. The patient must be instructed on several behavioral and activity modifications to help protect the repair and ensure an optimal outcome.

Protection

- Sling for 2 to 4 weeks (removed two to three times per day in order to perform exercises).
- Sling must be worn during sleep.
- Biceps tenotomy patients will use sling just for discomfort and wean off as symptoms decrease.
- Avoid shoulder extension beyond the plane of the body; sleep with towel under elbow.
- No excessive external rotation (ER) range of motion (ROM) stretching.
- No shoulder active range of motion (AROM), lifting of objects, and active or active assistive biceps contraction.
- Limit terminal motion.

TIMELINE 5-2 Postoperative Rehabilitation After Biceps Tenotomy/Tenodesis (Continued)

PHASE III (weeks 6 to 10)	PHASE IV	
	(weeks 10 to 14)	(weeks 14 to 24)
• D/C sling • PT modalities as needed • Cryotherapy as needed • PROM/AROM exercises (full for shoulder/elbow/forearm) • Mobilizations as needed • Focus on incorporation of the entire kinetic chain (lower extremity/trunk/shoulder) • Scapular exercises: PREs • TAS: begin biceps/triceps/forearm supination/pronation PREs starting with very light resistance • GH joint exercises: PREs (high repetition-low resistance) • Rotator cuff exercises: PREs • PNF exercises • OKC rhythmic stabilization exercises (Bodyblade) • CKC exercises • CKC manual perturbation exercises	• PT modalities as needed • PROM/AROM (full, nonpainful) • Mobilizations as needed • TBS/TAS/TLS activities as recommended and tolerated • Scapular exercises: PREs • TAS: biceps/triceps PREs • GH joint exercises: PREs • Rotator cuff exercises: PREs • Thrower's 10 • PNF exercises • OKC rhythmic stabilization exercises • CKC exercises • CKC manual perturbation exercises • Plyometrics: two-arm progressing to one-arm • Initiate upper extremity weightlifting program (emphasize large muscle groups) • Begin sport-specific exercises • Overhead athletes can begin interval throwing progression • Nonathletes can initiate endurance program	• PROM (maintain full motion) • Mobilizations as needed • TBS/TAS/TLS activities as recommended and tolerated • Scapular exercises: PREs • TAS: biceps/triceps PREs • GH joint exercises: PREs • Rotator cuff exercises: PREs • Thrower's 10 progress intensity • PNF exercises • OKC rhythmic stabilization exercises • CKC exercises • CKC manual perturbation exercises • Plyometrics: two-arm progressing to one-arm 90/90 plyos • Overhead strengthening exercises • Sport-specific exercises progressed • Overhead throwing athletes complete an interval throwing program • Return to sport

Management of Pain and Swelling

- Cryotherapy
- Use of home transcutaneous electrical nerve stimulation (TENS) unit
- Oral pain medications
- Therapeutic modalities: electrotherapy stimulation, TENS
- Patient education: using pillows and bolsters to find a position of comfort to reduce stress on repaired structures of the shoulder
- Manual therapy treatments to decrease spasms

Techniques for Progressive Increase in Range of Motion

Manual Therapy Techniques

- Glenohumeral, sternoclavicular, and scapulothoracic mobilizations as indicated
- Begin manual shoulder PROM in all planes to tolerance.

Stretching and Flexibility Techniques for the Musculotendinous Unit

- Codman's pendulum exercise
- PROM elbow flexion/extension and forearm supination/pronation
- AROM wrist/hand
- Cervical ROM
- Shoulder PROM in all planes with elbow slightly bent

Activation of Primary Muscles Involved in Injury Area or Surgical Structures

- Shoulder shrugs with elbow bent
- Gripping (ball squeezes)

Neuromuscular Dynamic Stability Exercises

- Scapular PNF techniques
- Scapular retraction and clock exercises with elbow bent

Milestones for Progression to the Next Phase

- Appropriate healing of surgical incision
- 80% PROM (full PROM for biceps tenotomy) of shoulder and elbow compared to non-involved side
- No increase in pain/swelling after treatments
- Completion of Phase I activities without pain

Phase II (weeks 2 to 6 postop)

Goals

- Minimize shoulder pain and inflammatory response.
- Gain full PROM of shoulder.
- Achieve gradual restoration of AROM.
- Wean off of the sling by the end of postoperative weeks 2 to 4.
- Increase activity tolerance and work-related tasks.

Clinical Pearl

A key rehabilitation exercise used during Phase II is the lawn chair progression. This rehabilitation exercise allows transitioning from supine PROM/active assisted range of motion (AAROM)/AROM to a more functional AROM exercise sitting upright. If any upper trapezius activation is taking place, side-lying shoulder flexion is a good alternative exercise. Once side-lying shoulder flexion is achieved correctly, the lawn chair progression should be initiated.[28]

Protection

- Discontinue use of sling as tolerated.
- Continue patient education: posture, joint protection, positioning, activity/behavioral modification.

Management of Pain and Swelling

- Continued cryotherapy for pain and inflammation
- Oral pain medications as needed.
- Electrotherapy (TENS and IFC) as needed

Techniques for Progressive Increase in Range of Motion

Manual Therapy Techniques

- Manual PROM in all planes to patient tolerance with emphasis on obtaining full PROM
- Glenohumeral, sternoclavicular, and scapulothoracic joint mobilizations as needed

Soft Tissue Techniques

- Scar massage if necessary

Stretching and Flexibility Techniques for the Musculotendinous Unit

Progress shoulder PROM to AAROM and AROM in all planes to patient tolerance—wand exercises, table slides in flexion, pulley flexion/scaption, wall climb

- Lawn chair progression for shoulder (Figure 5-13)
- Begin incorporating posterior capsule stretching as needed—side-lying internal rotation stretch (sleeper stretch) and cross-body adduction stretch (Figure 5-14)
- May begin light lower extremity strengthening
- Core stability exercises

Activation of Primary Muscles Involved in Injury Area or Surgical Structures

- Active elbow flexion/extension and forearm supination/pronation—full ROM allowed

Techniques to Increase Muscle Strength, Power, and Endurance

- Submaximal isometrics with the arm at the side for rotator cuff or deltoid strengthening (Figure 5-15)
- Manual scapular resistive exercises—scapular protraction, retraction, and depression in side lying with a towel roll or pillow between arm and body [29]

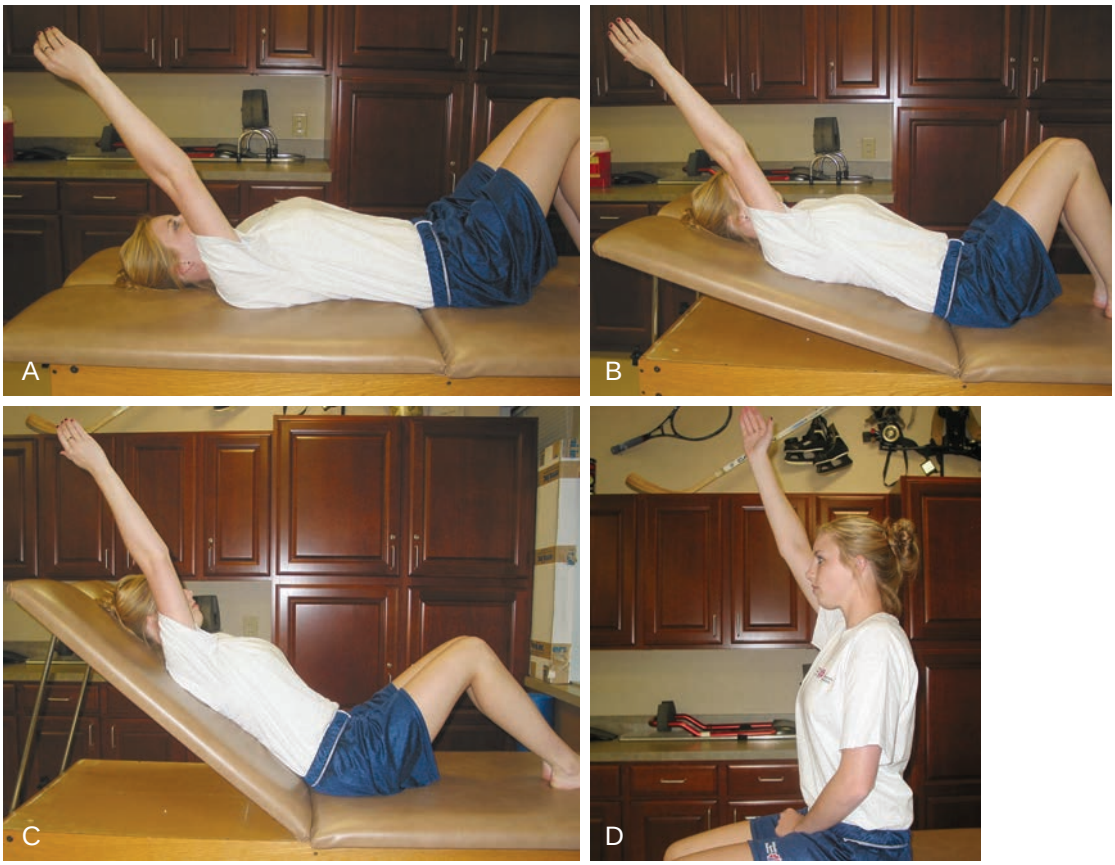

FIGURE 5-13. Lawn chair range of motion exercise progression from supine to sitting.

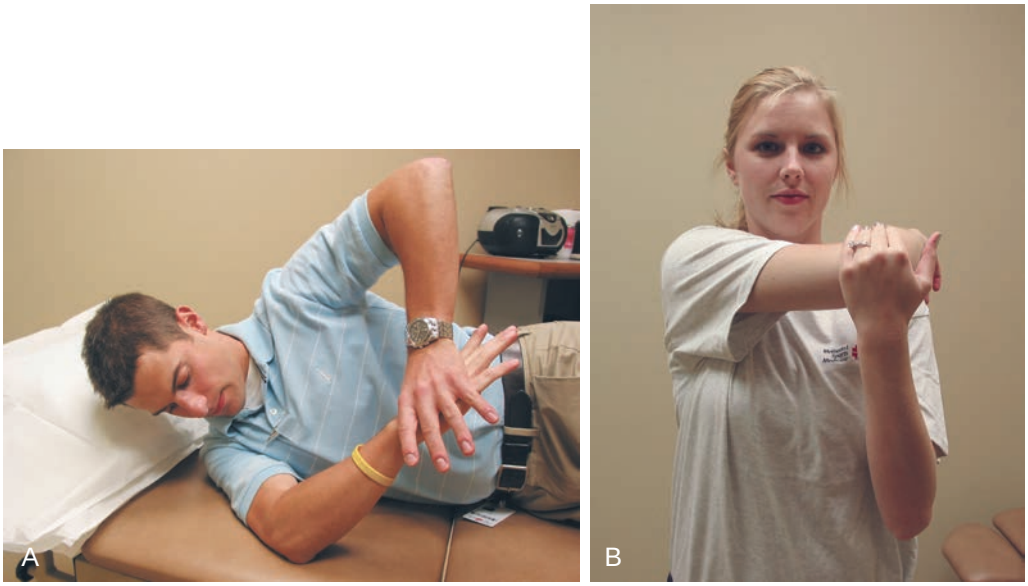

FIGURE 5-14. Sleeper stretch done in scapular plane (**A**) and in cross-body adduction (**B**) for posterior capsule stretching. Cross-body adduction can be done in a door frame to control scapular positioning.

FIGURE 5-15. Submaximal isometric flexion (**A**), abduction (**B**), internal rotation (**C**), and external rotation (**D**) with arm against side.

- Active punches—scapular protraction and retraction[30]
- Prone row and extension by side

Neuromuscular Dynamic Stability Exercises

- Advance scapular PNF exercises
- Rhythmic stabilizations, ER/IR with arm supported, 90° of flexion

Milestones for Progression to the Next Phase

- Restore full AROM of shoulder and elbow
- Appropriate scapular posture at rest and scapulohumeral rhythm with ROM and functional activities
- Completion of Phase II activities without pain

Phase III (weeks 6 to 10 postop)

Goals

- Increase strength, endurance, and neuromuscular control
- Normalize arthrokinematics

Clinical Pearl

Proprioception and neuromuscular re-education exercises are important during Phase III to counteract the inhibitory effects that pain and inflammation have on the rotator cuff and scapular stabilizers. Neuromuscular re-education exercises should include multijoint and multiplanar endurance exercises. Proper scapular stabilization will provide a stable base for glenohumeral joint movement, as well as maintain optimal length-tension relationships for the rotator cuff muscles.[29-33]

Management of Pain and Swelling

- Continued cryotherapy for pain and inflammation as needed

Techniques for Progressive Increase in Range of Motion

Manual Therapy Techniques

- Continue PROM and glenohumeral, sternoclavicular, and scapulothoracic mobilizations if needed.

Stretching and Flexibility Techniques for the Musculotendinous Unit

- Continue A/PROM of shoulder and elbow as needed/indicated.

Other Therapeutic Exercises

- Strengthening exercises should focus on incorporation of the entire kinetic chain, including coordinated lower extremity, trunk, and shoulder movements in multiple planes.[31,34]

Activation of Primary Muscles Involved in Injury Area or Surgical Structures

- Initiate biceps curls with light resistance, progress as tolerated.
- Initiate resisted supination/pronation.[35]

Techniques to Increase Muscle Strength, Power, and Endurance

- Gain muscular endurance with high repetition (30 to 40) and low resistance (1 to 3 lb).
- Initiate standing Thera-Band strengthening exercises—ER/IR with towel between arm and body, extension and rows to the plane of the body.
- Initiate resisted side-lying ER with towel roll—weighted and manual resistance (light).
- Progress prone rotator cuff strengthening program—progress prone horizontal abduction from palm down to thumb up. Prone rowing at 30/45/90 degrees of abduction to neutral arm position.[34]
- Isotonic active flexion/scaption/abduction/D2 to standing when able to perform without shoulder hiking. Limit flexion/scaption/abduction to 90° and make sure thumb is up to avoid impingement.[34,36]
- Push-up plus exercise with emphasis on serratus (wall, counter, knees on floor, floor)
- Initiate Throwers 10 Program for overhead athletes.

Neuromuscular Dynamic Stability Exercises

- Body blade rhythmic stabilization exercises at varying shoulder/elbow positions
- Rhythmic stabilizations—ER/IR in the scapular plane and flexion/extension/abduction/adduction at various angles of elevation

Milestones for Progression to the Next Phase

- Full nonpainful ROM
- Good scapulohumeral rhythm
- Appropriate rotator cuff and scapular muscular performance (4/5 or better)
- Completion of Phase III activities with minimal pain

Phase IV (weeks 10 to 14 postop)

Goals

- Improve muscular strength, endurance, power, and stability
- Optimize neuromuscular control and dynamic shoulder stability
- Initiate interval or functional progressions to return to sport
- Initiate functional activities and gradually return to full functional activity
- Athletes—return to previous level of sport participation

Clinical Pearl

> The increased risk for impingement outweighs the potential benefits of heavy resistance strengthening exercises in positions above 90° of elevation or long lever arms. Exercises with longer level arms and exercises above 90° arm elevation are used for muscle endurance and neuromuscular re-education only.[28,31,32]

Management of Pain and Swelling

- Cryotherapy as needed

Techniques for Progressive Increase in Range of Motion

Manual Therapy Techniques

- Glenohumeral and scapulothoracic mobilizations as needed

Stretching and Flexibility Techniques for the Musculotendinous Unit

- Continue P/AROM of shoulder/elbow as needed.

Other Therapeutic Exercises

- Progressive return to upper extremity weight lifting program emphasizing the larger, primary upper extremity muscles (deltoid, latissimus dorsi, pectoralis major).

Activation of Primary Muscles Involved in Injury Area or Surgical Structures

- Advance biceps/supination strengthening as tolerated.

Techniques to Increase Muscle Strength, Power, and Endurance

- Progress previous strengthening program—continue to increase resistance with isotonics if patient does not

demonstrate compensatory strategies, is not painful, and has no residual soreness.
- Focus exercises on eccentric strengthening of posterior rotator cuff and scapular muscles.[34]
- Nonathletes initiate endurance program that simulates desired work activities/requirements.

Plyometrics

- Plyometric exercises should be chosen individually for each athlete based on sport-specific demands.
- Plyometric exercises are advance from two-arm, short-lever-arm activities below 90° of arm elevation to single-arm long-lever-arm activities above 90° of elevation.[37]

Sport-Specific Exercises

- Initiate appropriate interval throwing, pitching, tennis, and golf program as appropriate.

Criteria for Return to Sport

General

- Clearance from treating surgeon
- No complaints of pain
- Isokinetic test that fulfills criteria to throw: minimum of 90% (side-to-side) symmetry on isokinetic testing and ER/IR ratio of at least 70%
- Normal ROM, strength, and endurance of rotator cuff and scapular musculature as compared with hand-held dynamotor and/or isokinetic test in comparison with noninvolved upper extremity
- Compliance with continued home exercise program
- Successful completion of functional progression back to sport specifics—interval throwing/pitching, tennis, and golf programs.

Overhead Throwing

- Need to have normal scapulothoracic and glenohumeral mechanics with full AROM.
- Minimum of 90% (side-to-side) symmetry on isokinetic testing and ER/IR ratio at least 70%
- Completion of functional interval throwing program specific to player's position (see The Methodist Sports Medicine Center's Functional Throwing Progression and Functional Mound Progression protocols in Boxes 5-1 and 5-2).

Golf

- Golfer needs to have full, nonpainful shoulder range of motion, a satisfactory clinical examination, normal strength measures for the rotator cuff and scapular musculature, and appropriate progression with rehabilitation program.

BOX 5-1 The Methodist Sports Medicine Center Functional Throwing Progression

The purpose of the throwing progression is to gradually allow the athlete to increase the intensity of throwing while minimizing the chance for a re-occurrence of injury. The athlete must follow the intensity and number of throws closely to help prevent the chance for re-injury and to properly condition the arm and the entire body. The athlete can progress from one level to the next as long as no pain occurs and proper throwing mechanics can be maintained throughout the phase. If pain occurs or if there's a breakdown of throwing mechanics, then the progression should be backed off, and then resumed as able.

Before throwing, the athlete must partake in an appropriate warmup routine. This should consist of whole body movements that will increase the heart rate and increase blood flow. Light stretching before throwing is optional. The athlete should start throwing at the shorter distances and work their way up to the workout distance. When at 75 ft and further, a step and throw technique should be used to help incorporate the lower body. Following throwing, the athlete should perform any strengthening and stretching exercises as prescribed, along with optional ice application.

A. 30-Foot Phase: Perform 3x Week at a Light Intensity

WEEK 1	WEEK 2
Warmup 15 throws at 30 feet Perform strengthening and stretching Ice	Warmup 25 throws at 30 feet Perform strengthening and stretching Ice

B. 45-Foot Phase: Perform 3x Week at a Light Intensity

WEEK 3	WEEK 4
Warmup 15 throws at 30 feet 15 throws at 45 feet Perform strengthening and stretching Ice	Warmup 15 throws at 30 feet 15 throws at 45 feet Rest 5 minutes 10 throws at 30 feet 10 throws at 45 feet Perform strengthening and stretching Ice

BOX 5-1 The Methodist Sports Medicine Center Functional Throwing Progression *(Continued)*

C. 60-Foot Phase: Perform 3x Week at a Light to Medium Intensity

WEEK 5	WEEK 6
Warmup 15 throws at 30 feet 15 throws at 45 feet 10 throws at 60 feet Perform strengthening and stretching Ice	Warmup 15 throws at 30 feet 10 throws at 45 feet 10 throws at 60 feet Rest 5 minutes 10 throws at 30 feet 10 throws at 45 feet 10 throws at 60 feet Perform strengthening and stretching Ice

D. 75-Foot Phase: Perform 3x Week at a Medium Intensity

WEEK 7	WEEK 8
Warmup 15 to 20 throws 30 to 60 feet 15 throws at 60 feet 10 throws at 75 feet Perform strengthening and stretching Ice	Warmup 15 to 20 throws at 30 to 60 feet 10 throws at 60 feet 10 throws at 75 feet Rest 5 minutes Warmup throwing (15 throws 30 to 60 feet) 10 throws at 60 feet 10 throws at 75 feet Perform strengthening and stretching

E. 90-Foot Phase: Perform 3x Week at a Medium to High Intensity

WEEK 9	WEEK 10
Warmup 10 throws at 30 to 45 feet 10 throws at 45 feet 10 throws at 60 feet 10 throws at 75 feet 10 throws at 90 feet Perform strengthening and stretching	Warmup 10 throws at 30 to 45 feet 10 throws at 45 to 60 feet 10 throws at 60 to 75 feet 10 throws at 75 feet 10 throws at 90 feet Rest 5 minutes 10 throws at 30 to 45 feet 10 throws at 45 to 60 feet 10 throws at 60 to 75 feet 10 throws at 75 to 90 feet 10 throws at 90 feet Perform strengthening and stretching

F. 110-Foot Phase: Perform 3x Week at a High Intensity

WEEK 11	WEEK 12
Warmup 15 throws at 30 to 60 feet 10 throws at 60 to 75 feet 10 throws at 75 to 90 feet 10 throws at 90 feet 15 throws at 110 feet	Warmup 15 throws at 30 to 60 feet 10 throws at 60 to 75 feet 10 throws at 75 to 90 feet 10 throws at 90 to 100 feet 20 throws at 110 feet

G. 120-Foot Phase: Perform 3x Week at a High Intensity

WEEK 13	WEEK 14
Warmup 20 throws at 30 to 75 feet 10 throws at 75 to 90 feet 10 throws at 90 to 110 feet 10 throws at 110 to 120 feet 10 throws at 120 feet Perform strengthening and stretching	Warmup 20 throws at 30 to 75 feet 10 throws at 75 to 90 feet 10 throws at 90 to 110 feet 15 throws at 110 feet 20 throws at 120 feet Perform strengthening and stretching

BOX 5-2 The Methodist Sports Medicine Center Functional Mound Progression

The purpose of the mound progression is to gradually allow the athlete to increase the intensity of throwing while minimizing the chance for a re-occurrence of injury. The flat ground phase is used to help the athlete work on mechanics, different pitch types, and to regain confidence before throwing off the mound. All major mechanical flaws should be corrected before moving to the mound. Before throwing, the athlete must partake in an appropriate warmup routine. Light stretching before throwing is optional. The warmup step for each phase will differ from person to person. For some this may consist of long toss, for others this may be throwing to 100 feet, then coming back in to 60 feet. Follow the prescribed number of throws closely because this is designed to help increase strength and endurance. All throwing with the exception of the warmup and long toss should be done with the catcher down in a squat position. Last, be sure to perform the prescribed strengthening and stretching exercises after you throw. As always, never progress to the next phase if there is pain or mechanical issues.

Flat Ground Portion

Day 1 Fastball only—light intensity: 20 to 25 pitches
Day 2 Day off
Day 3 Fastball only—light intensity: 25 to 30 pitches
Day 4 Day off (may long toss up to 120 feet, no more than 20 throws at 120 feet)
Day 5 Day off
Day 6 Fastball only: 15 pitches light intensity; 15 pitches medium intensity
Day 7 Day off
Day 8 Fastball only: 15 pitches at light intensity; 20 pitches at medium intensity
Day 9 Day off
Day 10 Fastballs: 20 pitches at medium intensity
Change-ups: 15 pitches at light to medium intensity
Day 11 Day off (may long toss up to 120 feet, no more than 20 throws at 120 feet)
Day 12 Day off
Day 13 Fastballs: 15 pitches at medium-high intensity
Change-ups: 10 pitches at medium intensity
Breaking balls: 10 pitches at light intensity
Day 14 Day off

Move to the Mound

Day 15 Fastballs: 30 to 45 pitches at light intensity
Day 16 Day off
Day 17 Fastballs: 15 to 20 pitches at light
Day 18 Day off (may play long toss up to a maximum of 120 feet no more than 15 to 20 throws at 120 feet)
Day 19 Fastballs: 15 to 20 pitches up to medium intensity; 10 pitches at medium-high
Change-ups: 10 pitches at medium intensity
Day 20 Day off (may have a light catch, no more than 15 to 20 throws at 90 feet)
Day 21 Fastballs: 10 pitches at medium intensity; 10 pitches at medium-high intensity; 10 pitches at high intensity
Change-ups: 10 pitches at medium intensity
Breaking balls: 10 pitches at medium intensity
Day 22 Day off (may have a light catch, no more than 15 to 20 throws at 90 feet)
Day 23 Fastballs: 15 pitches at high intensity
Change-ups: 15 pitches at high intensity
Breaking balls: 10 pitches at medium intensity
Day 24 Day off (may have a light catch, no more than 15 to 20 throws at 90 feet)
Day 25 Fastballs: 20 pitches at high intensity
Change-ups: 10 pitches at high intensity
Breaking balls: 10 pitches at high intensity
Day 26 Day off (may have a light catch, no more than 5 to 20 throws at 120 feet)
Day 27 Fastballs: 30 pitches at high intensity
Change-ups: 10 pitches at high intensity
Breaking balls: 10 at high intensity
Day 28 Day off (may have a light catch, no more than 15 to 20 throws at 90 feet)
Day 29 Live batting practice 40 to 45 pitches mixing in change-ups and breaking balls at a high intensity
Day 30 Day off (may have a light catch, no more than 15 to 20 throws at 90 feet)
Day 31 Simulated game consisting of three innings up to 50 pitches total mixing in change-ups and Breaking balls with 5-minute rest periods between innings
Day 32 Day off, rest and recover

Pitcher may return to games if no pain or problems exist at this time. The athlete needs to take into account the number of pitches and innings he or she has built the arm and body up to at this time. It is recommended to start with a pitch count of 50/game and no more than 25/inning. Additional rest between outings or not pitching back to back days may also need to be figured in initially upon returning to games.

Summary of the Golfer's Program

- Warm-up: general, dynamic and golf specific progression before play
- General strength and neuromuscular training: squat dominant, upper body push, lunge, upper body pull, shoulder-specific rehabilitation and training
- Stability and core training: golf-specific and shoulder-specific flexibility training
- Plyometric training and cardiovascular training
- Interval golf program will gradually reintroduce the stresses of the golf swing and help the golfer gradually restore the normal biomechanics of the golf swing.

After Return to Sport

Continuing Fitness or Rehabilitation Exercises

- Strengthening of biceps/triceps, rotator cuff, deltoid, and scapular stabilizers should be performed 2 to 3× per week and advanced as tolerated
- Maintenance of dynamic neuromuscular control—strength, mobility, and proprioception
- Endurance program advanced as necessary
- Continue stretching and flexibility rehabilitation exercises

Exercises and Other Techniques for Prevention of Recurrent Injury

- Maintenance of appropriate rotator cuff/scapular stabilization musculature specific to overhead athletes—"Throwers 10" program
- Core stabilization exercise training

Evidence

Ellenbecker T, Cools A: Rehabilitation of shoulder impingement syndrome and rotator cuff injuries: An evidence-based review. *Br J Sports Med* 44:319–327, 2010.

This manuscript provides a thorough review on evidence-based clinical rehabilitation exercises and their inherent objective muscular activity characteristics to guide clinicians in the development of an individualized rehabilitation program for treatment of the patient with shoulder impingement. (Level II evidence)

Hsu A, Ghodara N, Provencher M, et al: Biceps tenotomy versus tenodesis: A review of clinical outcomes and biomechanical results. *J Shoulder Elbow Surg*. 20:326–332, 2011.

The purpose of this review was to analyze research on biceps tenotomy vs. tenodesis in incidence of cosmetic deformity and load to tendon failure for each technique. The results of this review demonstrated a higher incidence of cosmetic deformity in patients treated with biceps tenotomy, with an associated lower load failure compared with patients treated with biceps tenodesis. Complications were similar for each treatment, with a higher likelihood of bicipital pain associated with tenodesis. Individual patient factors and needs should guide surgeons on whether to use tenotomy or tenodesis. (Level III evidence)

Kelly A, Drakos M, Fealy S, et al: Arthroscopic release of the long head of the biceps tendon: Functional outcome and clinical results. *Am J Sports Med* 33(2):208–213, 2005.

This case series 44 patients were evaluated the clinical and functional outcomes of arthroscopic release of the long head of the biceps tendon. At 2 years the American Shoulder and Elbow Surgeons scores were 75.6. 68% were rated as good, very good or excellent. No patient reported arm pain at rest distally or proximally. Tenotomy may be an acceptable surgical intervention for a specific cohort of individuals. (Level III evidence)

Krupp R, Kevern M, Gaines M, et al: Long head of the biceps tendon pain: Differential diagnosis and treatment. *J Orthop Sports Phys Ther* 39(2):55–70, 2009.

The purpose of this manuscript was to review current evidence-based anatomic, functional, and clinical information regarding the long head of biceps tendon, including conservative treatment, surgical treatment, and postsurgical rehabilitation regimens. (Level II evidence)

Mazzocca A, Bicos J, Santangelo S, et al: The biomechanical evaluation of four fixation techniques for proximal biceps tenodesis. *Arthroscopy: J Arthroscop Rel Surg* 21(11):1296–1306, 2005.

The purpose of this study was to compare the cyclic displacement and ultimate failure strength of four proximal bicep tendon tenodesis fixation methods: the open subpectoral bone tunnel biceps tenodesis, the arthroscopic interference screw technique, the open subpectoral interference screw fixation technique, and the arthroscopic suture anchor tenodesis. Out of 22 fresh-frozen cadaver shoulders the subpectoral bone tunnel biceps tenodesis group showed statistically significant greater displacement than other tenodesis methods. There were no statistically significant differences in ultimate failure strength between any of the biceps tenodesis methods tested. (Level II evidence)

Reinold M, Escamilla R, Wilk K: Current concepts in the scientific and clinical rationale behind exercises for glenohumeral and scapulothoracic musculature. *J Orthop Sports Phys Ther* 39(2):105–117, 2009.

The purpose of this extensive review was to provide the clinician with a thorough overview of the available literature relevant to develop a safe, effective, and appropriate exercise program for injury rehabilitation and prevention of the glenohumeral and scapulothoracic joints. (Level II evidence)

Multiple Choice Questions

QUESTION 1. During what phase of rehabilitation is the lawn chair progression most appropriate?

A. Phase I
B. Phase II
C. Phase III
D. Phase IV

QUESTION 2. What are current indications for a biceps tenodesis?

A. Young athletic individual who requires supination and elbow flexion strength
B. Chronic atrophy/dysfunction of the biceps tendon
C. Patient does not accept "Popeye" deformity
D. All of the above

QUESTION 3. During what phase of rehabilitation can you begin active elbow flexion following a biceps tenodesis?

A. Phase I
B. Phase II
C. Phase III
D. Phase IV

QUESTION 4. During what phase of rehabilitation can you begin plyometrics following a biceps tenodesis?

A. Phase I
B. Phase II
C. Phase III
D. Phase IV

QUESTION 5. When should full AROM of the shoulder and elbow be achieved following a biceps tenotomy?

A. 2 weeks
B. 4 weeks
C. 6 weeks
D. 8 weeks

Answer Key

QUESTION 1. Correct answer: **B** (see postoperative Phase II rehabilitation)

QUESTION 2. Correct answer: **D** (see Indications for Surgical Treatment)

QUESTION 3. Correct answer: **B** (see postoperative Phase II rehabilitation)

QUESTION 4. Correct answer: **D** (see postoperative Phase IV rehabilitation)

QUESTION 5. Correct answer: **B** (see postoperative Phase I rehabilitation)

BEYOND BASIC REHABILITATION: RETURNING TO WEIGHTLIFTING AFTER BICEPS TENODESIS

Brian Armstrong, MPT, and Eric C. Hall, MS, ATC, CSCS

Introduction

Aspects of Weight Lifting that Require Special Attention in Rehabilitation

- Power – the ability to generate force in a brief amount of time
- Strength – the ability to produce maximal force
- Coordination – the ability to generate proper muscle firing patterns to manipulate joint motion
- Flexibility – the ability to move a joint in the desired range of motion.
- Proper balance of joint stability and mobility[1,2]

Biceps Tenodesis in the Weightlifter: Key Aspects

- Biceps injuries alone are not the most frequent injuries among the serious weightlifting population, but are very frequently involved with other comorbidities within the shoulder complex. Common physical adaptations that occur with the serious weightlifting population are increased muscle mass, decreased flexibility, and decreased strength, all three of which can lead to impingement syndromes, a common cause of proximal biceps tendon injury.[3-5]
- Kolber et al. reported in their review that 36% of all documented resistance training injuries occurred within the shoulder complex.[6]
- Andrews and McLeod reported that out of 297 athletes who underwent shoulder arthroscopy for anterior shoulder pain, 13 had pain related to weightlifting.[7]
- Cope et al. reported that approximately 50% of all biceps ruptures involve the long head of the muscle. In three reported case studies of bodybuilders, they note that one patient admitted to use of anabolic steroids. In this industry, use of various types of steroids are common, and along with that comes tendon ruptures.[8]

Return to Weightlifting After Biceps Tenodesis: Literature

- In the Cope et al. case studies described, all three cases involved tenodesis as their course of treatment for a biceps rupture. At 6 months postoperatively, all three patients exhibited equal strength and power bilaterally and returned to their preinjury levels of weightlifting.[8]
- Ahmad and ElAttrache performed a review of tenodesis procedures and reported that this procedure has certain advantages over the biceps tenotomy procedure, such as proper maintenance of length-tension relationship, prevention of muscle atrophy, maintenance of elbow flexion and supination strength, and avoidance of cramping sensations and deformity.[9]
- In the event of failed conservative treatment for proximal biceps tendon disorders, an arthroscopic release of the tendon is a common treatment option. In a study by Kelly et al., it was found that 38% of their subjects who underwent an arthroscopic release had early fatigue and discomfort with resistance exercises. They do not advocate this procedure for heavy lifters or those who frequently perform resistance activities of the biceps muscle.[10]

Advanced Strength and Conditioning Programs

Periodization

The strategy of periodization should be based on the level of the athlete and the constraints of the competitive season. When returning to weightlifting following a shoulder injury, one must consider how to manipulate volume loads, progress from general basic lifts to more multijoint explosive movements, and dissipate fatigue.[2,11]

- Linear and undulating—depends on the goals, the desired finished product, and the scheduling demands of the athlete
  - Linear programs are more step by step in nature. An athlete may train for one specific adaptation within one microcycle, then train for another adaptation in the next microcycle, and so forth.
  - Undulating (Nonlinear)—consists of variations of training techniques within a given week or microcycle. An athlete may train for more than one specific adaptation during this time period.[1,2]
- Macrocycles—specifically geared to help an athlete peak at the most important competition within the calendar year

Table 5-1 Integrated Periodization for a Power Sport

Months	1	2	3	4	5	6	7	8	9	10	11	12
Training phases	Preparatory					Competitive					PS	Transition
Subphases	*General*		*Specific*		*PC*	*League Competition*						*Transition*
Strength	Anato-mical adapta-tion	Max stre-ngth	Power	Max stren-gth	Conversion	Maintenance						Compensation

PC, precompetition; PS, postseason (playoffs, finals, championships)
Data from references 1, 2, 11, 13, and 24.

- Mesocycles—can last anywhere from weeks to months, depending on the preferred structure for the individual. Often times scheduled accordingly with smaller preparatory competitions throughout the calendar year.
- Microcycles—utilized to vary exercise frequency, volume, and intensity to achieve the desired responses of performance gains.[1,2,11,12]
- See Table 5-1 for an example of a periodization table for a strength and power sport.

Program Design/Performance Training Program

Sport-Specific Concepts of Integrated Training

- The first thing to look at is the athletes' base level of function. How far have they gotten with their formal rehabilitation program? It is common now for athletes to start to incorporate sport-specific training principals prior to their full release or clearance from their doctor and physical therapist.
- The certified athletic trainer (ATC) and the certified strength and conditioning specialist (CSCS) are appropriate professionals to help bridge this gap from rehabilitation to sport. Good communication and a good working relationship between the ATC or strength coach and the physical therapist (PT) is critical in the late stages of the formal rehabilitation program.
- While the PT is still working on the shoulder specifically, an ATC or CSCS can start the athlete on core training and aerobic/anaerobic conditioning, and assist in maintenance exercises prescribed by the PT. This communication helps avoid any potentially dangerous exercises.[13]
- The following are some concepts the athlete might be able to get a head start on while completing the terminal phases of rehabilitation:
  - Lifting form and technique—posture training
  - Core training—without loading the upper extremity
  - Movement correction exercises
  - Balance training
  - Aerobic/anaerobic conditioning[1,13-16]
- Once the physical therapist has tested the athlete and they have met the discharge criteria, the athlete is released to begin upper body resistance training activities, the ATC or CSCS may now begin to focus on the following:
  - Muscular strength
    - Bench press/incline press
    - Dead lifts—traditional or Romanian
    - Squat variations—front squat, back squat; single leg squats
    - Isolating muscle groups: bicep, triceps, latissimus, trapezius (low, mid, upper), hamstrings, quadriceps, gastrocnemius, core muscle groups
  - Muscular power and (Strength Power Potentiating Complex Training) SPPC
    - Similar lifts used above but with heavier weight, lower reps, higher intensities, and longer rest intervals
    - Progress to SPPC Exercises
      - Olympic lifts
      - Explosive jumps
      - Explosive lunges
      - Medicine ball throws
      - Kettle bell training[17]
  - Multiplanar and multijoint resistance activities
  - Continued focus on prescribed maintenance exercises—typically performed at the end of a workout—it is suggested to at least pick one exercises from each of the concepts listed below
    - Dynamic joint stability—with repositioning of the bicep tendon from the tenodesis procedure, it is thought that the GH joint stability could be

TIMELINE 5-3 **Beyond Basic Rehabilitation—Returning to Weightlifting after Biceps Tenodesis**

PHASE I (weeks 1 to 2)	PHASE II (weeks 3 to 6)	PHASE III (weeks 6 to 12)
• Protection phase: wear sling, gentle PROM and postural exercises only, • Bonus exercises: elbow, forearm, wrist, cervical—gentle AROM of AAROM • Pain control modalities as needed	• Protect tissue • Control pain • Progress with ROM exercises • Implement posture correction exercises	• Protect tissue • Achieve end ranges of motion • Maintenance posture exercises • Address movement impairments • Implement PREs for GH joint/elbow/wrist • Implement joint stability /proprioception exercises • Implement cardiovascular conditioning

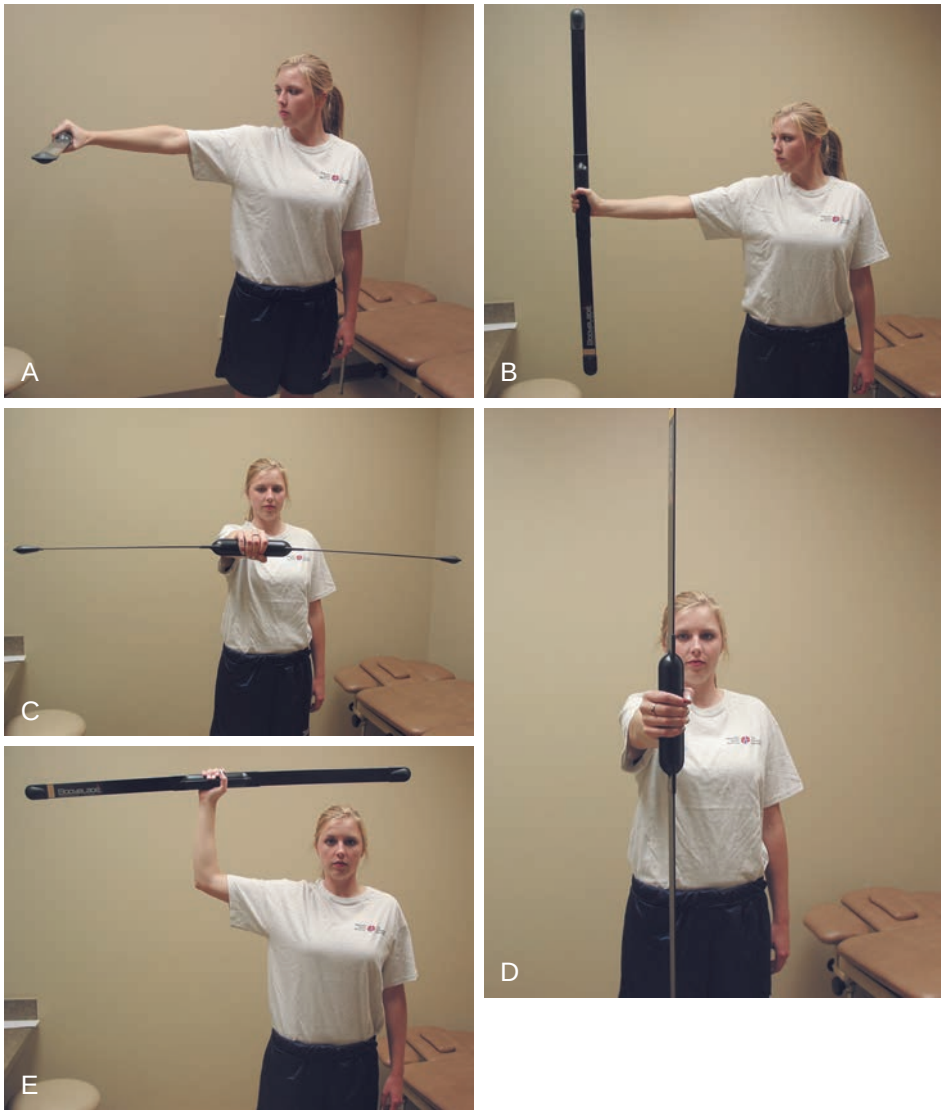

FIGURE 5-16. (**A-E**) Bodyblade routine. Perform each position consecutively for 10 seconds for 3 sets

affected. The following exercises will help address this potential issue.
  - Bodyblade routines (Figure 5-16)
  - Rhythmic stabilization exercises
  - Low-level ballistic/plyometric exercises
- Flexibility/Mobility—a common finding among the weightlifting population is decreased mobility in all ranges and poor agonist/antagonist muscle balance ratios. The smaller muscles, such as the lower trapezius, should not be forgotten.[18]
  - General whole body flexibility
  - Specific stretches for glenohumeral internal rotation, horizontal adduction/abduction, and forward elevation (Figure 5-17 for common shoulder stretches).
  - Specific mobility exercises for scapular mobility—focusing on lower trapezius activation and pectoralis major/pectoralis minor flexibility (Figure 5-18 for low trap activation and pectoralis minor stretches)

TIMELINE 5-3 Beyond Basic Rehabilitation—Returning to Weightlifting after Biceps Tenodesis (Continued)

PHASE IV (weeks 12 to 16)	PHASE V (weeks 16 to 24)	PHASE VI (weeks 24)
• Maintenance of ROM, joint mobility, joint stability, posture, and correct movement patterns • Progress with PRE intensity for GH joint/elbow/wrist • Implement basic large- muscle group weightlifting activities • Focus on lifting techniques • Implement light plyometric exercises	• Continue maintenance exercises • Progress with weight-lifting activities—increasing intensity • Progress intensity with plyometric exercises • Initiate competition-specific lifting techniques—light weight	• Begin customized periodization training program for desired weightlifting • Competitions • Continue regular maintenance exercises

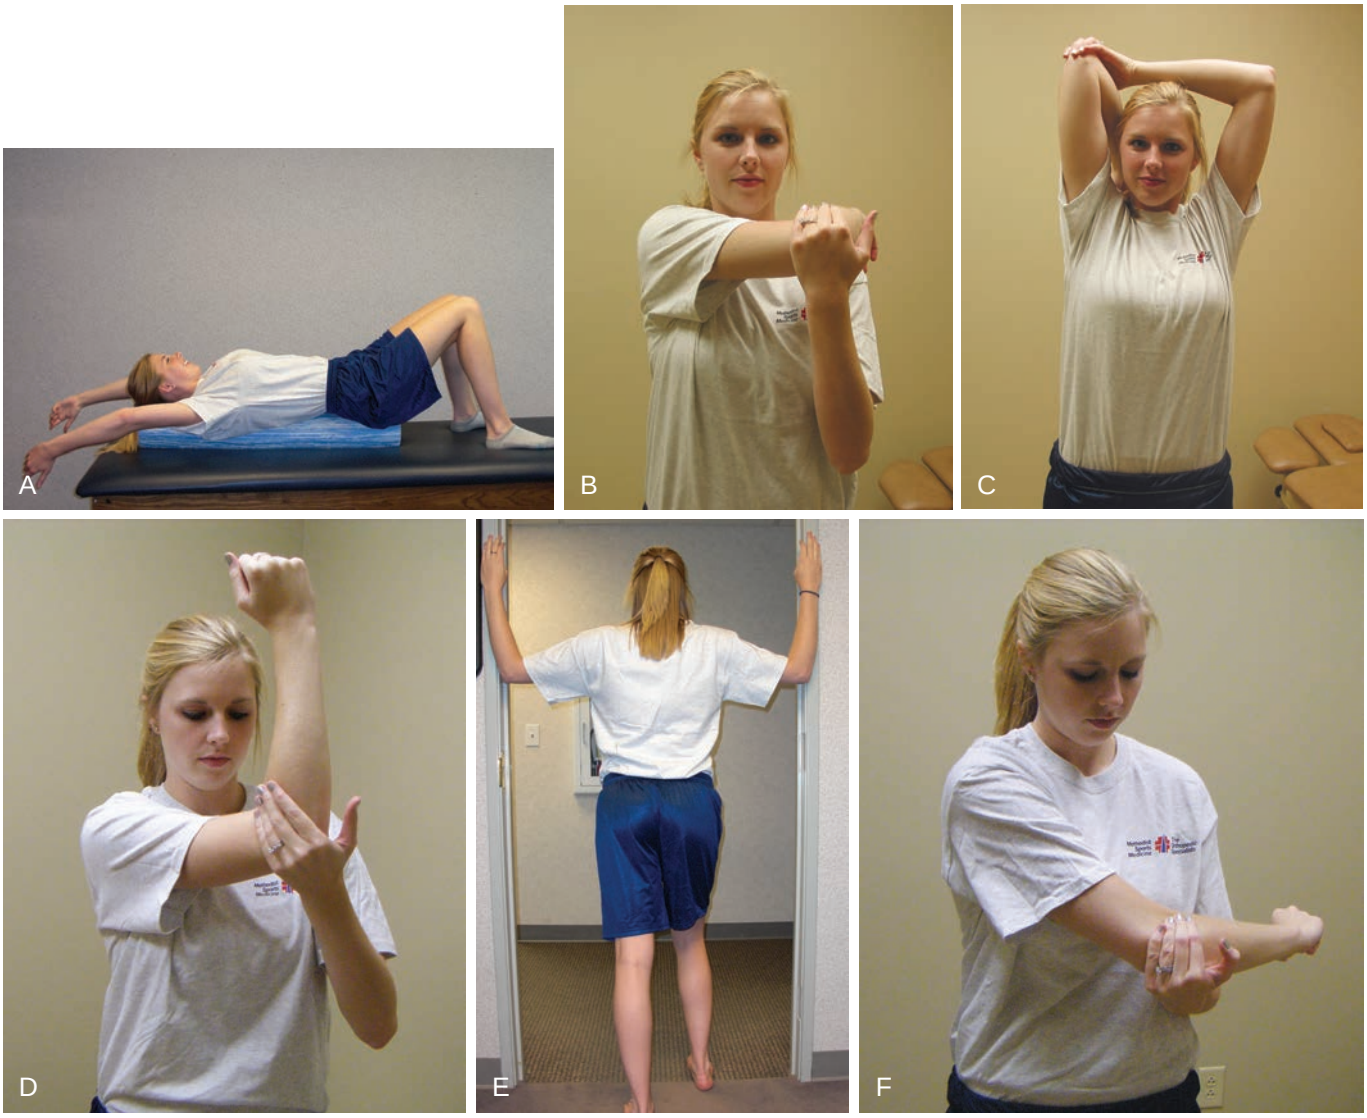

FIGURE 5-17. (**A-F**) Common maintenance shoulder stretches.

- Sensorimotor/balance training
  - Training D1 and D2 patterns
- Core training [1,4,14,15,19]
- See Figure 5-19 for a description of a performance restoration pyramid

Olympic Lifts Used in the Training Program

- Olympic lifts are typically not recommended for an injured athlete until optimum strength, flexibility, and appropriate muscle balances are achieved.
- Once athletes have reached a decent level of training for the concepts listed above, then they may start low-intensity Olympic lifts, focusing on form and technique, and then gradually increasing intensity through appropriate progressions.
- Common Olympic lifts are:
  - Power cleans
  - Clean and jerk
  - Snatch[1,2,17]

Training Principles Used in the Design of the Program

- Principle of progression
- Principle of overload
- Principle of variation
- Principle of individualization
- Principles of specificity—specific adaptation to imposed demands

Application of Acute Training Variables

- Hypertrophy/Endurance Phase
  - Intensity—low to moderate (50% to 75% of 1 rep max)
  - Volume—moderate to high (3% to 6sets of 10 to 20 reps)
- Basic Strength Phase
  - Intensity—high (80% to 90% of 1 rep max)
  - Volume—moderate (3 to 5sets of 4 to 8 reps)

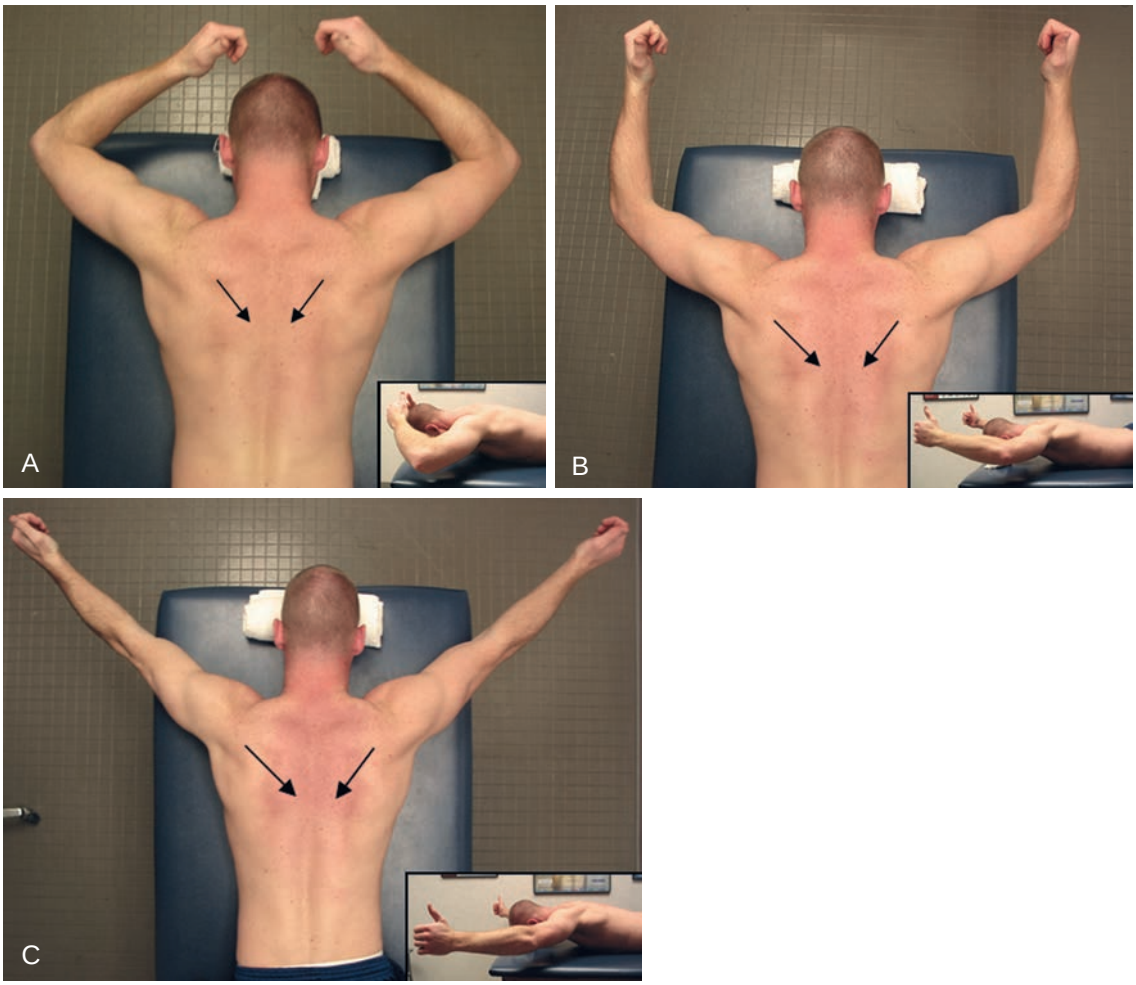

FIGURE 5-18. (**A-C**) Common low trap activation/strengthening exercises. Verbally cue the athlete to squeeze shoulder blades down and together, with minimal glenohumeral involvement.

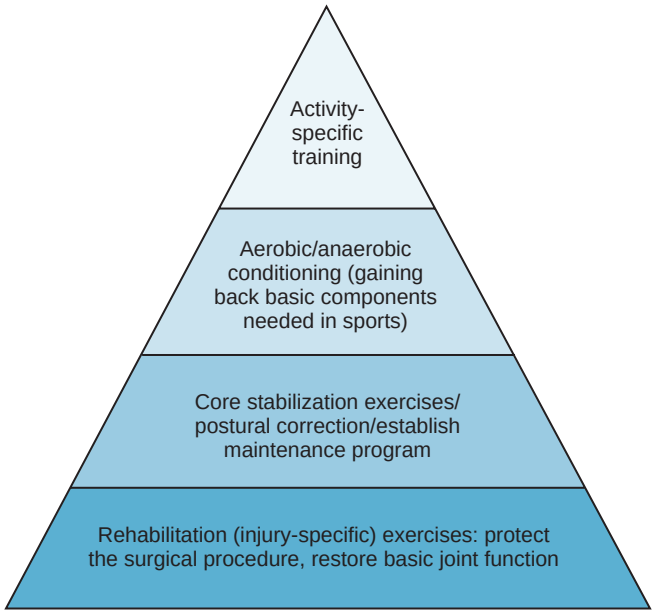

FIGURE 5-19. Performance restoration pyramid following shoulder injuries. *(Data from references 1, 4, 5, and 17.)*

- Strength/Power Phase:
  - Intensity—high (75% to 95% of 1 rep max)
  - Volume—low (3 to 5 sets of 2 to 5 reps)
- Maintenance Phase
  - Intensity—moderate (80% to 85% of 1 rep max)
  - Volume—moderate (2 to 3 sets of 6 to 8 reps)
- Competition Period
  - Intensity—very high (>90% of 1 rep max)
  - Volume—very low (1 to 3 sets of 1 to 3 reps)[1,2,11,12]

Sports Performance Testing

General Information

- General history
- Subjective questionnaires
- Medical history
- Sports injury history
- Surgical history
- Chronic conditions/medication

Specific Criteria for Progression to the Next Phase to Determine Readiness for Weightlifting

- Static/dynamic postural assessments
  - Standing alignment (back view)
    - Symmetry of slope of shoulders
    - Scapula
      - Abduction/adduction (normally 3 in. from spinous process to vertebral border at spine of scapula
      - Prevalence of winging
      - Anterior tilt (normal within 9° to 20°)
      - Depression/elevation (normal: root of spine of scapula aligned with T3)
    - Spine
      - Normal, kyphotic, lordotic
  - Standing Alignment (side view)
    - Scapula—confirm anterior tilt
    - Humerus—humeral head relative to acromion process
      - Normal—no greater than 1/3 humeral head anterior to anterolateral corner of acromion
    - Spine—normal, kyphotic, lordotic,
    - Standing alignment (front view)
      - Clavicles—upward slope from medial to lateral approximately 25°
  - Standing movement tests
    - Bilateral shoulder flexion and return from flexion
      - Acromion should elevate slightly
      - Scapula should upwardly rotate without excessive abduction or adduction
      - Scapula should posteriorly tilt
      - Clavicle should retract and elevate
      - Symmetric glenohumeral creases[20]
- Isokinetic muscle performance testing—Cybex testing
  - ER/IR in 90deg of GH abduction—supine
    - 3 sets
      - #1 6 reps at 90°/sec
      - #2 6 reps at 210°/sec
      - #3 6 reps at 300°/sec
  - Performance Criteria—see Figure 5-19
    - ER/IR ratio of 65% to 75%
    - Dominant vs nondominant = 15% to 20% difference
    - Body weight ratio
      - 90°/sec—30% of IR and 20% of ER
      - 210 and 300°/sec—10% of IR and 10% of ER[19,21,22]
- Movement performance testing—functional movement screen
  - A score of greater than 15 is recommended for all competitive athletes.
  - A study by Kiesel et al. found that professional football players with dysfunctional fundamental movement patterns, as measured by the Functional Movement Screen, are more likely to suffer an injury than those scoring higher on the FMS.[16]
- Sport-specific testing
  - When returning from any injury, a functional progression needs to take place to help ensure safe return to play. For example, a baseball player may want to complete a throwing program prior to returning to pitching. An offensive lineman may want to progress through a series of dummy drills and individual drills, prior to being involved in team drills and games. For competitive weightlifting, one would want to start with safer lifts, lighter weight, and make use of a spotter. Then as strength and power progresses, all while maintaining good form and technique, one may start to work into more high-powered and explosive lifts with heavy weight.[1,2]

Specific Criteria for Release to Unsupervised Complete Participation in Weightlifting

- The athlete must present with postural alignments within normal limits and demonstrate proper scapulohumeral movement patterns.
- The athlete must have a score of greater than 14 on the Functional Movement Screen and produce Cybex testing results that meet the suggested performance criteria.
- Specifically for weightlifting, the athlete must demonstrate the ability to perform all lifts with light weight and demonstrate proper form and technique.
- Last, the athlete must understand the importance of maintenance exercises and how to incorporate them into the training program.

Recommended Ongoing Exercises for the Weightlifter

- Studies (references) show that people who are seriously involved in resistance training exercises often develop some form of muscular imbalance. It is important that proper exercises are prescribed to maintain an appropriate balance of agonist and antagonist muscle groups, to maintain proper joint mobility and stability, while at the same time keeping in consideration the necessary physical requirements needed to perform specific movements for the particular sport they are training for.

- A common imbalance of the weightlifting population is decreased glenohumeral internal rotation and poor lower trapezius strength in relation to body mass. It is recommended that all serious weightlifters perform regular lower trapezius strengthening exercises and stretches for the posterior rotator cuff.[18]
- Specifically for athletes following a tenodesis procedure, the athlete must routinely perform rotator cuff strengthening and dynamic stabilization exercises. Even without much reliable and valid evidence of the exact role the proximal bicep tendon plays in the function of the glenohumeral joint,[4,5,9,10,23] we must address any possible deficits in shoulder stability that may occur with relocation of the origin of the bicep tendon.[4,5,23]

Evidence

Craig B: The basics of resistance training program design: Where do I start? *Strength Cond J* 31:75–77, 2009.

This article addresses the basics of program design for strength and conditioning. The author addresses concepts such as periodization, progressive resistance, and tapering techniques. He explains the importance of knowing the athlete prior to program design, such as sport played, position played, energy systems used, and timing of competitive events. He provides resources for the general public to use to find information on program designs that might closely relate to them. (Level V Evidence)

Kolber M, Beekhuizen K, Cheng M: Shoulder joint and muscle characteristics in the recreational weight training population. *J Strength Cond Res* 23:148–157, 2009.

The purpose of this study was to investigate the common adaptations of the shoulder joint with weightlifters and the associated risk factors that come with them. They evaluated 60 subjects who regularly participated in resistance training exercises and 30 subjects with no record of resistance training. They found the resistance training group had a significant decrease in shoulder mobility, except for shoulder external rotation, and strength ratios for major muscle groups were greater with the resistance training group. They concluded it is important to implement specific exercises within a weight training program that address and prevent these common adaptations that could lead to injury. (Level III Evidence)

Kolber M, Beekhuizen K, Cheng M, et al: Shoulder injuries attributed to resistance training: A brief review. *J Strength Cond Res* 24:1696–1704, 2010.

The purpose of this article was to get a general idea of the level of frequency of shoulder injuries that occur within the resistance training population. Their review indicated a 36% incident of shoulder injury of all injuries related to the resistance training population. Trends that were associated with the injuries were muscle imbalances and poor posture and lifting techniques. They note very little evidence exists as to predictive variables that might lead to shoulder injuries. (Level IV Evidence)

Krieger J: Determining appropriate set volume for resistance exercise. *Strength Cond J* 32:30–32, 2010.

This article provides evidence-based information to help determine the appropriate number of sets and reps for the weightlifting population. It concludes that the noncompetitive weightlifter who would like some strength gains, but is limited with time and resources, would benefit from performing 1 set of exercises, to failure, for a specific muscle group. For someone who is more serious about strength gains, then 3 sets are necessary. He also suggests that anything above 3 sets is not necessary for optimal gains. (Level II Evidence)

Turner A: The science and practice of periodization: A brief review. *Strength Cond J* 33: 34–46, 2011.

The purpose of the article was to review the evidence behind periodization and its effectiveness. They concluded there is enough evidence to prove its effectiveness in a given year or single cycle of a competitive season, but further evidence is needed for the elite level of athletes who are training to peak at longer intervals, such as 4 years. (Level V Evidence)

Wittstein J, Queen R, Abbey A, et al: Isokinetic strength, endurance, and subjective outcomes after biceps tenotomy versus tenodesis. *Am J Sports Med* 39:857–865, 2011.

The purpose of this article was to study the outcomes of both the tenodesis and tenotomy procedures and which one is more effective at restoring muscle strength and endurance. With 19 tenotomy and 16 tenodesis procedures, at 2 years postoperatively, there was no difference in subjective outcome scores between the two groups. Both groups had similar shoulder flexion strength compared to contralateral side. The tenotomy group had significant lower forearm supination strength compared bilaterally, whereas the tenodesis group maintained close to equal supination strength. Furthermore, 4 of the 19 tenotomy subjects developed a "Popeye" deformity and two complained of cramping sensations. Two of the 16 tenodesis subjects exhibited point tenderness at the tenodesis site. (Level III Evidence)

Multiple-Choice Questions

QUESTION 1. When designing a resistance training program for an athlete following a tenodesis procedure, which of the following concepts should be considered?

A. Current status of rehabilitation program
B. What sport is the athlete getting back to?
C. What energy systems are predominantly used for their sport?
D. All of the above

QUESTION 2. What concept below plays the most critical role in how a strength and conditioning program should be structured for an athlete who is preparing for a competitive event?

A. Periodization
B. Progressive resistance
C. Tapering
D. Hypertophy phase

QUESTION 3. Following a biceps tenodesis procedure, what is a normal timeframe to expect close to normal strength measurements compared bilaterally?

A. 3 months
B. 6 months
C. 1 year
D. 2 years

Answer Key

QUESTION 1. Correct answer: **D** (see Program Design/Performance Training section)

QUESTION 2. Correct answer: **A** (see Periodization section)

QUESTION 3. Correct answer: **B** (see Cope et al. study listed under the return to play section)

Chapter 6

Rotator Cuff Injuries

INTRODUCTION

Laura M. Lundgren, PA-C, BS, MPAS, and Timothy S. Mologne, MD

Epidemiology

Age

- Rotator cuff pathology can be seen in a vast array of age groups, from the young athletes to sedentary, geriatric patients.

Sport

- Sports associated with rotator cuff pathology include overhead sports (such as throwing sports, tennis and volleyball), weightlifting, and swimming.

Important Definitions

- **Primary outlet impingement/impingement syndrome:** Pain and inflammation in the subacromial space as a result of the rotator cuff impinging against the undersurface of the acromion, coracoacromial ligament, and undersurface of the acromioclavicular joint.[1]
- **Secondary impingement:** Pain and inflammation in the rotator cuff and subacromial space due to an inability to keep the humeral head centered, thus causing altered humeral mechanics and compression on rotator cuff. It is usually seen in younger patients who may have glenohumeral laxity or instability and often have poor scapular control. It can also be associated with weakness of the rotator cuff.[2]
- **Internal impingement:** Repetitive contact of the greater tuberosity and articular surface of the posterior rotator cuff on the posterosuperior glenoid in the abducted, externally rotated position. It is usually seen in throwers and can result in partial articular sided rotator cuff tears and posterosuperior glenoid labral tears. It can be associated with subtle glenohumeral instability, posterior capsular tightness and internal rotation deficits, and scapular dyskinesia.[3,4]
- **Glenohumeral internal rotation deficit (GIRD):** Usually seen in pitchers and athletes in overhead sports (tennis) and is defined as less than 25° of internal rotation or a total arc or motion 25° less than the contralateral shoulder (total arc of motion, both internal and external rotation, should be equal between shoulders, with the throwing shoulder having more external rotation with correspondingly less internal rotation).[5]

Pathophysiology

Intrinsic Factors

I. Primary outlet impingement/impingement syndrome
- Tendon degeneration
- Hypovascular zone in the supraspinatus tendon
- Posterior capsular tightness
- Acromial and coracoacromial arch morphology (association of rotator cuff pathology and bony excrescences from the undersurface of the acromion) (Figure 6-1)
- Kinematic abnormalities
- Subacromial bursitis
- Acromioclavicular arthrosis
- Overuse syndrome
- Os acromiale
- Suprascapular neuropathy
- Cervical degeneration/cervical radiculopathy

II. Internal impingement
- Excessive external rotation
- Tight posterior capsule, leading to loss of internal rotation and a posterosuperior shift of the humeral head with humeral elevation.
- Subtle anteroinferior shoulder instability

III. Secondary impingement
- Glenohumeral instability and laxity
- Rotator cuff weakness

FIGURE 6-1. Type 3 acromion with a large bony excrescence from the undersurface of the acromion.

- Scapular stabilizer muscle weakness with scapular dyskinesia

Extrinsic Factors

I. Outlet impingement/impingement syndrome
- Repetitive use injuries
- Smoking
- Tensile overload
- Indiscriminate cortisone injections

II. Internal impingement
- Repetitive throwing or positioning in the abducted, externally rotated position

III. Secondary impingement
- Repetitive overhead activities, including sports like swimming, and throwing sports

Traumatic Factors

- Repetitive throwing
- Fall on outstretched arm
- Fall directly onto the shoulder

Classic Pathological Findings

I. Stages of rotator cuff impingement[1]
- Stage I: Acute rotator cuff inflammation/subacromial bursitis and hemorrhage (Figure 6-2).
- Stage II: Fibrosis and tendonitis of the rotator (Figure 6-3)
- Stage III: Partial and complete rotator cuff tendon tears (Figure 6-4*A*,*B*)

II. Internal impingement
- Repetitive contact of the undersurface of the infraspinatus on the posterior superior glenoid, resulting in articular sided partial infraspinatus tendon tears and posterosuperior glenoid labral tears (Figure 6-5)

III. Secondary impingement
- Glenohumeral laxity or instability
- Rotator cuff impingement signs in young patients

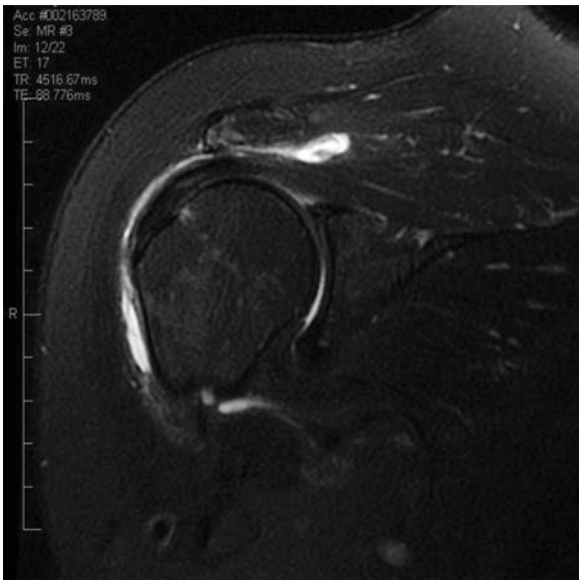

FIGURE 6-2. Acute subacromial bursitis and inflammation.

FIGURE 6-3. Rotator cuff tendinosis and fibrosis.

Clinical Presentation

History

I. Primary outlet impingement/impingement syndrome
- Painful overhead motion
- Grinding, catching and popping in the subacromial space with rotational and overhead motion
- Weakness, which may be caused by pain or can be due to rotator cuff tearing
- Night pain (very common complaint in patients with a rotator cuff tear)
- Posterior capsular tightness is common

II. Internal impingement
- Usually seen in throwers or athletes that put their shoulders in the abducted externally rotated position repetitively

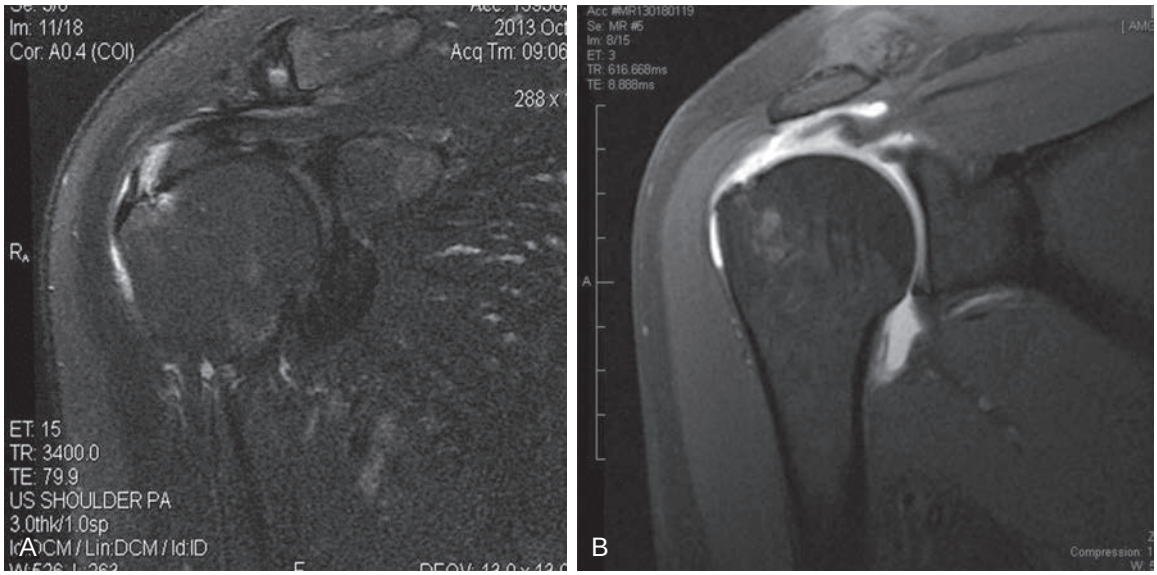

FIGURE 6-4. A, B, Partial and full thickness rotator cuff tears.

FIGURE 6-5. MR with intraarticular gadolinium in the ABER position (abduction-external rotation), showing an articular sided partial tear of the infraspinatus in a professional baseball pitcher.

- Pain in the abducted, externally rotated (ABER) position, relieved with a posterior directed force on the humerus (Jobe relocation test).
- Possible complaints of catching and grinding due to labral tearing
- Complaints of weakness and easy fatigue
- Thrower may notice decreased velocity

III. Secondary impingement

- Painful overhead motion
- Can present with grinding, catching, and popping in the subacromial space caused by subacromial bursitis
- Complaints of weakness and easy fatigue
- "Dead arm" symptoms with throwing
- Possible complaints of shoulder subluxation
- Poor scapular control with scapular dyskinesia and often winging of the scapula when lowering the arm from overhead

Physical Examination

I. Primary outlet impingement/impingement syndrome

1. **Abnormal findings:**
   - Painful arc (Neer and Hawkins impingement signs)
   - Posterior capsular tightness
   - Pain with rotator cuff strength testing
   - Weakness caused by pain and/or tendon disruption
2. **Pertinent normal findings:**
   - Intact and normal strength in patients without cuff tearing
   - Normal motor and sensory exam
   - Normal and asymptomatic biceps function
   - Complete and symmetric range of motion
   - Normal and asymptomatic cervical range of motion
   - Stable shoulder to anterior, posterior and inferior translations

II. Internal impingement

1. **Abnormal findings:**
   - Pain in the abducted, externally rotated position (ABER position)
   - Possible glenohumeral internal rotation deficit (GIRD)
   - Pain with rotator cuff strength testing, particularly resisted external rotation
   - Weakness of the external rotators can be seen in patients with significant partial tearing of the infraspinatus
   - Labral tearing can result in positive active compression test (O'Brien test), Speed's test, and compression-rotation test
2. **Pertinent normal findings:**
   - Intact and normal strength in patients without cuff tearing
   - Normal motor and sensory exam
   - Normal and asymptomatic cervical range of motion

- Stable shoulder to anterior, posterior and inferior translations

III. Secondary impingement

1. **Abnormal findings:**
   - Painful arc (Neer and Hawkins impingement signs can be positive)
   - Pain with rotator cuff strength testing
   - Weakness caused by pain
   - Possible increase in glenohumeral joint translations in various directions (can be multidirectional laxity or instability)
   - Scapular dyskinesia: Poor scapular control with activities and possible winging when lowering the arm from overhead
2. **Pertinent normal findings:**
   - Usually with intact and normal strength
   - Normal motor and sensory exam
   - Normal and asymptomatic biceps function
   - Complete and symmetric range of motion
   - Normal and asymptomatic cervical range of motion

Imaging

- Imaging of the shoulder is always done and starts with radiographs in all patients, regardless of the presumed diagnosis
- X-rays (AP, axillary, and supraspinatus outlet views of the shoulder)
- Supraspinatus view used to assess acromial morphology
- MRI if indicated by exam
- MR with intraarticular gadolinium can be helpful in diagnosing undersurface partial rotator cuff tear and the presence of internal impingement (MR sequencing in the ABER position)
- Ultrasound can be used to help identify pathology in the rotator cuff, biceps, and subacromial space
- CT arthrogram can be used to assess for rotator cuff pathology in patients that cannot have an MRI

Differential Diagnosis

- Cervical radiculopathy
  - The patient's history may include a history of neck pain or decreased neck range of motion. The exam may show neural tension signs, weakness in a nerve root distribution, distal motor weakness, dermatomal sensory deficits, and possible diminished deep tendon reflexes.
- Biceps pathology (tenosynovitis, partial and complete tearing, and subluxation)
  - The physical exam may reveal tenderness over the biceps groove, positive Speed's test, and pain with resisted supination. Patients may complain of pain radiating from the shoulder and into the anterior brachium.
- Acute brachial neuritis (Parsonage Turner Syndrome)
  - Acute onset of intense, nontraumatic shoulder pain, which, occasionally, follows a viral illness. The intense pain is followed by weakness in the upper extremity. It can affect multiple areas of the brachial plexus, but can be isolated to a single nerve (suprascapular nerve).
  - MRI of the shoulder may show edema in the supraspinatus and infraspinatus if they are deinnervated.
- Suprascapular neuropathy
  - Can be caused by compression of the nerve at the suprascapular notch. This results in weakness of the supraspinatus and infraspinatus muscles.
  - Spinoglenoid ganglion cyst causing compression of the suprascapular nerve and weakness of infraspinatus only.
  - The physical exam will find increased weakness of external rotation only if the suprascapular nerve is affected at the spinoglenoid notch.
- Calcific tendinitis
  - The patient's history will indicate an acute onset of pain often associated with actual redness of the shoulder and the presence of calcium in the rotator cuff on X-ray.
- Adhesive capsulitis
  - Patients present with shoulder pain with overhead activities. As the overhead motion causes intense pain, providers often do not test range of motion for symmetry. Loss of motion in all planes (but especially external rotation at the side and internal rotation) is diagnostic.
- Contusions
  - The patient's history will indicate a specific injury.

Treatment

Nonoperative Management

- Activity modifications/rest
- Physical therapy
- Nonsteroidal antiinflammatory medicines (oral and topical)
- Subacromial injection

Guidelines for Choosing among Nonoperative Treatments

- Activity modifications/rest
  - Most patients have already begun to modify their activities based upon pain and symptoms. However, if their occupation or hobbies require overhead repetitive movements work restrictions or a discussion on specific modifications may be helpful. In most circumstances this will be combined with additional treatment.
- Physical therapy[6]
  - Helpful in restoring full and symmetric motion, preventing muscle atrophy, and improving pain. In the event of a rotator cuff tear, therapy can still be helpful in achieving full range of motion prior to any surgical intervention to avoid postoperative complication of adhesive capsulitis.
- Nonsteroidal antiinflammatory medicines
- Patients with evidence of stage I or stage II impingement are offered an antiinflammatory medicine.

- Subacromial injection
  - Diagnostic injection with anesthetic can help to assess strength in an acutely inflamed shoulder that is examining with weakness. An injection with corticosteroid and anesthetic can be diagnostic as well as therapeutic. An injection is not indicated in the presence of a rotator cuff tear and should not be used indiscriminately. Due to damaging effects of atrophy and decreased quality of tissue, no more than three injections are recommended and they should be spaced at least three months apart.

Surgical Indications

- There are no absolute indications for surgical intervention in rotator cuff pathology. Relative indications are as follows:
  - Failure of conservative treatment
  - Symptomatic full thickness rotator cuff tear
  - Symptomatic partial thickness rotator cuff tears that are greater than 50% of the thickness of the tendon
  - Persistent symptoms in patients with internal impingement that fail to improve with 3 months of therapy.
  - Persistent symptoms in patients with secondary impingement that fail to improve with 3 to 6 months of therapy

Aspects of History, Demographics, or Exam Findings that Affect Choice of Treatment

- Length of symptoms and amount of dysfunction
- Age of patient
- Comorbidities affecting anesthesia clearance
- The patient's desire to return to sports/hobbies or a physically demanding profession
- In the presence of a rotator cuff tear the amount of atrophy or fatty infiltration of the muscle belly, tendon retraction and elevation of the humeral head

Aspects of Clinical Decision Making When Surgery Is Indicated

- Coracoacromial arch morphology
- Symptomatic acromioclavicular arthrosis
- Concomitant pathology including involvement of biceps tendon and/or labrum
- Arthroscopic versus open rotator cuff repair and distal clavicle resection
- Benefit of tendon transfers for irreparable tendon tears
- Risks and benefits of concomitant versus staged surgery when there is a component of adhesive capsulitis associated with rotator cuff tendon tear
- Type of fixation for repair (anchor configuration, stitch configuration, anchor material, etc.)

Evidence

Arroyo JS, Hershon SJ, Bigliani LU: Special consideration in the athletic throwing shoulder. *Orthop Clin North A* 28:69–78, 1997.

In this review article, the authors remind us that the rotator cuff can become inflamed and injured due to instability in the young athlete. These patients are usually successfully treated with a coordinated rehabilitation program. (Level IV evidence)

Morrison D, Frogameni A, Woodworth P: Nonoperative treatment of subacromial impingement syndrome. *J Bone and Joint Surg* 79:732–737, 1997.

This retrospective study looked at the results of conservative treatment for subacromial impingement syndrome in 616 patients (636 shoulders). Overall 67% had a satisfactory result. Results were better in patients with symptoms less than 4 weeks and in those with a type I acromion. (Level III evidence)

Myers JB, Laudner KG, Pasquale MR, et al: Glenohumeral range of motion deficits and posterior shoulder tightness in throwers with pathologic internal impingement. *Am J Sports Medicine* 34:385–391, 2006.

The authors compared humeral rotations in 11 throwing athletes with clinical and MR evidence of internal impingement to 11 matched throwing athletes that had no history of shoulder ailments. The symptomatic throwing athletes had greater internal rotation deficits and posterior capsular tightness as compared to the controls. (Level III evidence)

Neer CS: Anterior acromioplasty for the chronic impingement syndrome in the shoulder. A preliminary report. *J. Bone and Joint Surg* 54:41–50, 1972.

In this classic article, Dr. Neer described the concept of impingement and outlet obstruction by bone from the acromion, resulting in irritation of the supraspinatus and, occasionally, the biceps tendon. (Level III evidence)

Paley KJ, Jobe FW, Pink MM, et al: Arthroscopic findings in the overhead throwing athlete: evidence for posterior internal impingement of the rotator cuff. *Arthroscopy* 16:35–40, 2000.

The authors described the arthroscopic findings in 41 professional overhead throwing athletes that underwent surgery for painful shoulders. All had contact of the undersurface of the rotator cuff with the posterosuperior glenoid or osteochondral lesions. Undersurface cuff fraying was found in 93% and posterosuperior glenoid labral fraying was seen in 88%. These findings support the concept and diagnosis of internal impingement as a cause of shoulder pain in the throwing athlete. (Level III evidence)

Walch G, Liotard JP, Boileau P, et al: Postero-superior glenoid impingement. Another shoulder impingement. *Rev Chir Orthop Reparatrice Appar Mot* 77:571–574, 1991.

Walch initially described a case of internal impingement, with partial tearing of the articular side of the rotator cuff caused by impingement of the tendon on the posterosuperior aspect of the glenoid in the throwing position. (Level III evidence)

Multiple-Choice Questions

QUESTION 1. The physical exam finding that changes the diagnosis from internal impingement only to glenohumeral internal rotation deficit (GIRD) is:

A. Less than 35° of internal rotation on the affected shoulder.
B. Less than 25° of internal rotation or the total arc of motion is 25 ° less than the contralateral shoulder.
C. External rotation is 20° more in the contralateral shoulder.
D. Evidence of a partial articular sided rotator cuff tear on MRI.

QUESTION 2. Which of these factors is an intrinsic factor for primary impingement syndrome?

A. Smoking
B. Trauma
C. Os acromiale
D. Repetitive overhead activities

QUESTION 3. A patient presents with a painful arc of motion, poor scapular control and winging with lowering the arm from overhead, asymptomatic biceps function and complete and symmetric range of motion. The most likely diagnosis would be:

A. Primary impingement syndrome
B. Glenohumeral internal rotation deficit
C. Secondary impingement
D. Adhesive capsulitis

QUESTION 4. A patient who presents with weakness of the external rotators only would have a likely diagnosis of:

A. Suprascapular neuropathy affected at the spinoglenoid notch
B. Calcific tendonitis
C. Cervical radiculopathy
D. Biceps pathology

QUESTION 5. Appropriate first line treatment of impingement syndrome would be:

A. Surgery
B. Activity modifications and narcotic pain medicines
C. Activity modifications, physical therapy and NSAIDs
D. Narcotic pain medications

Answer Key

QUESTION 1. Correct answer: **B** (see Important Definitions)

QUESTION 2. Correct answer: **C** (see Pathophysiology)

QUESTION 3. Correct answer: **C** (see Physical Examination)

QUESTION 4. Correct answer: **A** (see Differential Diagnosis)

QUESTION 5. Correct answer: **C** (see Treatment)

NONOPERATIVE REHABILITATION OF ROTATOR CUFF IMPINGEMENT SYNDROME

Kari L. Sturtevant, DPT, OCS, Molly Van Zeeland, DPT, Laura M. Lundgren, PA-C, BS, MPAS, and Timothy S. Mologne, MD

Phase I: Acute Phase (weeks 0 to 2)

Goals

- Alleviate pain and inflammation (nonsteroidal antiinflammatory agents)
  - Possible subacromial injection of local anesthetic and a corticosteroid
- Use of modalities (cryotherapy, iontophoresis, phonophoresis, TENs unit, ultrasound, E-stim) to help alleviate pain
  - Note that research does not support the use of passive modalities including ultrasound, low-level laser therapy, and electromagnetic field therapy as effective treatments for impingement syndrome so these modalities should only be used to adjunct treatment and not the premise of treatment in this phase.[3]

GUIDING PRINCIPLES OF NONOPERATIVE REHABILITATION

- All aspects of rehabilitation for shoulder impingement are evaluation driven and include a logical progression of exercises to correct the biomechanical deficits identified in the evaluation.
- Avoid positions and activities that compromise the subacromial space and stress injured structures of the shoulder.
- A systematic evaluation must be performed to identify the specific cause and subtle underlying cause of shoulder impingement.[1] One must be cognizant that multiple causes may be responsible for the shoulder pathology.
  - Determine type of impingement
    - Primary
    - Secondary
    - Internal
  - Special tests to determine the mobility of the glenohumeral joint are key aspects of evaluation of the patient with rotator cuff impingement.
    - Evaluate to identify glenohumeral hypermobility and subtle instability as well as glenohumeral hypomobility.[1]
    - "Failure to identify patients with glenohumeral joint hypermobility and underlying instability properly can result in the inappropriate use of capsular stretching and mobilization techniques that could further jeopardize shoulder stability and decrease the potential success of the rehabilitation program."[1]
  - Resting scapular position and dyskinesis.
- Exercises must be performed with proper technique, including good scapular control. If proper technique cannot be maintained, the exercise must be modified.
- Based on the results of systematic review by Kuhn[2], it is recommended that patients receive supervised physical therapy for exercise and manual therapy 2 to 3 times per week initially. When manual therapy is no longer warranted and the patient demonstrates good technique with their home exercise program, frequency of physical therapy visits may be reduced to progress the patient's home exercise program as needed.
- Kuhn[2] concludes that range of motion and flexibility exercises be performed daily and strengthening performed 3 times a week.
- Proprioception and neuromuscular control exercises should be practiced multiple times daily.
- Conservative treatment of shoulder impingement is thought to be unsuccessful if no improvement is seen with 12 weeks of an evaluation-driven rehabilitation program and coordinated medical care. By 6 to 9 months, maximum medical improvement is typically obtained.
  - Activity modifications and rest, avoiding activities that exacerbate symptoms
    - Patient education on activity modification and avoidance is very important in this phase so healing is not delayed
- Acquire full passive ROM
- Retard muscle atrophy by beginning submaximal, pain-free isometrics for internal and external rotation
- Address abnormal resting scapular positioning and scapular dyskinesis by neuromuscular control exercises to normalize scapular muscle firing patterns
  - Consider scapular taping to improve resting scapular positioning as evidenced by Selkowitz et al.[4]

Techniques for Progressive Increase in Range of Motion

Manual Therapy Techniques

- Techniques used are evaluation based.
  - Glenohumeral joint mobilizations are
    - Empty end feels—Use grades I and II mobilizations for pain control and relaxation
    - Firm capsular end feels—Use grades III and IV to address motion deficits
  - Thoracic spine mobilization/manipulation is often necessary and should be included in this phase in patients who demonstrate increased thoracic kyphosis. Thoracic kyphosis causes an anterior tilt of the scapula, which reduces the subacromial space.
    - Thoracic spine extension exercises/flexibility exercises should be encouraged as part of a home excercise program
    - Patient education on proper sitting posture to maintain thoracic spine extension

Soft Tissue Techniques

- Some research supports the use of deep friction massage to the rotator cuff tendon insertion and radial nerve stretching for pain management in patients with impingement syndromes.[5]

Stretching and Flexibility Techniques for the Musculotendinous Unit

- Stretching and flexibility exercise prescription is evaluation based. Can include exercises for flexion, scaption, internal rotation and external rotation.
- Manual PROM, stretching and exercise prescription of stretching/flexibility for glenohumeral internal and external rotation should be ONLY done when patient has loss of total shoulder joint motion (external rotation ROM plus internal rotation ROM) compared to contralateral side. Note: IR/ER measurements should be done in the scapular plane at 90° abduction avoiding scapular compensation. Place hand on coracoid to feel for compensation (Figure 6-6).
- Stretching/flexibility exercises should be modified to limit pain or avoid subacromial impingement with endrange stretching.
  - Keep in mind that glenohumeral internal rotation deficiency (GIRD) or loss of internal rotation and increased external rotation caused by humeral retroversion in overhead athletes is normal and provided

FIGURE 6-6. Technique for measuring glenohumeral joint internal rotation with scapular stabilization at 90° abduction.

the patient does not lack total arc of motion, internal rotation should not be stretched.[6]

- Note end feel of ROM to determine if the patient truly has tightness. An empty end feel is limited by pain, and stretching and aggressive joint mobilizations are not necessarily appropriate. Address capsular end feel and treat firm capsular end feels with grades III and IV joint mobilizations or firm muscular end feels with stretching. Oftentimes patients with motion loss have tightness of both noncontractile tissue (i.e., capsule, fascia) and contractile tissue (i.e., musculo-tendon) unit and both joint mobilizations and stretching exercises are appropriate.
- Gentle range of motion exercises to address motion deficits. Motion exercises should be only done in a manner that limits symptoms and may need to be done initially as passive or active-assisted motions.
- Pure abduction usually leads to increased symptoms and is usually avoided in the early phases. Stretching should be done in the scapular plane to avoid impingement of the structures in the subacromial space. (This may require a towel roll under elbow to stretch internal and external rotation.)
- Stretching, particularly the posterior capsule, is often necessary in patients presenting with glenohumeral joint hypomobility and should be made a part of the HEP in this phase. There is little evidence supporting frequency and duration of flexibility exercises, but common practice encourages 3 times 60-second stretches for each exercise, 2 to 3 times per day.
  - Stretches may include the posterior capsule sleeper's stretch (Figure 6-7), the cross body stretch (Figure 6-8), the rope IR stretch (Figure 6-9), the T-bar ER stretch and passive/active assisted flexion stretch (Figure 6-10)

Other Therapeutic Exercises

- Address flexibility of lower extremities, trunk and contralateral arm and prescribe a program to be done 3 times a week.

TIMELINE 6-1: **Nonoperative Rehab of Rotator Cuff Impingement**

PHASE I (weeks 0 to 2)

- Alleviate pain and inflammation
  - Subacromial injection
  - NSAIDS
  - Cryotherapy
  - Activity modification
  - Grade I and II joint mobilizations
- Acquire full passive ROM
  - For firm capsular end feels, use grade III and IV joint mobilizations
  - Stretch muscular and capsular end feel with
  - Flexion
  - Scaption
  - External rotation at side and 90° abduction
  - Internal rotation
- Address posture and increased thoracic kyphosis
  - Posture education
    - Scapular positioning
    - Spine posture
  - Thoracic joint mobilizations
- Neuromuscular reeducation for scapular muscular and rotator cuff
  - Prone extension with external rotation
  - Sidelying external rotation
  - Submaximal isometrics for IR/ER
- Total body strengthening
  - Flexibility
  - LE and contralateral UE strengthening
  - Cardiovascular exercise
- Home exercise program

PHASE II (weeks 2 to 8)

- Alleviate pain and inflammation
- Manual therapy as in Phase I
- Address scapular muscle imbalances
  - Forward flexion in side lying
  - Prone horizontal abduction with external rotation
  - Prone extension with external rotation
  - Wall or counter top pushup plus
- Progressive rotator cuff isotonics
  - Side lying external rotation with towel roll under arm
  - Theraband internal and external rotation with towel roll under arm
  - Once 3 × 20 can be performed of above isotonics with reasonable resistance, progress to:
    - Scaption
    - Prone external rotation at 90° abduction
    - D2 flexion
- Begin rhythmic stabilization, CKC rhythmic stabilization, Bodyblade, TB external rotation with oscillation
- Continue whole body flexibility, strength, and cardiovascular fitness

PHASE III (weeks 6 to 24)

- Continue manual therapy
- Progress rotator cuff strengthening
  - Thera-Band IR/ER at 90° abduction
  - Isokinetics if available
- Progress scapular muscle strengthening
  - Pushup plus in modified quadruped PIC
  - Prone horizontal abduction at 135° abduction
  - High and low rows
  - Military press
  - Lat pulldowns
- Progress proprioception and closed chain exercises
  - Stabilization on wobble board in quadruped or plank positions
  - Perturbations throughout range with Thera-Band exercises
  - Stabilization on stability ball
- Plyometrics
  - Trampoline toss
  - Catch and toss ball in 90°/90°

FIGURE 6-7. Posterior capsule/sleeper stretch to improve internal rotation range of motion and posterior capsule tightness.

- Lower extremity strengthening and cardiovascular exercise should continue and be encouraged especially in athletes planning to return to sport. Typically, strengthening and cardiovascular exercise for an athlete should be done 3 times a week at a minimum.

Activation of Primary Muscles Involved

- Choices of strengthening exercises should be made on an evaluation-based approach.
- Scapular dyskinesis
  - Defined as alterations in dynamic scapular motion patterns
  - Alterations of resting position may also exist and need to be addressed
  - Three axes of rotation of the scapula provide three individual motions:
    - Upward/downward rotation about a horizontal axis perpendicular to the plane of the scapula, near the center of the scapula
    - Internal/external rotation about a vertical axis through the plane of the scapula
    - Anterior/posterior tilt about a horizontal axis through the scapula
  - The most common scapular dyskinesis patterns involve a downward rotation, internal rotation, and anterior tilt of the scapula. Lack of proprioception and delayed or decreased activity of the serratus anterior and lower trapezius are thought to contribute to scapular dyskinesis.
  - Some degree of scapular dyskinesis is evident in the majority of injured shoulders.
  - The physical examination should determine whether an altered resting position and scapular dyskinesis exist.
  - Restoring normal scapular position and control is a vital portion of a successful rehabilitation program for the shoulder joint.
    - Identify if the scapular dyskinesis is a result of poor neuromuscular recruitment or decreased muscle strength.

FIGURE 6-8. Cross arm stretch to improve posterior capsule tightness.

FIGURE 6-9. Internal rotation stretch with hand behind back using a rope and handle to improve internal rotation range of motion.

FIGURE 6-10. Flexion AAROM and stretching exercise to improve flexion range of motion.

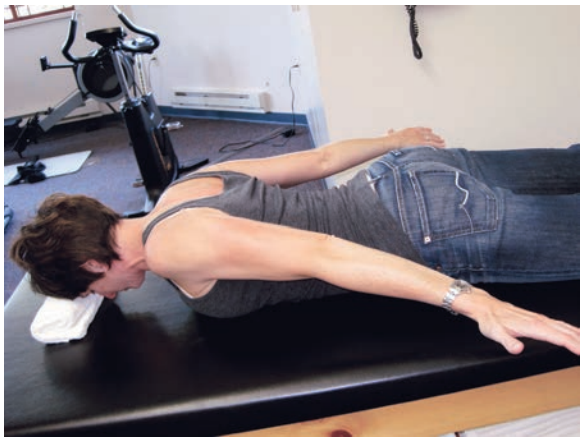

FIGURE 6-11. Prone extension with external rotation for middle trapezius and lower trapezius neuromuscular reeducation, strengthening and restoration of trapezius muscle imbalances.

  - Phase 1 of scapular muscle training involves restoring normal resting position and proprioception exercises with the arm at the side.
  - Phase 2 focuses on muscle control and normalizing muscle imbalances. Typically, the upper trapezius (UT) is overactive in comparison to the lower trapezius (LT), middle trapezius (MT) and serratus anterior (SA). Exercises that minimize the UT/LT, UT/MT and UT/SA ratios by selectively activating the less active muscle are ideal for this phase.[6,7]
  - Phase 3 of scapular muscle training includes general scapular muscle strengthening.
- Exercises appropriate for this phase of rotator cuff impingement:
  - Prone shoulder extension with external rotation. Focus on posterior tilting scapula and middle trap recruitment. Work endurance by encouraging 10-second static hold with each repetition and repeat 10 times; 1 to 2 times per day (Figure 6-11).
  - Side-lying external rotation with rolled towel under arm in a pain-free range of motion. Perform 3 sets of 10 to 15 repetitions. Perform 1 time per day. (Figure 6-12).
  - Scapular orientation exercises to focus on correcting faulty resting position should be performed several times per day to make it habit.

FIGURE 6-12. Side-lying external rotation with dumbbell.

Milestones for Progression to the Next Phase

- Shoulder AAROM/PROM restored and symmetric to contralateral shoulder.
- Shoulder active range of motion should be painless for internal and external rotation. End range flexion may still be painful caused by impingement and painful arc may still exist with abduction.
- Manual muscle testing of the rotator cuff should not be painful and should be at least 3 or greater on a 5 point scale for manual muscle test before progressing patient.
- Good scapular resting position which constitutes scapula is flush to the thorax without evidence of a scapular internal rotation (prominent medial border), anterior tilt (prominent inferior angle) or downward rotation (inferior angle closer to thoracic spine than superior angle).

Phase II: Intermediate Strengthening (weeks 2 to 8)

Goals

- Patients can begin strengthening in a completely pain-free manner: shoulder external, internal rotators, and scapular stabilizers. Strengthening should generally begin with the arm at the side and emphasize the small stabilization muscles as opposed to deltoid, pectorals, lats, etc.
- Patient must be able to demonstrate good scapular control with all strengthening exercises. When patient fails to maintain good scapular mechanics, it is a sign of fatigue or too rapid progression during this phase.
- Goal in this phase is to achieve full pain-free AROM.

Management of Pain and Swelling

- Continue modalities as recommended in Phase I as needed

Techniques for Progressive Increase in Range of Motion

Manual Therapy Techniques

- Manual therapy techniques should continue until patient has full, nonpainful ROM.
- Aggressive endrange joint mobilizations for patients with hypomobility may be required

Soft Tissue Techniques

- Continue as in Phase I
- To restore normal, pain-free AROM

Stretching and Flexibility Techniques for the Musculotendinous Unit

- Stretching/flexibility exercises should continue until patient has full, nonpainful ROM.
- Continue exercises from Phase I as needed. Emphasis should be on self-capsular stretching and HEP during this phase.

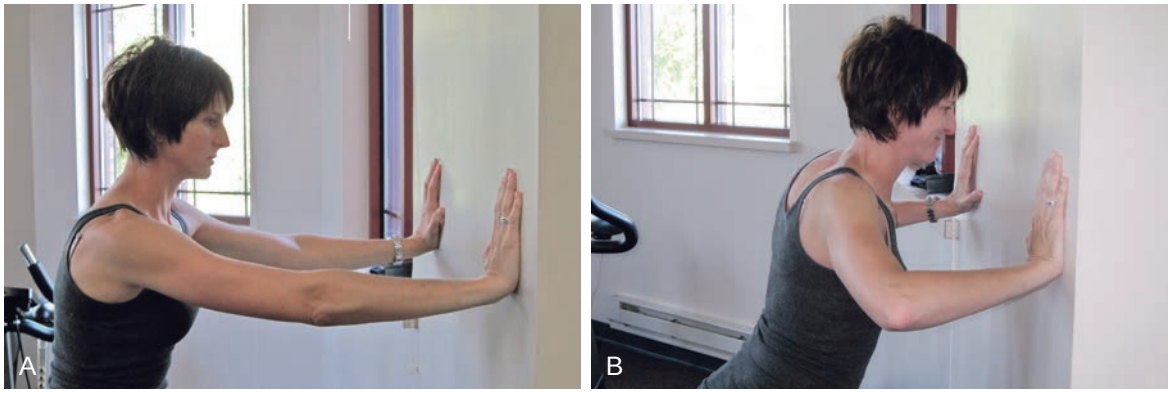

FIGURE 6-13. Wall pushup for serratus anterior strengthening.

- Once patient achieves this pain-free ROM, stretching/flexibility exercises should continue for maintenance of ROM and should be encouraged as part of HEP.

Other Therapeutic Exercises

- Progressive scapular stabilizer exercises that address patients' neuromuscular control deficits, weaknesses, or muscular imbalances.
  - Exercises focusing on lower trap facilitation and strengthening with low upper trap/lower trap ratio
    - Forward flexion in side-lying with dumbbell.
    - Prone horizontal abduction with external rotation. Add a dumbbell when appropriate.
  - Exercises focusing on middle trap strengthening with low upper trap/middle trap ratio
    - Prone extension with external rotation with dumbbells.
  - Wall pushup plus for serratus anterior (Figure 6-13)
- Progressive rotator cuff isotonics. Exercise prescription should be 3 sets of 15 to 20 reps to create a fatigue response as these muscles are designed to be fatigue resistant, and restoring muscular endurance is important for shoulder stabilization with repetitive overhead movements.[1]
  - Progress side-lying external rotation with dumbbell and towel roll under elbow
  - Begin standing Thera-Band internal and external rotation (Figures 6-14 and 6-15)
- Once patient can demonstrate good scapular control and minimal fatigue with 3 full sets of 20 of the progressive scapular stabilizer exercises and progressive rotator cuff isotonics, progress to the following exercises. The patient must be able to perform the following exercise with perfect scapular control. If the patient cannot demonstrate perfect control, the patient may need to begin with AROM with or without gravity.
  - Standing and/or prone full can scaption with dumbbell for supraspinatus[8]
  - Prone external rotation at 90° abduction with dumbbell for infraspinatus[8]
- Final progression includes the start of multiple angle submaximal strengthening such as D2 flexion PNF with Thera-Band with good scapular control (Figure 6-16).

Activation of Primary Muscles Involved

- Muscle activation/strengthening of lower trap, middle trap, and serratus anterior muscles to improve scapular mechanics/upward rotation with overhead activities.
- Strengthening of the rotator cuff muscles are necessary to improve or normalize glenohumeral joint stability

FIGURE 6-14. Thera-Band internal rotation at 0° abduction with towel roll to increase the subacromial space.

FIGURE 6-15. Thera-Band external rotation 0° abduction with towel roll to increase subacromial space and optimize infraspinatus muscle activity.

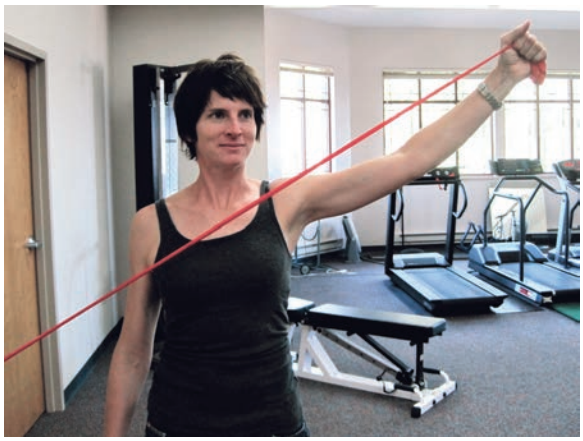

FIGURE 6-16. Thera-Band diagonal 2 flexion PNF for combined glenohumeral joint flexion, external rotation, and horizontal abduction and scapular upward rotation.

and arthrokinematics. Since impingement syndrome often leads to specific weakening of the supraspinatus and infraspinatus muscles caused by impingement on their tendons in the subacromial space, special attention should be given to these muscles.

Sensorimotor Exercises

- Begin with rhythmic stabilization—3 sets for 30 to 60 seconds
- Progress to higher level closed kinetic chain (CKC) stabilization exercises—3 sets for 30 to 60 seconds
  - Stabilization exercises using small medicine ball against the wall with manual perturbations (Figure 6-17).

FIGURE 6-17. Rhythmic stabilization with medicine ball against the wall at 90° abduction using the scapular plane. Perturbations applied until fatigue.

FIGURE 6-18. Bodyblade stabilization in the 90°/90° position using the scapular plane.

Techniques to Increase Muscle Strength, Power, and Endurance

- Begin rotator cuff endurance exercises. Exercises should be done for 3 reps of 30 to 60 seconds at a time or until fatigued.[1]
  - Bodyblade—IR/ER at 0° abduction with progression to IR/ER at 90° abduction (Figure 6-18)
  - TB external rotation oscillation (Figure 6-19)

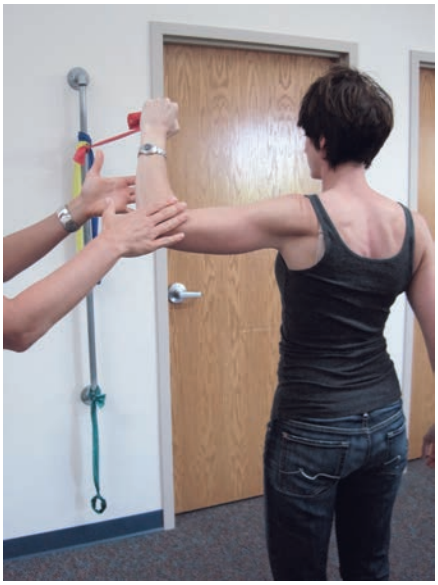

FIGURE 6-19. Stabilization exercise with perturbations applied while the patient maintains their upper extremity in the 90°/90° position using the scapular plane.

Milestones for Progression to the Next Phase

- Full, nonpainful AROM
- Seventy percent strength compared to contralateral side. The most valid and reliable measurement would be to use a hand-held dynamometer for manual muscle tests of all shoulder muscles (including rotator cuff muscles, biceps, triceps, and deltoids), and then comparing the results to the contralateral side.
- No pain or tenderness

Phase III: Advanced Strengthening (weeks 6 to 24)

Goals

- Goals of this phase of rehabilitation are to regain full shoulder strength. The patient should be able to resume all daily activities with no pain, weakness, or fatigue issues after this phase. Most patients do not require formal physical therapy beyond this phase unless they plan to return to higher-level sport, activity, or vocation.

Techniques for Progressive Increase in Range of Motion

- Patient should have full AROM/PROM in all planes and independence with a stretching/flexibility program for maintenance at this point.

Manual Therapy Techniques

- Continue as in Phases I and II for maintenance of ROM as needed.

Soft Tissue Techniques

- Continue as in Phases I and II for maintenance of ROM as needed.

Stretching and Flexibility Techniques for the Musculotendinous Unit

- Continue as in Phases I and II for maintenance of ROM as needed.

Other Therapeutic Exercises

- Progress rotator cuff isotonics
  - Increase weight or resistance of side-lying ER, Thera-Band IR/ER at neutral but keep repetitions high (3 sets of 10 or more repetitions, 3 times a week) as the rotator cuff is an endurance group of muscles.
  - Progress to Thera-Band IR/ER at 90° abduction—3 sets of 10 or more repetitions. Do 3 times a week.
  - Prone horizontal abduction in 135° abduction with external rotation—10 times 10-second holds, once a day
- Progress serratus anterior strengthening to quadruped or plank position—3 times 10 reps; 3 times a week
- Progress scapular stabilizer strengthening exercises
  - High and low rows for upper trap, middle trap and lower trap strengthening—3 times 10 reps; 3 times a week
  - Military press for upper trap strengthening—3 times 10 reps; 3 times a week

Activation of Primary Muscles Involved

- Progression of exercises should be towards doing exercises at 90° abduction in scapular plane especially when preparing an athlete to return to overhead sports.[1]

Sensorimotor Exercises

- Stabilization on wobbleboard in quadruped or plank position with manual perturbations—3 times 30-second holds; 3 times a week
- Perturbations throughout range with many exercises (D2 flexion, ER/IR with Thera-Band, etc.)
- Stabilization on stability ball—3 times 30-second holds; 3 times a week

Techniques to Increase Muscle Strength, Power, and Endurance

- Progress rotator cuff endurance exercises
  - Thera-Band external rotation stabilization exercise in 90°/90° position and manual perturbations by therapist—3 times 30- to 60-second holds with good scapular positioning.[1]
  - Isokinetic internal and external rotation strengthening if available

Plyometrics

- Initiate upper extremity plyometrics late in this phase of rehab only if patient plans to return to overhead athletics/vocation.
  - Trampoline toss and catch with light medicine ball—shoulder in 90°/90° position (Figure 6-20)
  - Supine catch and toss with medicine ball with shoulder in 90°/90° position
  - Eccentric internal and external rotation TB exercises with medicine ball or Thera-Band focusing on both cocking and follow-through phases of throwing/overhead sports

Milestones for Progression to Advanced Sport-Specific Training and Conditioning

- Full, nonpainful AROM
- Full shoulder strength and endurance
- No pain or tenderness
- Satisfactory clinical examination
- Able to resume all daily activities with no problems

Phase IV: Return to Sport/Vocation (weeks 24 and beyond)

- This phase of rehabilitation is only necessary for patients hoping to return to sport or high level manual labor vocations.
- Rehab focuses on sport-specific training and improving full body cardiovascular endurance, power, and strength.
- This phase may include a work hardening/work conditioning program and functional capacity evaluation or

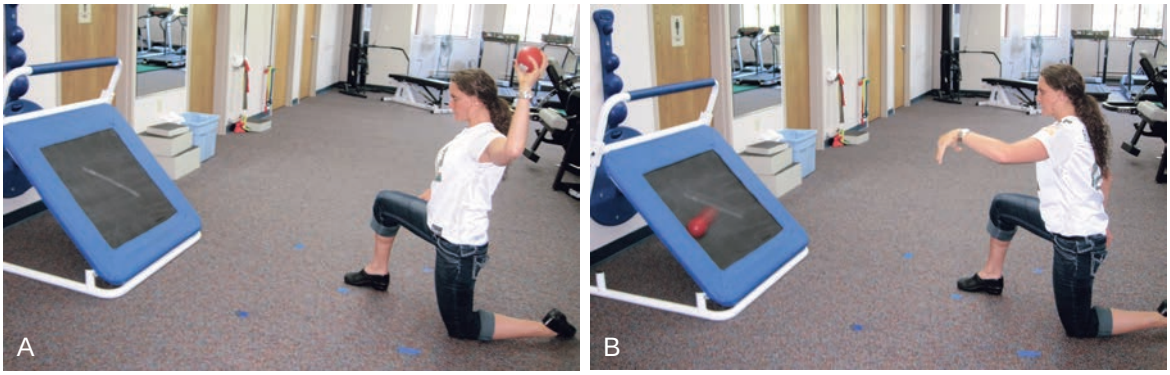

FIGURE 6-20. Medicine ball toss using rebounder for upper extremity plyometric training.

a progressive throwing, golf, or tennis program, etc. (see following sections).

Specific Criteria for Return to Sports Participation: Tests and Measurements

- At this point, the athlete should have full shoulder strength and endurance compared to contralateral side as evidenced by hand-held dynamometry measurements.
- Depending on their sport, athletes should pass specific upper extremity functional tests before returning. Examples include:
  - Closed kinetic chain upper extremity stability test (applies to any sport using upper extremities)
  - Seated shot put test (applies to any sport using upper extremities)
  - Functional throwing performance index (for baseball players)
  - Underkoeffler overhand softball throw (for softball players)
- Completion of interval program for the patient's specific sport. Brotzman and Wilk's *Clinical Orthopaedic Rehabilitation*, ed 2, 2009, *(pages 189–195)* provides several interval programs including a program for pitchers, a program for catchers, infielders, and outfielders, a program for tennis players, and a program for golfers.
- Returning to sport is dependent on the specific sport and the level of competition.

Evidence

Boettcher C, Ginn K, Cathers I: Which is the optimal exercise to strengthen supraspinatus? *Med Sci Sports Exerc* 41:1979–1983, 2009.

This article supports the use of selected rotator cuff and deltoid strengthening exercises based on their EMG results of five different exercises. (Level IV evidence)

Cools A, Dewitte V, Lanszweert F, et al: Rehabilitation of scapular muscle balance: Which exercises to prescribe? *Am J Sports Med* 35:1744–1751, 2007.

This controlled laboratory study looked at electromyographic activity of the upper trap, middle trap, lower trap, and serratus anterior muscles in 45 subjects during 12 commonly prescribed exercises. This study stresses selecting exercises in rehabilitation that not only strengthen weaker muscles but that also strengthen muscles to optimize muscle ratios of upper trap to lower trap, middle trap, and serratus anterior in individuals demonstrating muscle imbalances. This article supports the use of specific exercises with a low upper trap/lower trap ratio in patients diagnosed with subacromial impingement and demonstrate upper trapezius dominance. (Level IV evidence)

Ellenbecker T, Cools A: Rehabilitation of shoulder impingement syndrome and rotator cuff injuries: an evidence-based review. *Br J Sports Med* 44:319–327, 2010.

This comprehensive review of the literature supports the use of using a comprehensive evaluation to drive the treatment of athletes with shoulder impingement and suggest that treatment should be multifactorial including techniques to restore ROM, rotator cuff and scapular strength and glenohumeral joint stabilization. (Level V evidence)

Kelly S, Wrightson P: Clinical outcomes of exercise in the management of subacromial impingement syndrome: a systematic review. *Clin Rehabil* 24:99–109, 2010.

This review of eight studies that used exercise in the treatment of subacromial impingement syndrome suggests that exercise treatment is an effective treatment to some degree but suggests lack of consistency for exercise prescription including type of exercise, repetitions, supervision and length of programs. (Level 1A evidence)

Kibler B, Sciascia A: Current concepts: scapular dyskinesis. *Br J Sports Med* 44:300–305, 2010.

This article describes the role of the scapular as it relates to normal glenohumeral rhythm and supports the use of evaluating and treating scapular movement dysfunction when treating patients with shoulder impingement. (Level V evidence)

Kromer T, Tautenhahn U, deBie R, et al: Effects of physiotherapy in patients with shoulder impingement syndrome: A systematic review of the literature. *J Rehabil Med* 41:870–880, 2009.

This review of 16 randomized controlled trials of common physiotherapy interventions for shoulder impingement syndrome supports the use of physiotherapist-led exercises in combination with manual therapy for effective treatment of shoulder impingement. The review also determined limited evidence for the use of passive modalities including

ultrasound, low-level laser therapy, and electromagnetic field therapy. (Level 1A evidence)

Lombardi I, Guarnieri A, Fleury A, et al: Progressive resistance training in patients with shoulder impingement syndrome: A randomized controlled trial. *Arthritis Rheum* 59:615–622, 2008.

This randomized controlled trial of 60 patients diagnosed with shoulder impingement syndrome supports the use of a progressive resistance-training program as an effective treatment in improving pain, function, and quality of life. (Level 1B evidence)

Selkowitz DM, Chaney C, Stuckey SJ, et al: The effects of scapular taping on the surface electromyographic signal amplitude of shoulder girdle muscles during upper extremity elevation in individuals with suspected shoulder impingement syndrome. *J Orthop Sports Phys Ther* 11:694–702, 2007.

This multifactorial, repeated-measures, within-subjects design study discusses how scapular taping decreases upper trapezius and lower trapezius muscle activity in subjects with suspected shoulder impingement during functional overhead activity. (Level IV evidence)

Senbursa G, Baltaci G, Atay A: Comparison of conservative treatment with and without manual physical therapy for patients with shoulder impingement syndrome: a prospective, randomized clinical trial. *Knee Surg Sports Traumatol Arthrosc* 15:915–921, 2007.

This randomized control trial suggests that manual therapy consisting of joint mobilization and soft tissue mobilization in conjunction with a 12 session stretching and strengthening program is superior to exercise alone for improvements in pain and shoulder function. (Level IIB evidence)

Tate A, McClure P, Young I, et al: Comprehensive impairment-based exercise and manual therapy intervention for patients with subacromial impingement syndrome: a case series. *J Orthop Sports Phys Ther* 40:474–493, 2010.

This case series supports the use of a comprehensive impairment-based treatment philosophy in patients diagnosed with subacromial impingement syndrome. Eight of ten patients demonstrated improvements in shoulder symptoms and function with the use of a three-phase strengthening program in conjunction with manual stretching and manual therapy techniques for both the thoracic spine and the glenohumeral joint. (Level IV evidence)

Multiple-Choice Questions

QUESTION 1. What is the purpose of using grade III and IV joint mobilizations to the glenohumeral joint?

A. To gain all motion not equal to contralateral extremity
B. To treat the hypomobile shoulder with firm capsular end feel
C. To facilitate proprioception and neuromuscular control
D. To treat motion losses with empty end feel

QUESTION 2. To measure glenohumeral internal rotation:

A. Allow scapular motion with glenohumeral motion since it is more functional
B. Measure in side-lying since the scapula is stabilized by the patient's body
C. There is no need to measure internal rotation; it is not a useful motion for the athlete
D. Avoid scapular contribution and measure in the scapular plane

QUESTION 3. The most common scapular dyskinesis pattern is:

A. Anterior tilt, upward rotation, and external rotation
B. Posterior tilt, upward rotation, and internal rotation
C. Anterior tilt, downward rotation, and internal rotation
D. Anterior tilt, downward rotation, and external rotation

QUESTION 4. Lack of neuromuscular control and strength of which muscles are thought to contribute most to scapular dyskinesis?

A. Serratus anterior and lower trapezius
B. Middle trapezius and rhomboids
C. Upper trapezius and serratus anterior
D. Middle trapezius and lower trapezius

Answer Key

QUESTION 1. Correct answer: **B** (see Phase I)

QUESTION 2. Correct answer: **D** (see Phase I: Stretching Techniques)

QUESTION 3. Correct answer: **C** (see Phase I)

QUESTION 4. Correct answer: **A** (see Phase I)

POSTOPERATIVE REHABILITATION AFTER SUBACROMIAL DECOMPRESSION

Stephen C. Weber, MD, and Donald Torrey, PT

Indications for Surgical Treatment

- Failure of nonoperative treatment over 3 to 6 months
- Persistent activity-related pain that limits function
- Previous attempts at nonoperative care, including nonsteroidals, activity modification, and a consistent rehabilitation program
- Although prospective studies have found it difficult to establish the long-term benefits of steroid injections, the authors' experience would indicate minimal risk and general benefit to their use in both diagnosis and treatment
- Normal passive range of motion
- Imaging studies negative for other findings, and consistent with the diagnosis of impingement, such as appropriate acromial morphology on radiographs (Figure 6-21), and imaging findings on MRI consistent with impingement
- Temporary pain relief with the instillation of local anesthetic into the subacromial space

Brief Summary of Surgical Treatment

Major Surgical Steps

- General anesthesia or scalene block at the preference of the surgeon
- Lateral decubitus or beach chair position
- Diagnostic arthroscopy to establish pathology, and to rule out other causes of shoulder pain
- Treat associated intraarticular lesions as indicated
- Arthroscope is then shifted to the subacromial space, and other subacromial pathology excluded (Figure 6-22)
- Transection or anterior release of the coracoacromial ligament
- Inflamed bursal tissue (usually anterior half) is removed with a shaver or radiofrequency wand
- Viewing posteriorly, initially remove 4 to 8 mm of the undersurface of the anterolateral acromion, depending on preoperative radiographs
- Anterior acromion removed to this level and flush with remaining acromion
- Avoid acromioclavicular (AC) joint unless this joint is symptomatic. However, a coplaning can be done to remove an inferior osteophyte at the AC joint that may also be causing "impingement" of the rotator cuff
- Scope switched to anterolateral portal, and using "cutting block" technique the acromioplasty completed (Figure 6-23); ensure that enough bone remains so that the risk of fracture (and stress fracture) is minimized
- Sling for comfort postoperatively

Factors That May Affect Rehabilitation

Anesthetic

- Regional anesthesia can create issues with rebound pain and other unique complications to this anesthetic

FIGURE 6-21. Scapular lateral film, showing acromial prominence.

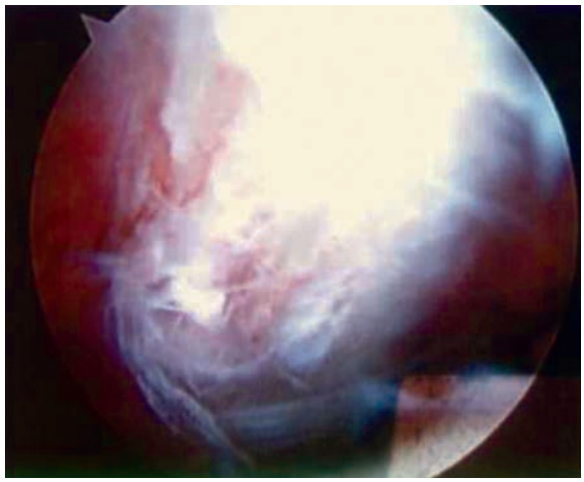

FIGURE 6-22. Preoperative view of undersurface of acromion, suggesting impingement.

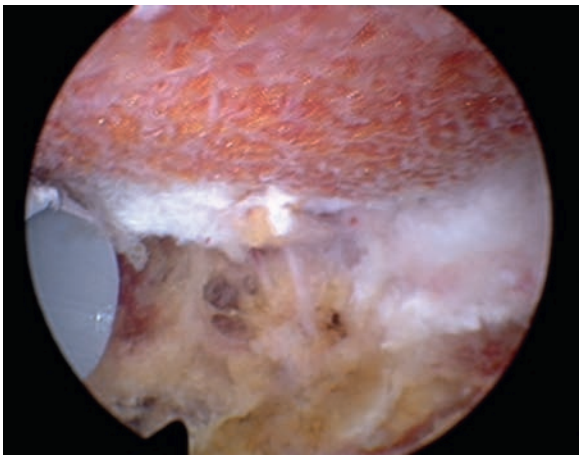

FIGURE 6-23. Completed acromioplasty, viewed from posterior.

Surgical

- Ancillary procedures performed, such as labral or rotator cuff repair, may impose restrictions on early mobilization.
- If case is performed open, additional restrictions may apply to protect from injury to the attachment of the deltoid.

GUIDING PRINCIPLES OF POSTOPERATIVE REHABILITATION

- Understand whether the procedure involves simple acromioplasty, or repair of other structures that require additional rehabilitation restrictions
- Although early motion is permitted, forced passive motion or early strengthening inhibit the healing process and can actually cause stiffness and protracted recovery
- One needs to respect rate of ROM progression within these guidelines

After Surgery—Postoperative Rehabilitation: Overview of Goals, Important Milestones, and Guidelines

See Table 6-1.

Table 6-1 Postoperative Rehabilitation Guidelines

Postoperative Time	Immobilization	ROM, rehab	Restrictions
0–14 days	Sling as needed	Pendulum exercises	ADLS
2–4 weeks	None	Passive and active assisted ROM	ADLS, LE exercises only, stationary bike for aerobic exercise
4–8 weeks	None	Thera-Band exercises	Add running
8–12 weeks	None	Assisted stretching if not full ROM	Avoid overhead weight work sport-specific exercise
>12 weeks	None	Resume full ROM	Sport-specific exercise until return to sport unrestricted

Phase I: Immediate Postoperative Period (days 0 to 14)

Clinical Pearls

- Patients need to be carefully monitored for stiffness regularly (no more than 3-week intervals). Early gentle ROM to minimize long-term problems is helpful. Early recognition of the development of postoperative stiffness can minimize this complication.
- Passive stretching is to be avoided early to prevent increased pain and inflammation that can lead to later stiffness and prolonged recovery.

Goals

- Minimize the effects of immobilization
- Decrease pain and inflammation
- Check for signs of complications (infection, neurologic injury, poor pain management). Review of postoperative scapular lateral radiograph can identify any early complications or inadequate bone resection. If these issues are not a problem, the next phase can be initiated.

Protection

- Sling as needed for comfort
- No other protection needed for isolated acromioplasty

Management of Pain and Swelling

- Pain pumps are generally contraindicated
- Oral pain medications or tylenol
- As nonsteroidals can inhibit healing and decrease platelet function, these should be avoided for 5 to 7 days
- Ice every 20 minutes an hour is reasonable
- Cryotherapy units can burn skin and are outside FDA black box warning for 24 hours postoperatively if any local anesthetics are used
- Patient Education: Using pillows or bolsters to find a position of comfort; sleep is often aided by a more vertical positioning

Techniques for Progressive Increase in Range of Motion

Manual Therapy Techniques

- Codman's Pendulum exercises are generally adequate
- Exercises for hand, wrist and elbow can be initiated

Other Therapeutic Exercises

- Stationary biking can begin immediately after surgery
- LE strength training with machines
- Treadmill walking in sling as tolerated

Phase II (weeks 2 to 4)

Goals

- Maintain program of treatment of pain and inflammation
- Minimize effects of early loss of motion
- Decreasing pain and improving ROM

Protection

- Sling can be discontinued

Management of Pain and Swelling

- Oral narcotics can be tapered or discontinued
- Continue nonsteroidals or Tylenol
- Although modalities can be useful, they are not a substitute for a supervised home therapy program

Techniques for Progressive Increase in Range of Motion

Manual Therapy Techniques

- Patients are instructed in active-assisted ROM exercises with a pulley and stick (Figure 6-24)

FIGURE 6-24. Use of pulleys to improved external rotation.

- These are to be performed several times a day
- Exercises for hand, wrist, and elbow to continue

Stretching and Flexibility Techniques for the Musculotendinous Unit

- Passive stretching to be avoided

Phase III (weeks 4 to 8)

Goals

- AROM 150° forward flexion
- AROM 50° external rotation arm at side
- Normalizing glenohumeral and scapulothoracic mechanics
- Initiation of strengthening exercises

Management of Pain and Swelling

- Nonsteroidals as indicated
- Ice as needed 20 minutes an hour and post exercise 2 to 3 times a day
- Heat before initiation of stretching and exercise

Techniques for Progressive Increase in Range of Motion

Manual Therapy Techniques

- Done as needed, primarily for patients having trouble with ROM. If needed, a prescription for 1 to 2 times per week normally will start at 3 weeks if not improving. Less than 20% of patients should need help.

Stretching and Flexibility Techniques for the Musculotendinous Unit

- Pulley and wand exercises continue, with table slides, and wall walking exercises. All ROM exercises are done for 3 minutes 3 times per day. ROM work usually lasts for 1 to 2 months.

Techniques to Increase Muscle Strength, Power, and Endurance

- Thera-Band exercises begin in flexion, internal, external rotation and extension. Exercises are done 45 to 60 reps per day in sets of 15 (Figure 6-25 and 6-26).
- Keep all exercises below 90° plane.
- Attention to scapular stabilization by doing exercises in mirror if necessary.

TIMELINE 6-2: **Postoperative Rehabilitation After Subacromial Decompression**

PHASE I (days 0 to 14)	PHASE II (weeks 2 to 4)
• Sling as needed • Ice • Codman's pendulum exercises • Stationary bike	• Sling discontinued • Pulley and wand exercises • Modalities if needed

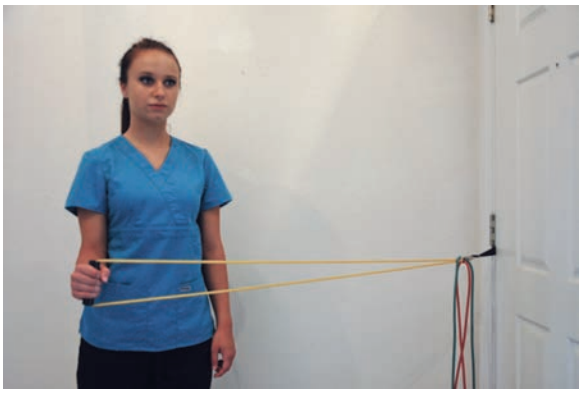

FIGURE 6-25. Band exercises for external rotational exercises.

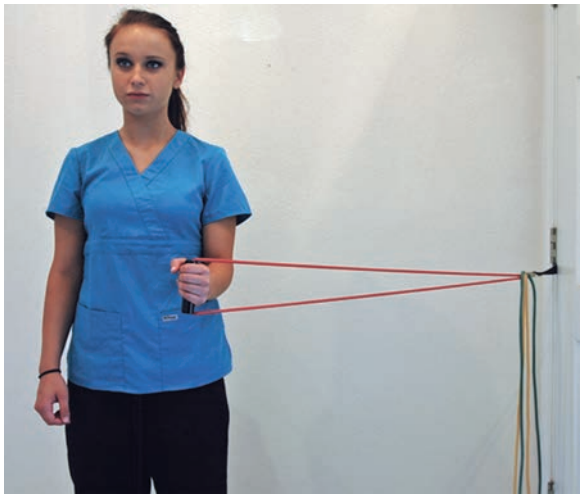

FIGURE 6-26. Band exercises for internal rotation strengthening.

- Scapular stabilization exercises
- Band exercises only for first 6 weeks minimum; lasts 2 to 3 months

Phase IV (weeks 8 to 12)

Clinical Pearls

- If full passive ROM has not been achieved, passive stretching can be initiated at this time. Heat and modalities can be helpful, but are not required. Focus at this point on passive stretching can avoid later complications with stiffness requiring later manipulation or arthroscopic release.
- Studies have demonstrated that athletes who maintain appropriate scapulothoracic mechanics have significantly less injury. Avoiding loss of motion, especially internal rotation, can prevent development of glenohumeral internal rotation deficit (GIRD) and subsequent impingement.

Goals

- Normal scapulohumeral rhythm
- Full PROM in all planes
- AROM near full with minimal pain
- Strength MMT 4/5 in all planes

Management of Pain and Swelling

- Oral NSAIDs, Tylenol
- If pain continues to be a limiting factor, the patient should be returned to the surgeon for reassessment
- Soft tissue techniques can be useful, but vigorous release techniques are generally counterproductive
- Scar mobilization reasonable

Other Therapeutic Exercises

- Sport-specific exercises can be initiated for upper extremity work such as Jobe exercises using a gradual approach limiting resistance and increasing repetitions
- High intensity above shoulder resistance work should be avoided until 12 weeks

Phase V (weeks 12+)

Management of Pain and Swelling

- Ice application postexercise

Techniques for Progressive Increase in Range of Motion

- Patients should have achieved full AROM by this time

Stretching and Flexibility Techniques for the Musculotendinous Unit

- Passive stretching to continue if indicated

Techniques to Increase Muscle Strength, Power, and Endurance

- Although impingement is not generally a diagnosis of young throwing athletes, throwing athletes may begin

TIMELINE 6-2: Postoperative Rehabilitation After Subacromial Decompression (Continued)

PHASE III (weeks 4 to 8)	PHASE IV (weeks 8 to 12)	PHASE V (weeks 12+)
• Continue pulley and wand exercises • Start Thera-Band exercises • Hold other upper extremity exercises	• Continue pulley and wand exercises • Continue Thera-Band exercises; initiate low resistance, high repetition exercise program below shoulder level • If full PROM not present, initiate gentle passive stretching exercises • Attention to scapular mechanics	• Continue Thera-band • Start sport-specific exercise programs, Jobe exercises • Monitor return to sports carefully

light tossing at shorter distances and are instructed to avoid full windup throws until 20 weeks postoperatively. Interval training programs can be useful. Limited overhead stroke work for swimmers, tennis, and volleyball players.
- Progression of throwing intensity may begin at 14 to 16 weeks as long as the patient demonstrates good mechanics. Throwing should be closely monitored and discontinued if the athlete exhibits any compensatory movement patterns or shoulder girdle discomfort. Resumption of other overhead sports can be managed similarly.
- Progression to formal strength and conditioning commences once athletes have 4+/5 rotator cuff strength, full AROM, and are pain-free with activity.

Criteria for Return to Sport

General

- Normal scapulothoracic and glenohumeral mechanics
- Full AROM
- Normal strength to manual muscle testing
- Athletes at risk can benefit from isokinetic testing, emphasizing a 90% or better side-to-side difference in internal and external rotation.

Sport-Specific

- Coaches and trainers can be helpful in assessing specific sport rehab issues
- Although no hard and fast rules apply, most patients without appropriate supervision return too soon, and reinjure or inflame previously injured or operated structures

After Return to Sport

Continuing Fitness or Rehabilitation Exercises

- Total upper extremity and total body strengthening exercises

Exercises and Other Techniques for Prevention of Recurrent Injury

- Prevention of injury is best accomplished by maintaining the shoulder rehabilitation program throughout athletic participation, with specific emphasis on rotator cuff strengthening.

A program aimed at strengthening rotator cuff and scapular muscles, with stretching and manual therapy aimed at thoracic spine and the posterior and inferior soft-tissue structures of the glenohumeral joint appeared to be successful in the majority of patients. (Level IV evidence)

Multiple-Choice Questions

QUESTION 1. The diagnosis of impingement is made by:

A. Normal passive range of motion
B. Imaging studies negative for other causes of pain
C. Pain relief with subacromial lidocaine injection
D. All of the above

QUESTION 2. Correct surgical technique for acromioplasty:

A. Can only be done beach chair
B. Always involves resection of the distal clavicle
C. Use of "cutting block" technique
D. Can be done blindly if visualization is poor

QUESTION 3. Postoperative pain and swelling can be managed by:

A. Immediate use of nonsteroidals
B. Pain pumps
C. Cryotherapy pumps
D. Oral pain meds or tylenol

QUESTION 4. Scapulothoracic function _____:

A. Is not important
B. If dysfunctional usually represents a nerve injury
C. Can be related to glenohumeral internal rotation deficits (GIRD)
D. Requires manual therapy

QUESTION 5. Return to sport varies, but must involve:

A. Full ROM
B. Normal strength
C. No pain
D. All of the above

Answer Key

QUESTION 1. Correct answer: **D** (see Indications for Surgical Treatment)

QUESTION 2. Correct answer: **C** (see Surgical Technique)

QUESTION 3. Correct answer: **D** (see Phase I: Management of Pain and Swelling)

QUESTION 4. Correct answer: **C** (see Phase IV)

QUESTION 5. Correct answer: **D** (see Criteria for Return to Sport)

BEYOND BASIC REHABILITATION: RETURN TO PITCHING AFTER SUBACROMIAL DECOMPRESSION

Michael G. Ciccotti, MD, and Scott P. Sheridan, PT, ATC, CSCS

Introduction

- The overhead or throwing athlete is exposed to a tremendous variety of forces during the act of throwing. This complex baseball throwing motion has been thoroughly evaluated by multiple authors.[1–3]
- The precise shoulder muscle activity in each of the five phases of pitching (Figure 6-27) has been defined by several electromyographic studies.[2,4]
- Other authors have identified the importance of the scapula, core, hips, and legs in this activity[5–8] Kibler[9] has described this Kinetic Chain Theory wherein the force imparted on a ball begins at the ground, is amplified through the legs, hips and core, and transmitted to the upper extremity via the shoulder.
- Most often there is a precise balance in the musculoskeletal system that allows these athletes to perform this throwing maneuver painlessly and effectively. Not infrequently, though, that balance may be lost and injury may occur.
- This injury takes a wide spectrum of form that often involves the rotator cuff and presents with impingement-like symptoms.
- The etiologic factors vary from primary rotator cuff tendon failure, altered scapular mechanics, posterior capsular and posterior rotator cuff contracture, anterior

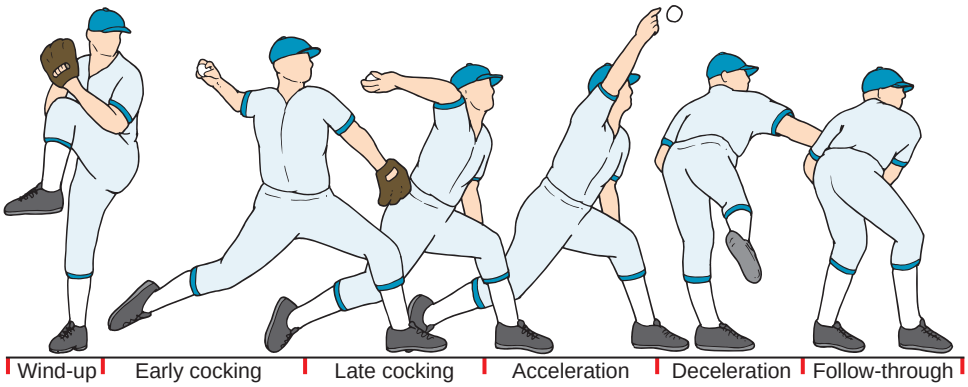

FIGURE 6-27. The phases of throwing. *(Redrawn from Ciccotti MG, Jobe FW. Medial collateral ligament instability and ulnar neuritis in the athlete's elbow. American Academy of Orthopedic Surgery Instructional Course Lectures 48:384, 1999, figure 1.)*

capsular strain or laxity, labral fraying and tearing, to even infrequently primary subacromial impingement.

- Primary subacromial impingement is defined as a repetitive injury to the anterolateral aspect of the rotator cuff (especially the supraspinatus portion) caused by supraspinatus outlet narrowing.
- Kibler has proposed that the subacromial space is a dynamic region whose borders are affected by numerous intrinsic and extrinsic factors.[10]
- Intrinsic factors occur within the subacromial space and include acromial bone spurs, coracoacromial ligament hypertrophy, bursitis, calcific enthesopathy, and os acromiale.
- Extrinsic factors occur beyond the subacromial space and include superior humeral head translation or altered scapulothoracic rhythm. Superior humeral head translation may result from rotator cuff tear or tendonopathy or labral injury. Altered scapulothoracic rhythm may be a result of glenohumeral instability, perishoulder contracture or inflexibility, scapular dyskinesis, acromioclavicular arthrosis or instability, biceps tendonopathy, or neurologic injury.
- Rotator cuff impingement in the throwing athlete may be the result of any number of these etiologic factors occurring concomitantly. The thrower may be exposed to a cascade of events that result in some combination of several or all of these pathologies.[11] With repetitive throwing, rotator cuff and periscapular muscle weakness can develop. With this a posterior capsular and/or rotator cuff contracture or inflexibility ensues. In throwing athletes with these two events, a posterior superior humeral instability occurs when the arm is abducted and externally rotated in the throwing mechanism. This creates an extrinsic subacromial impingement and glenohumeral peel back mechanism. This peel back force can lead to superior labral and posterior superior rotator cuff fraying or tearing. Although several pathologies may be present in these athletes, the main presentation may be that of subacromial impingement.
- Previous sections in this chapter have outlined nonsurgical rehabilitation of rotator cuff impingement syndrome. If this structured nonsurgical protocol does not allow the athlete to return to preinjury performance, then surgical treatment may be necessary.
- Surgical treatment focuses on the specific pathologies present. For those overhead or throwing athletes with primary, intrinsic subacromial impingement, subacromial decompression has been proposed.[12–15]
- Initial reports on subacromial decompression in the overhead athletic population have noted inconsistent outcomes.[12–15] These authors suggest this may be a reflection of the complex nature of this injury in the throwing athlete, which most often involves several of the previously described, inter-related pathologies. All of these factors require focused attention for a truly successful postoperative outcome.
- In throwers, primary impingement is most likely to be an incomplete diagnosis, with varying degrees of rotator cuff injury, labral fraying or tearing, posterior capsular or rotator cuff contracture, and even anterior capsular laxity present. These shoulder-specific, concomitant pathologies may require focused surgical attention as well, including rotator cuff debridement or repair, labral debridement or repair, posterior capsular release, or infrequently even anterior capsular plication.[16–22]
- Furthermore, nonshoulder sources of disability such as core, hip, and leg weakness or inflexibility may be present in the throwing athlete. These nonshoulder abnormalities mandate focused attention in the postsurgical rehabilitation program after subacromial decompression. And, in fact, failure to correct these issues may be just as likely as the specific surgical technique to prevent a throwing athlete from returning to preinjury level of sport.

Postsurgical Rehabilitation Program

- The postsurgical rehabilitation after subacromial decompression depends on the specific surgical treatment performed.
- For those throwers with primary, intrinsic subacromial impingement having undergone isolated subacromial decompression with, at most, debridement of the rotator cuff or labrum, the postsurgical rehabilitation follows principles similar to nonsurgical rehabilitation.

- For those throwers undergoing concomitant rotator cuff or labral repair, special attention is focused on allowing biologic healing while preventing capsular contracture and muscular weakness. In addition, postsurgical rehabilitation after subacromial decompression in the throwing athlete necessitates attention to the extrinsic and nonshoulder factors described previously. Therefore, the rationale for the phased, progressive postsurgical rehabilitation after subacromial decompression in the throwing athlete is predicated on the specific contributing pathologies, the individual demands of throwing, and known biomechanical and kinesiologic principles.
- The purpose of this chapter is to discuss the end stages of rehabilitation after subacromial decompression in the throwing athlete. The acute and intermediate phases of rehabilitation have been discussed in the previous chapter. (see Chapter 6: Post Surgical Rehabilitation after Subacromial Decompression). However, it will be important to complete a thorough review of what has been accomplished in those phases and what should be evaluated to determine the readiness of an athlete to progress to the functional phase of rehabilitation after this surgical procedure.
- The basic goals that should have been accomplished in the initial phases of rehabilitation are full, pain-free arc of motion, ability to complete basic rotator cuff and scapular stability exercises without symptoms, and total body conditioning that is expected for baseball.
- Range of motion is particularly important in throwers. Of concern is placing the shoulder at risk by not properly identifying glenohumeral internal rotation deficit (GIRD) or changes in total rotational motion (TRM). GIRD, as defined by Burkhart et al.[7], is a greater than 20° loss of internal rotation on the throwing shoulder in comparison to the nonthrowing shoulder. Burkhart indicates the traction forces placed on the shoulder with throwing cause GIRD, and over time a thickening of the posterior inferior capsule occurs.[7]
- Wilk proposed the TRM concept, where the amount of external rotation (ER) and internal rotation (IR) at 90° of abduction are added and a TRM arc is determined.[23]
- Both concepts are appropriate ways to determine the shoulder at risk for injury, although pitchers with GIRD and TRM differences outside the 5° window are at the greatest risk of injury.[24]
- In addition to range of motion, the scapula plays a significant role in the rehabilitation of the throwing athlete. The scapula serves as a base for muscle attachment, positions the glenoid to encourage osseous stability of the glenohumeral joint, and acts as a link in proximal-to-distal sequencing for the function of the shoulder.[6] The goal is to make sure that scapular asymmetry or scapular dyskinesis has been relatively eliminated.
- Lastly, with the understanding of the kinetic chain as noted earlier in this chapter, the previous phases should evaluate several other aspects as they relate to return to throwing. These items are posture, spinal movement/mobility, lower extremity range of motion/flexibility, and conditioning of the athlete.
- Once all the above factors have been completed, evaluated, and are satisfactory, the progression to the functional phase of rehabilitation can be initiated.
- As indicated above, this chapter is dedicated to beyond basic rehabilitation and return to pitching after subacromial decompression. For the purpose of this chapter, a throwing program for a starting pitcher is discussed as opposed to a relief pitcher. The overall program in regards to exercise, conditioning, and techniques is similar, however, the total time dedicated to throwing and mound progressions for return to pitching would differ.
- Periodization is the planned manipulation of training variables (load, set, and repetitions) to maximize training adaptations and prevent the onset of overtraining syndrome.[25] Periodization of the exercises in this phase would be nonlinear or undulating.
- In general, some modification of the exercise variables would be made on a weekly or biweekly basis. Exercises in this particular phase would be initiated at one set of 10 to 15 repetitions. The long-term goal would be to progress to 2 to 3 sets of exercises with repetitions of 25 to 30 per set.
- Starting pitchers will need to prepare for a significant number of repetitions over the course of pitching in games, but also long tossing on a daily basis.
- In the off-season, the program may be completed on a 3 to 4 times per week basis; as spring training and the season begins, however, the program in place will be accomplished 7 days per week.
- In some cases the speed of exercises will be increased, however, with the realization that no particular exercise can mimic the significant velocity involved in actually throwing or pitching a baseball.
- Shoulder internal rotation during a pitch is the fastest human movement recorded, and it occurs in excess of 7250° per second.[26]
- Most programs are performed with minimal rest periods and exercise order may be the most important factor to modify.
- When a throwing program is just being initiated, the order may be less important (other than the necessity to accomplish a dynamic warmup before throwing).
- As the number of throws, distance, and mound progressions are accomplished, limited strength work is completed before throwing.
- Once the pitcher is back to games, the program should be reevaluated to accommodate the typical 5-day rotation that is set up for a starting pitcher.
- Overall this phase of rehabilitation will be broken down into three programs: Advanced strength and conditioning, Performance enhancement techniques, and Sport-specific training. This is done to better define each area; however it should be understood that these programs are all occurring and overlapping during the functional phase of rehabilitation after subacromial decompression. These programs are initiated at approximately 8 to 10 weeks after isolated subacromial decompression and 16 weeks after decompression with either labral or rotator cuff repair. In addition and more importantly, during these programs it will be necessary to continually reevaluate each of the areas discussed above.

ASPECTS OF PITCHING THAT REQUIRE SPECIAL ATTENTION IN REHABILITATION

- Pitching exposes an athlete to a variety of forces during the act of throwing. With repetitive throwing, rotator cuff and periscapular muscle weakness can develop after which posterior capsular and/or rotator cuff contracture or inflexibility ensues.
  - In throwing athletes with posterior capsular and rotator cuff contracture, a posterior superior humeral instability occurs when the arm is abducted and externally rotated in the throwing mechanism creating an extrinsic subacromial impingement and glenohumeral peel back mechanism.
  - Peel back force can lead to superior labral and posterior rotator cuff fraying or tearing.
  - The main presentation may be subacromial impingement, although several pathologies may present.
- In throwers, primary impingement is most likely to be an incomplete diagnosis, with varying degrees of rotator cuff injury, labral fraying or tearing, posterior capsular or rotator cuff contracture, and even anterior capsular laxity present.
- Failure to correct nonshoulder abnormalities, such as core, hip, and leg weakness or inflexibility, may be just as likely as a specific surgical technique to prevent a throwing athlete from returning to preinjury level of sport.

Phase I: Advanced Strength and Conditioning Programs

Program Design/Performance Training Program

- Includes exercises and activities relative to spinal movements, core exercises, and the lower extremity, all of which are key in returning the throwing athlete after subacromial decompression.

Sport-Specific Concepts of Integrated Training

- The initial sport-specific concepts to be addressed in this program are to make sure lower extremity flexibility and spinal mobility are maintained or improved. The exercises and manual therapy skills to be initiated are determined through the evaluation process described above.
- Specific techniques used to address the posterior chain restrictions include:
  - Hamstring progressions in a True Stretch device [27] (Figure 6-28).
  - In addition to the athlete performing these motions in the True Stretch, the therapist can assist in providing additional stability or manual contacts to address specific limitations (Figure 6-29).
  - Furthermore, as part of the regular shoulder stretch routine, a general spinal stretch can be included (Figure 6-30).

Training Principles Used in the Design of the Program

- Typical limitations seen in the overhead athlete include, but are not limited to, posterior chain myofascia, hip

TIMELINE 6-3: **Beyond Basic Rehabilitation: Return To Pitching After Subacromial Decompression***

PHASE I	PHASE II
Advanced Strength and Conditioning: Begins at 8 to10 weeks after isolated SAD or 16 weeks after SAD with labral or rotator cuff repair	***Performance Enhancement Training:*** Begins at 8 to 10 weeks after isolated SAD or 16 weeks after SAD with labral or rotator cuff repair
• Lower extremity flexibility • Hip internal and external rotation • Posterior myofascial work (True Stretch Device) • Spinal mobility • Core stabilization (multiplanar lunges) • Interval running and agilities	• Shoulder and scapular exercises • Basic tubing exercises progress from split stance, to single leg, and finally split stance, narrow base on a balance pad • Impulse machine • Manual resistive exercises (PNF) • Rhythmic stabilization • Passive stretching for upper body and spine

FIGURE 6-28. Hamstring progressions in a True Stretch device during Phase I.

FIGURE 6-29. Therapist providing additional stability and manual contact for athlete while in True Stretch device during Phase I.

internal and external rotation, and spinal motion in positions of side bending and rotation.

- It is important to maximize functional range of motion for baseball. However with the progression of mobility that is created from these activities, it will be important to perform strengthening within the newly gained motions. As stated by Gary Gray, "do not create mobility without sufficient stability".[27]
- With the mobility program in place, exercises to include multiplanar actions and core stability need to be initiated. There are several options for exercises in this area with many modifications that can be made, limited only by the imagination of the therapist. Some particular concepts that are beneficial are multiplanar lunges with progressions of upper body and spinal movements. Even within these simple exercises, there are endless options of progressions. It is important that the lunges are performed in each plane and that one progression is the addition of either bilateral overhead flexion (Figure 6-31) or opposite lunge side rotations

TIMELINE 6-3: **Beyond Basic Rehabilitation: Return To Pitching After Subacromial Decompression*** (Continued)

PHASE III	PHASE IV	PHASE V
Sport Specific Training: Begins at 12 to14 weeks after isolated SAD or 20 weeks after SAD with labral or rotator cuff repair • Tossing/throwing program • Fielding • Hitting • Base running	***Throwing Progressions—Tossing:*** Begins at 12 to 14 weeks after isolated SAD or 20 weeks after SAD with labral or rotator cuff repair • Initiated 3 ×/week • Progress to 2 days on and 1 day off • Continue daily tossing with recovery day built in • Begin with 20–30 throws; increase to 100 throws, splitting into 2 sets • Initial throwing distance is 35–40 ft; increase to 120 ft/more (increase beyond 120 ft is debatable) • Beyond 90 ft, a drop step is used with each throw	***Throwing Progressions—Mound Pitching:*** Begins after completion of the Tossing Program • Athlete must demonstrate quality mechanics, arm strength with throwing, and good response to throwing on consecutive days • Begin with 15 throws from mound • Begin with 2–3 days between sessions progressing to every other day • # of throws gradually progresses up to 70–80 if starting pitcher • The number of throws will be split into groups of ~20 with brief rest periods to simulate "up and down" in a game • All throwing begins with fastballs, followed by change-ups • Breaking pitches are only added when athlete comfortable with velocity and control of fastballs and change-ups • Progress to throwing to batters (BP) • Simulated game • Initial return to play involves careful monitoring of innings pitched, types of pitches, and time of game

*The acute and intermediate phases of rehabilitation have been discussed in the previous section Postsurgical Rehabilitation after Subacromial Decompression.

FIGURE 6-30. General spinal stretch during Phase I.

(Figure 6-32). These types of exercises involve multiple, coordinated movements, and special attention should be paid to activation of the core/transverse abdominis muscles during their completion by the athlete.

FIGURE 6-32. Opposite lunge side rotation while lunging during Phase I.

Phase II: Performance Enhancement Training Techniques

Program Design/Performance Training Program

- The performance enhancement training techniques program includes concepts that are specific to the upper body and essential in returning the throwing athlete after subacromial decompression.
- Initially shoulder and scapular exercises are performed to address individual muscles and are performed in isolation.
- The goal of this program is to perform those same exercises, but add other components to increase the functionality of the exercise. One particular way this is accomplished is by adding balance components, lower extremity movements, or changing the surface upon which the exercise is performed to advance the quality of the exercise.

Training Principles Used in the Design of the Program

- One exercise progression can be taken from basic tubing exercises that are performed for scapular muscles in which they are progressed from split stance, to single leg, and finally split stance narrow base on a balance pad (Figures 6-33 to 6-35).

FIGURE 6-31. Bilateral overhead flexion while lunging during Phase I.

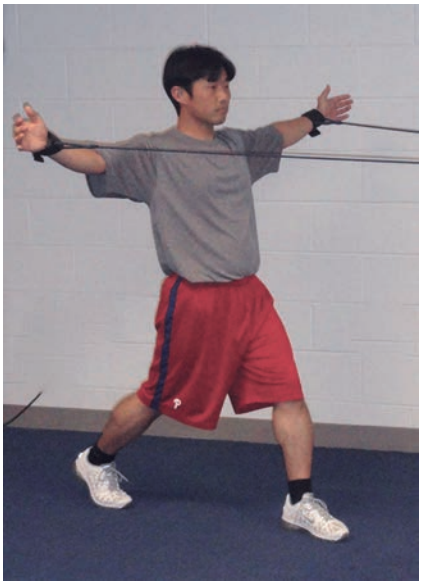

FIGURE 6-33. Bilateral middle trapezius exercise in split stance during Phase II.

FIGURE 6-34. Exercises on single leg for stance side during Phase II.

FIGURE 6-36. Lower trapezius exercise in split stance during Phase II.

FIGURE 6-35. Exercises in split stance on pad during Phase II.

FIGURE 6-37. Lower trapezius exercise on stance side during Phase II.

- Understanding the importance of balance on the stance side leg for pitching and incorporating that activity into the shoulder program is an important progression.
- Also, exercises with an Impulse Machine can both increase the velocity at which exercises are performed and also involve balance progressions (Figures 6-36 and 6-37).
- In addition to exercises performed by the athlete alone, manual resistive exercises become a significant part of the shoulder program. Manual resistive exercises are often termed PNF exercises, however, they frequently do not follow the exact principles defined by proprioceptive neuromuscular facilitation. For the purpose of this chapter, these exercises will be referred to as manual resistive exercises. These techniques can mimic DI and D2 PNF patterns (Figures 6-38 and 6-39) or simple isolated internal and external shoulder rotation.
- Other variables within these exercises are rhythmic stabilization, emphasis on eccentric loading, or isometric holds. The benefit of these types of exercises being performed on a regular basis is that the therapist can gain valuable knowledge on how the quality of movement and strength are progressing.
- Furthermore, passive stretching routine is incorporated into the program at this time. This passive upper body and spinal mobility program should include scapular mobility in multiple positions, passive range of motion in multiple planes, joint mobilizations, contract-relax techniques, pectoralis stretching, and spinal mobility or joint mobilizations (Figures 6-40 to 6-42).

FIGURE 6-38. Manual resistive exercises in a D1 pattern during Phase II.

FIGURE 6-39. Manual resistive exercises in a D2 pattern during Phase II.

FIGURE 6-40. Side-lying scapular mobility exercises during Phase II.

- Lastly, within this program, any soft tissue techniques can be used to assist in the rehabilitation process. Moving out from anatomical and osteopathic circles, the concept that fascia connects the whole body in an 'endless web' has steadily gained support.[28,29]

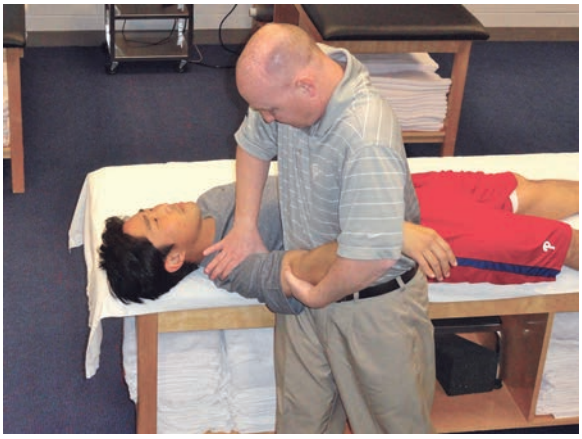

FIGURE 6-41. Posterior glide joint mobilization during Phase II.

FIGURE 6-42. Pectoralis minor stretch in supine position with bolster during Phase II.

Phase III: Sport-Specific Training

Program Design/Performance Training Program

- The sport-specific training program includes the throwing program, functional activities, and baseball conditioning to allow for return to pitching after subacromial decompression. To return to pitching in a game, several baseball specific activities must be accomplished. The obvious activities are long toss and throwing off the mound. However, other activities to be included at this time are hitting, base running, and fielding practice for pitchers.
- Of those, the ability of the pitcher to field his position is paramount and is accomplished with the baseball coaching staff. It consists of what is termed pitcher's fielding practice (PFPs). These activities involve fielding bunts, covering first base, and making the appropriate decisions to back up bases when indicated.
- In preparation for these activities, the conditioning program will include interval running and agilities.

Sport-Specific Concepts of Integrated Training

- Often pitching is considered to be an endurance activity that has inspired many to advise their athletes to complete long distance running. However, the activity of a starting pitcher is an interval activity. It is composed of an average of 15 to 17 pitches in an inning followed by a rest period of approximately 5 to 10 minutes.
- Therefore, it appears to be more appropriate to progress toward interval training as the athlete approaches return to game situations.
- Lastly within this program is the most functional activity of long toss and pitching. The progression from long tossing to pitching on the mound is the paramount exercise of the entire rehabilitation program.

Training Principles Used in the Design of the Program

- It is crucial that the athlete is reevaluated prior to initiating a throwing program to ensure that the athlete is ready for this phase. Once it has been determined that a throwing program can be initiated, the trainer or therapist will need to consider the number of throws, distance, intensity, and frequency of the program.
- There are many well-documented throwing programs[30–32] and there is no research indicating one program is better than another. Therefore, the following program is a guideline, identifying important considerations as the athlete progresses in the throwing program.

Sports Performance Testing

Recommendations for Throwing Progressions

- Initially begin with throwing 3 times per week. Increase the frequency after the athlete is satisfied with the symptom response to throwing. Typically progress to 2 days on and 1 off and then to daily tossing with recovery days built in. A recovery day is not an off day, but a day where the athlete may throw less total throws or a shorter distance. In our experience, complete days off from throwing are not always beneficial. Most athletes report feeling that they "took a step back or felt more stiff" after true off days.
- The initials days of throwing may include 20 to 30 throws. As the number of throws increases, splitting the total number of throws into two sets is important. The challenge for many players is how they respond to throwing after cooling off. The goal for us has been to complete a total of approximately 100 throws with at least 25 at the maximum distance for that day.
- The initial distance at which a player will throw should be 30 to 45 feet. The big question is what distance they should progress to. This should be based on previous long-toss programs, age of the player, and quality of throwing. If a player has never long tossed beyond 120 feet, they will need to be monitored with any progress beyond that distance. Some pitching coaches believe that no long tossing should occur beyond 120 feet for pitchers. Our experience is that overall mechanics of throwing should not be altered to reach a certain distance. In addition, beyond the distance of 90 feet, a drop step should be incorporated with the throw. Lastly, quality of throwing would be defined as throwing the ball with a good release point and keeping the ball on a line (not a high arc) to achieve the distance to be thrown.
- The next decision is when to progress the athlete to the mound. There is no exact formula for this decision. The athlete must demonstrate quality mechanics, arm strength with throwing, and a good response to throwing on consecutive days. Additionally, all the areas reevaluated before initiating the throwing program must be at a satisfactory level. The initial time on the mound may involve as few as 15 throws and may be thrown at less than the full distance (either in front of the rubber or with the catcher in front of the plate). Often we will have 2 or 3 days between these sessions and then progress over time to every other day or back-to-back days. Much of this will be determined based on the type of pitcher and the overall response to throwing off the mound. The number of pitches on the mound will progress from 15 to as many as 70 or 80 for a starting pitcher. In addition, progressions from one set of throws on the mound to multiple sets must be accomplished for starters. This will be referred to as "up and downs" by many pitching coaches. As mentioned earlier, the ability to return to throwing after cooling off (simulating between innings) is often a challenge in the rehabilitation process. Furthermore, with respect to pitch types, typically fastball and change ups are initiated first; and when the athlete is comfortable and confident with his velocity and control of those two pitch types, then breaking pitches are added.
- Finally the athlete will progress back to game situations. This may initially be accomplished with throwing live batting practice to his teammates and then creating game simulated activities. The final decision to make is when to return the player to a game. This decision will be made based on performance in simulated games and when the quality of pitching is acceptable to the player, athletic trainer/physical therapist, and coaches. The initial game situations may involve limitations in innings, pitches, and even time of the game in which the athlete is used.
- The goal is for the player to return to his previous level of competition after subacromial decompression. It will be important to continue to monitor and reevaluate the player throughout the entire rehabilitation process and beyond.
- The player should be reminded of the need to continue with his rehabilitation program even after he has returned to pitching. The athlete must understand the need to address the entire kinetic chain as he continues to throw.
- It is the responsibility of the medical staff to constantly reevaluate the athlete and ensure that he is consistent with the program.

Evidence

Burkhart SS, Morgan CD, Kibler WB: The disabled throwing shoulder: spectrum of pathology: Part III: the SICK scapula, scapular dyskinesis, the kinetic chain, and rehabilitation. *Arthroscopy* 19:641–661, 2003.

The authors review all the available literature on the disabled athlete's throwing shoulder. The SICK scapula is precisely defined; scapular dyskinesis is described in terms of diagnosis and evaluation; the concept of the kinetic chain of throwing is elucidated with respect to the precise biomechanical cascade of events that occur from the ground up to the ball release. (Expert Opinion; Level V evidence)

Fleisig GS, Bolt B, Fortenbaugh D, et al: Biomechanical comparison of baseball pitching and long-toss: implications for training and rehabilitation. *J Ortho Sports Phys Ther* 41:296–303, 2011.

A controlled laboratory study was performed on 17 healthy, collegiate baseball pitchers throwing fastballs from varying distances (18.4 meters from a mound, 37 meters, 55 meters, and maximum distance). Kinematics and kinetics were evaluated with a three-dimensional motion analysis system. It was noted that hard effort, horizontal, flat-ground throwing was biomechanically similar to pitching from a mound. Maximum distance throwing produced higher shoulder internal rotation and elbow varus torques as well as kinematic changes, and so should be used cautiously for rehabilitation and training. (Controlled laboratory study)

Reinold MM, Wilk KE, Reed J, et al: Interval sport programs; guidelines for baseball, tennis, and golf. *J Ortho Sports Phys Ther* 32:293–298, 2002.

The authors present an interval sports program in conjunction with a structured rehabilitation for baseball, tennis, and golf based on the available literature. The specific components of strengthening, flexibility, plyometrics, dynamic stabilization and neuromuscular control are reviewed. Sport-specific warm-up procedures and technique of sports are also presented. (Expert Opinion; Level V evidence)

Wilk KE, Marcina LC, Fleisig GS: Correlation of glenohumeral internal rotation deficit and total rotation motion to shoulder injuries in professional baseball pitchers. *Am J Sports Med* 39:329–335, 2011.

One hundred and twenty-two professional pitchers were evaluated over a three-season period to determine if glenohumeral internal rotation deficit (GIRD; >20° loss of internal rotation) and any deficit in total rotational motion (external rotation and internal rotation) compared with the nonthrowing shoulder correlated with shoulder injury and need for surgery. Those pitchers with GIRD and with a total rotational motion deficit of >5° appeared to be at higher risk for injury and shoulder surgery. (Case series; Level IV evidence)

Wilk KE, Meister K, Andrew JR: Current concepts in the rehabilitation of the overhead athlete. *Am J Sports Med* 30:136–151, 2002.

The authors provide an evidence-based current concepts review of rehabilitation for the overhead throwing athlete. They highlight the challenges of the "thrower's paradox" as it relates to the delicate balance between mobility and functional stability in this unique athletic population. They provide a structured, multiphase rehabilitation approach, which emphasizes inflammation control, muscle balance, soft tissue flexibility, enhanced proprioception, and neuromuscular control. (Expert Opinion; Level V evidence)

Multiple-Choice Questions

QUESTION 1. Primary subacromial impingement is defined as:

A. Abrasion of the subscapularis tendon on the coracoid process with repetitive crossbody maneuvers.
B. Instability of the acromioclavicular joint in multiple planes with overhead lifting.
C. Repetitive injury to the anterolateral aspect of the rotator cuff caused by supraspinatus outlet narrowing.
D. Anterior laxity of the glenohumeral joint with the arm in an abducted, externally rotated position.

QUESTION 2. Subacromial impingement symptoms in the throwing athlete may be a result of intrinsic and extrinsic factors, which include:

A. Acromial bone spurs and subacromial bursitis.
B. Superior humeral head migration caused by rotator cuff tear.
C. Altered scapulothoracic rhythm caused by glenohumeral instability.
D. All of the above.

QUESTION 3. Nonshoulder sources of disability in the throwing athlete include all of the following except:

A. Core muscular weakness.
B. Hip rotational deficits.
C. Coracoid impingement.
D. Leg muscular weakness.

QUESTION 4. The initial phases of rehabilitation of the throwing athlete after subacromial decompression include:

A. Full pain free arc of motion.
B. Ability to complete basic rotator cuff and scapular exercises.
C. Overall body conditioning.
D. All of the above.

QUESTION 5. All of the following are true concerning the recommended, beyond basic rehabilitation after subacromial decompression in the throwing athlete except:

A. There are three overlapping programs including Advanced strength and conditioning, Performance enhancement, and Sport-specific training.
B. The sport-specific training program for the pitcher includes only throwing.
C. These programs may begin at approximately 8 to 10 weeks after isolated subacromial decompression.
D. These programs may begin at approximately 16 weeks after subacromial decompression with either labral/rotator cuff repair.

QUESTION 6. The ultimate distance to which a player long tosses is determined by all of the following except:

A. Age of the player.
B. Presurgical velocity of throwing.
C. Quality of throwing.
D. Previous long tossing program.

Answer Key

QUESTION 1. Correct answer: **C** (see Introduction)

QUESTION 2. Correct answer: **D** (see Introduction)

QUESTION 3. Correct answer: **C** (see Introduction)

QUESTION 4. Correct answer: **D** (see Postoperative Rehabilitation Program)

QUESTION 5. Correct answer: **B** (see Postoperative Rehabilitation Program)

QUESTION 6. Correct answer: **B** (see Recommendations for Throwing Program)

NONOPERATIVE REHABILITATION OF INTERNAL IMPINGEMENT

Mark Rogow, ATC, CSCS, and Charles E. Rainey, PT, DSc, DPT, OCS, SCS, CSCS, FAAOMPT

GUIDING PRINCIPLES OF NONOPERATIVE REHABILITATION

- Establish diagnosis: Identify if there is GIRD (Greater Internal Rotation Deficit), posterior capsular hypomobility, a lack of rotator cuff and/or scapular strength and endurance, acquired glenohumeral anterior instability, labral and/or rotator cuff injury, or a combination of a number of these dysfunctions/pathologies
- Establish a plan to address each of these conditions
- Optimize postural alignment
- Address SICK (Scapular malposition, Inferior medial border prominence, Coracoid pain and malposition and dysKynesis of scapular motion) scapula and/or scapular dyskinesis
- Restore glenohumeral and scapulothoracic joint mobility
- Address any and all mobility issues and fascial restrictions from nose to toes
- Reestablish and enhance dynamic stability/muscle synergy (balance)/neuromuscular control of both glenohumeral and scapula-thoracic joints
- Improve shoulder, trunk, lumbopelvic, and ankle stability
- Monitor progress closely and advance forward in the program as milestones are achieved
- Moving forward in a program is less determined by time than it is by goals attained; however, it is possible to be working in multiple phases given we are rehabilitating and improving the performance of the entire kinetic chain, rather than just a single body part
- Return to ADLs (Activities of Daily Living) without pain
- Increase strength, power, endurance, and myokinematics of entire kinetic chain
- Return to sport

Phase I: Movement-Mobility (weeks 2 to 4)

Goals

- Protect healing tissue and discontinue mechanism of injury
- Do not sleep on shoulder, do not sleep with arm/shoulder in overhead position (prone, supine or side-lying)
- Reduce pain, inflammation, point tenderness
- Improve pliability of inferior and posterior capsule, posterior rotator cuff, upper trap, pectoralis minor
- Restore pain-free range of motion of glenohumeral, scapulothoracic, acromioclavicular and sternoclavicular joints
- Restore scapular equilibrium, scapular mechanics, upper extremity proprioception, dynamic stability, and neuromuscular control of the scapula
- Evaluate and correct cervical, thoracic, lumbopelvic, hip, and ankle mobility dysfunctions
- Once spine, pelvis and ankle motions are sufficient, begin trunk, hip, and ankle stability exercises
- Emphasize correct posture 24/7 through Home Exercise Program and education
- Minimize muscle atrophy
- Be active/productive while healing
- Address cardiovascular fitness

Protection

- To optimize healing, for nonoperative care, minimize hyperangulation (no hyperabduction, no external rotation at 90/90 or ER above 90 abduction).
- Do not sleep on the injured shoulder or with the arm in an overhead position.

TIMELINE 6-4: **Nonoperative Rehabilitation of Internal Impingement**

PHASE I (weeks 2 to 4)	PHASE II (weeks 4 to 8)
• Protect healing tissue • Avoid sleeping on shoulder or sleeping in overhead position • Decreased pain, inflammation, point tenderness • Increase mobility of inferior/posterior capsule, posterior rotator cuff, upper traps, and pectoralis minor • Restore pain-free ROM of all scapulothoracic joints • Restore scapular equilibrium, scapular mechanics, upper extremity proprioception, dynamic stability, and neuromuscular control of the scapula • Correct cervical, thoracic, lumbopelvic, hip, and ankle mobility dysfunctions • Start trunk, hip, and ankle stability exercises • Postural education and HEP • Minimize muscle atrophy • Address cardiovascular fitness	• Continue protecting healing tissue • Continue shoulder stretching, emphasize horizontal adduction and sleeper position • Begin rotator cuff strengthening (isometrics, concentric, eccentric) at a low intensity using proper scapular mechanics/alignment • Maintain cervical, thoracic, lumbopelvic, and ankle mobility • Advance scapular, cervical, thoracic, lumbopelvic/hip/lower extremity stability training • Continue neuromuscular stability training • Advance and challenge cardiovascular fitness

- Establish or maintain good posture and good scapulothoracic position throughout the day. Kinesiological taping may help reinforce and/or reeducate critical postural and suprascapular muscles.

Management of Pain and Swelling

- Electrotherapy (INF/TENS/high voltage galvanic) may be used if there is pain, inflammation, spasm, or muscle guarding
- Oral NSAIDs and pain medications as prescribed by physician
- Iontophoresis may be indicated
- Cryotherapy as needed for pain and swelling
- Compression/sports wrap if swelling

Techniques for Progressive Increase in Range of Motion

Physical therapy begins immediately after evaluation by a physician and rehabilitation specialist. This phase should include an evaluation, discussion, and plan. Active physical therapy care should begin as soon as possible.

Manual Therapy Techniques

- Manual therapy in Phase I is indicated if there is palpable muscle spasm, tightness, and point tenderness to anterior, posterior, superior, and inferior structures of the glenohumeral joint.
- Manual therapy techniques to include contract/relax PNF and muscle energy. The authors have found better results with using contract-relax techniques during both self-stretching and therapist-assisted stretching versus passive stretching alone.
- Begin gentle mobilization of posterior and inferior capsule if patient has tight posterior capsule and/or restrictive inferior glenohumeral ligament complex. Use manual therapy for the scapulothoracic joint, lumbar, thoracic, cervical spine, and pelvis if range of motion is limited and lacks necessary mobility.

Soft Tissue Techniques

- Soft tissue massage/mobilizations, IASTM (instrumental assisted soft tissue mobilization), and trigger point dry needling are all indicated to reduce spasm, tightness, reset muscle tendon units, and improve joint restrictions. Cross friction massage is indicated for biceps tendon and teres minor tenderness/tendonitis which are common secondary side effects of internal impingement.
- Other soft tissue therapy techniques include using foam rolls, myofascial/lacrosse balls, and massage sticks. These are all also effective objective measurements of effectiveness and produce increased ROM and decreased pain level.
- This does not need to be a "passive" treatment. Be sure to include active movement while using these tools. Moving the joint or contracting the muscle while applying the pressure of the modality will educate the patient as to where there are soft tissue restrictions, muscle spasm/tightness, as well as trigger points. This "active" approach is effective while working on the pec minor, rhomboids, and posterior cuff (taking the shoulder through flexion, IR/ER, and abduct), as well as deep soft tissue structures in the hip (taking it through IR/ER and flexion).
- The common muscle tendon units/soft tissue that tend to be hypomobile lack pliability and/or are joints that lack mobility with internal impingement, such as pectoralis minor, levator scapulae, scalenes, upper trap, teres minor/infraspinatus, posterior capsule, scapula-thoracic joint, thoracic spine, and contralateral hip.
- Be sure to evaluate horizontal adduction, internal rotation, and the sleeper stretch position (Figure 6-43) bilaterally. While looking at horizontal adduction be sure the scapula is immobilized and in a neutral position (not retracted or protracted). The scapula needs to be fixed against the thorax before horizontally adducting the humerus.
- The intent of treatment during this phase is to address any and all soft tissue restrictions surrounding the shoulder and throughout the kinetic chain.
- Muscles that when tight affect, or can contribute to, scapular dyskinesis:
  - Pectoralis minor
  - Levator scapulae
  - Upper trapezius
  - Infraspinatus/teres minor
  - Latissimus dorsi

TIMELINE 6-4: **Nonoperative Rehabilitation of Internal Impingement** (Continued)

PHASE III (weeks 8 to 12)	PHASE IV (weeks 12+)
• Advance upper quarter strength and power • Maximize use of kinetic chain • No signs or symptoms of impingement returning • Improve dynamic neuromuscular control of scapula/trunk • Begin reintroducing mechanism of injury	• Return to sport with no symptoms, full function • Normal kinematics, including no scapular dyskinesis or SICK scapula • Improved neuromuscular control and muscle firing patterns throughout kinetic chain • Improve cardio and anaerobic function • Patient has knowledge/understanding of shoulder function, mechanical awareness, injury predispositions, and recovery needs • Continue maintenance drills, exercises, movement patterns, correctives, stretching, and sport-specific training

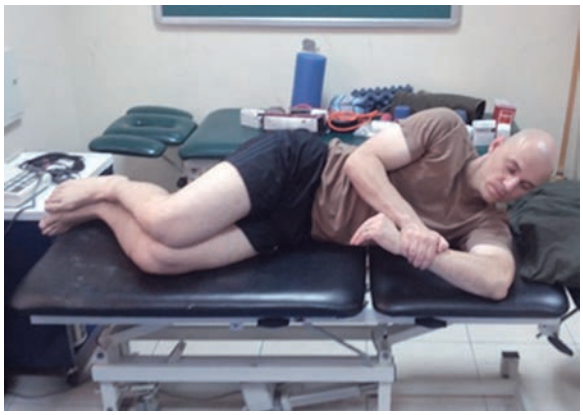

FIGURE 6-43. Sleep stretch at 90°.

- Techniques include, but are not limited to, if indicated:
  - Inferior and posterior glides during horizontal adduction and internal rotation of the humerus on the glenoid (low grade end range mobilization glides; performed by therapist)
  - Side-lying horizontal adduction stretch (self-stretch)
  - Standing with scapula pinned against wall; horizontally adduct humerus (self-stretch)
  - Standing with scapula pinned against wall; internally rotate humerus with shoulder abducted at 70° and at 90° (self-stretch)
  - Supine horizontal adduction stretch (therapist assisted)
  - Sleeper stretch/modified sleeper stretch at 70°, 90° and 110° (self and therapist assisted)
- If there is any anterior or subacromial pain while performing the sleeper stretch, modify the position by performing 1), 2) and/or 3), as the stretch should only be felt in the posterior and posteriolateral shoulder:
  1) Rotate torso away from elbow 10° to 20° then reattempt stretch.
  2) Increase the angle of the elbow from 90° out to 120° to 135°.
  3) Lower position of humerus from 90° abducted to 50° to 70°.
  - Corner stretch (self-stretch) (Figure 6-44)
  - Doorway pectoralis major/pectoralis minor stretch (self-stretch)
  - Pectoralis minor on foam roll stretch (self and assisted technique)
  - Side-lying, supine, and prone flexion stretch (therapist-assisted)
  - Side-lying on foam roll and actively flexing and extending shoulder (Figure 6-45)
  - Standing shoulder extension (self-stretch)
  - Supine shoulder extension (therapist assisted)
  - Backscratch/Apley's stretch (self-stretch with Thera-Band or towel)
  - Subscapularis release (therapist assisted)
  - Standing latissimus/thoracolumbar fascia stretch
  - Supine angular (diagonal) with rotation stretches (therapist assisted)

FIGURE 6-44. Corner stretch.

FIGURE 6-45. Side-lying on foam roller.

Clinical Pearls

- The authors have found better results with using contract-relax techniques during both self-stretching and therapist-assisted stretching versus passive stretching alone.
- The key is initiating the low intensity contraction at the "first barrier," the first feeling of tissue tension, not taking it to its end range, then giving a contraction. After contracting the muscle or muscle group the patient is trying to stretch, take the stretch to the next barrier, and then repeat. This technique also keeps the patient engaged and on task by making them an active participant in the stretch.
- It forces the patient to pay attention and be in tune with where their extremity is and the direction it is going in, what angles are the most effective, and tissue tension differences at different angles; in the long run it forces them to become less dependent upon the therapist.

Stretching and Flexibility Techniques for the Musculotendinous Unit

- Aerobic/cardiovascular conditioning to begin right away, however running should not begin until full pain-free range of motion in the shoulder is achieved
- Improve postural awareness
- Address SICK scapula and scapula dyskinesis if present
  - Initiate activity of the serratus anterior, rhomboids, and mid-lower trapezius
  - Low row
  - Active assistive shoulder flexion and in scaption with cane, pulley, UE Ranger, tubing, or cable
  - Sternal lift: While seated or standing, on exhalation, force sternum toward ceiling while performing scapular retraction and depression. Hold 5 seconds and return to normal resting position.
  - Shoulder dump: While standing in split stance (normal stride length distance), slowly perform a throwing motion (without a ball or other object) emphasizing depression and retraction of scapula when torso is upright, and performing elevation and protraction of scapula when torso is flexed and rotated over forward stride leg; then reverse the exercise slowly. (Arm can remain at side or can begin in abducted/externally rotated position depending on symptoms of patient.)
- Functional core stabilization exercises
  - Pelvic tilts
  - Partial crunches
  - Bridging (Figures 6-46 and 6-47)/single leg bridge (Figure 6-48)/bridge marching
  - Quadruped (alternate arms, alternate legs, alternate arms and legs) (Figure 6-49)
  - Dead bugs (alternate arms, alternate legs, alternate arms and legs)
  - Supermans
  - Physio ball wall squats
- Evaluate for and treat deep neck flexor inhibition (may need tissue work on suboccipitals, cervical extensors, and scalenes)
  - Supine active chin tuck
  - Supine cervical flexion
- Teach diaphragmatic/belly breathing
- Dynamic lower extremity exercises
  - Body weight squats
  - Lunges (in the sagittal, frontal, and transverse planes)
  - Step-ups
  - Lateral step-ups

FIGURE 6-46. Double leg bridge.

FIGURE 6-47. Double leg bridge with leg extension.

FIGURE 6-48. Single leg bridge.

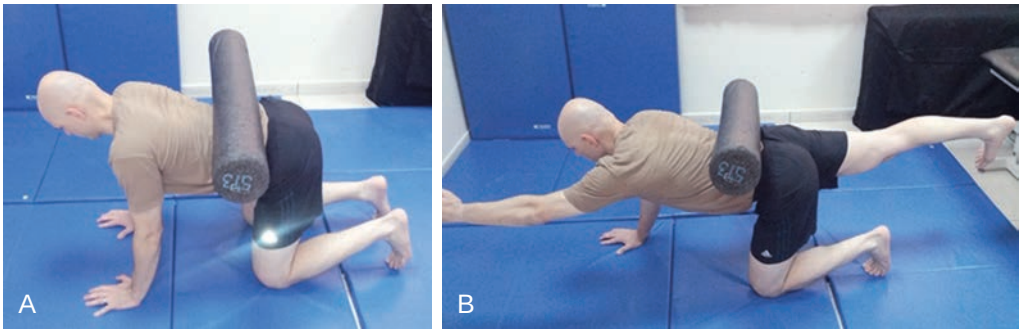

FIGURE 6-49. Quadruped diagonals. **A,** Start. **B,** Finish.

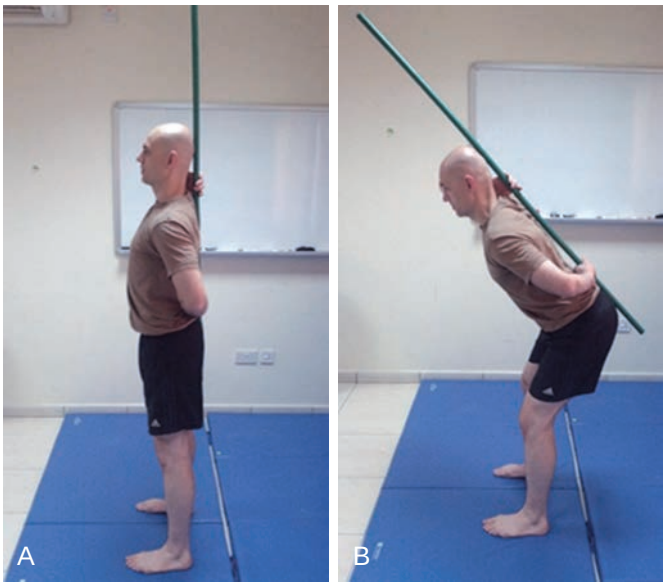

FIGURE 6-50. Deadlift. **A,** Start. **B,** Finish.

- Step-downs
- Trendelenburg exercise
- Thera-Band walking (forward, backward, side-step)
- Romanian deadlift (RDL) (body weight only) (Figure 6-50)
- Single leg RDL
- Good morning exercise (body weight only)
- Single-leg excursions (in the sagittal, frontal, and transverse planes)
- Calf exercises
- Hiking/incline on treadmill

- All exercises and stretches should be done pain free. If the patient experiences soreness and/or stiffness in the injured shoulder, these side effects from exercise should resolve within 24 to 48 hours.
- If they do not, then the clinician needs to reevaluate the exercise, treatment, and recovery programs of the patient as well as the quality of the reinforcement, movement, and mechanics when working on posture and scapular control.
- It is critical to achieve good scapular control by minimizing scapular dyskinesis during overhead ROM before increasing volume and intensity of strength training, or the underlying issue of scapular dyskinesis and poor scapular control will either slow the athlete's return to play or will significantly increase the athlete's predisposition to reinjury.

Activation of Primary Muscles Involved

- As part of the muscle reeducation process, the patient needs to learn to recruit proximal musculature (trunk/core/pelvis/hip) before recruiting distally (extremities). The purpose is to improve motor control.
- Avoid hyper-horizontal abduction, ER at 90/90 and ER above 90 ABD, and avoid any reproduction of symptoms.
- Using proprioceptive neuromuscular facilitation (PNF) for the scapula, manually cue the scapula to elevate/depress, upwardly rotate/downwardly rotate, retract/protract.

FIGURE 6-51. Packing the shoulder (supine).

Sensorimotor Exercises

- These activities are advisable and critical as soon as an axial load or perturbations can be performed without pain.
- Performing upper and lower extremity proprioception and balance exercises will activate, improve, and control muscle patterns which in turn will improve postural and neuromuscular control.
- They include, but are not limited to, single-leg stance on contralateral leg and single-leg stance on ipsilateral leg (eyes open and progress to eyes closed).
- If more challenge is needed, add upper extremity row and scapular retraction with tubing during SL stance.
- Kneeling, half-kneeling or standing with hand of injured arm on physio ball on floor or against wall doing up-and-down, left-and-right movement patterns, circles, rhythmic stabilization, and perturbations.
- Quadruped weight shifts, quadruped with hand of injured arm on ball or wobble board (all exercises must not elicit, reproduce pain, or compromise good scapular/postural position).
- Upper extremity sensorimotor exercises also include lying supine and balancing an object such as a kettlebell or dumbbell in the hand of injured arm. Be sure to "pack the shoulder," consciously contracting all periscapular musculature as if to squeeze tight one's armpit. The latissimus must be tonic. Each repetition is to be done for 15 to 30 seconds in length.
- Then move to side-lying with the arm extended toward the ceiling or sky and again "pack the shoulder." (Discontinue if painful.) This can also be executed with the arm outstretched while kneeling, half-kneeling, or standing, depending upon the patient's ability to maintain good core/trunk stability while performing the exercise (Figures 6-51 and 6-52).

Clinical Pearl

The rehabilitation program should move along a continuum. Its difficulty should increase over time with respect to the sport or desired activity[1] and evolve from bilateral to unilateral, supported to unsupported,[2] using active and passive movement, with and without load.[3]

FIGURE 6-52. Packing the shoulder (side-lying).

Open and Closed Kinetic Chain Exercises

- Closed kinetic chain (CKC) activities should take precedent over open kinetic chain (OKC) activities early on in the program, caused by their functionability and avoidance of unwanted stresses. CKC exercises improve sensorimotor function, joint proprioception and centralization, and stability.
- Perform multiplanar, frontal, sagittal, and transverse planes exercises and focus on the weakest, the most easily fatigued and poorest performing planes of motion.
- In Phase I all humeral movements should be kept below 90° of shoulder flexion and below 90° abduction.
  - CKC exercises include, but are not limited to:
    - Weight shifts left and right, up and down, forward and back, as well as diagonal and circular patterns with elbows at 90° or with elbows extended against wall, table, or floor
    - Pushup plus (slow and controlled concentric and eccentric components) on forearms or with elbows extended
    - Scapular clocks with arm extended against fixed surface, controlling movement of scapula/glenohumeral joint clockwise and counterclockwise
    - Ball/physio ball oscillations with arm outstretched
    - Seated towel slides protracting and retracting scapula
    - Seated towel slides upwardly rotate and downwardly rotate scapula (putting contralateral hand behind neck and actively cocontracting the contralateral scapula usually yields better dynamic scapular results)
    - Thumbtacks: Imagine gripping a thumbtack on the wall with each hand, then upwardly and downwardly rotate humerus/scapula and getting a scapular pinch end range external rotation)
    - Pulley exercise: This is an active exercise, not a passive one. Be sure the patient is firing their humeral and scapular depressors during both flexion/extension, scaption and abduction/adduction movement patterns. If pain free above 90°, you can take shoulder through full available pain-free ROM.

Clinical Pearl

The act of gripping has been shown to activate reflex contraction of the rotator cuff muscles which will stimulate glenohumeral mechanoreceptors.[4] This in turn increases joint compression and dynamic muscular cocontraction improving joint congruity, reducing shear forces, and stimulating joint proprioceptors while enhancing dynamic stabilization.[5]

Techniques to Increase Muscle Strength, Power, and Endurance

- In Phase I, work begins on lower extremity muscle strength, power and endurance.

Neuromuscular Dynamic

- Kneeling and half-kneeling (with narrow base) modified lifts and chops with or without resistance depending upon ability to stabilize hips and trunk (Figures 6-53 and 6-54)
- Quadruped (on all fours): Alternate arms, alternate legs, alternate opposite arms and legs
- Bridging/single-leg bridge/bridge marching
- Dead bugs: Alternate arms, alternate legs, alternate opposite arms and legs

Clinical Pearls

"*A key premise of the dynamic neuromuscular stability approach is that every joint position depends on stabilizing muscle function and coordination of both the local and distant muscles to ensure neutral or centered position of joints in the kinetic chain. The quality of this coordination is critical for joint function and influences not only local, but also regional and global anatomical and biomechanical parameters in the kinetic chain.*"[6]

The goals of neuromuscular rehabilitation according to Lephart et al.[7] are:

- To improve cognitive appreciation of the shoulder relative to position and motion
- To enhance muscular stabilization of the joint in the absence of passive restraints
- Restore synergistic muscular firing and coordinated movement patterns

Plyometrics

- Low-level lower extremity plyometrics can begin in the final 1 to 2 weeks of Phase I
  - Low-intensity dot drills, box drills, cone/footwork drills, jump rope, one- and two-legged hops, skipping, low-level bounding

Functional Exercises

- Ground-based exercises for the lower extremities (that do not load, compromise, or force the shoulder into flexion or abduction above 90°). Many are listed above, however the athlete should add additional exercises that incorporate movement patterns specific to the athlete's sport.

FIGURE 6-53. Half-kneeling chop. **A,** Start **B,** Finish.

FIGURE 6-54. Half-kneeling lift **A,** Start **B,** Finish.

Sport-Specific Exercises

- Review all sport-specific exercises related to the athlete's sport. Consider each exercise, movement pattern, or sport-related activity that does not invoke stress on the injured shoulder. Examples of this might include taking groundballs without throwing, foot work, and body positioning drills that do not involve the affected shoulder.
- Maintain indoor and outdoor cardiovascular/aerobic fitness.

Milestones for Progression to the Next Phase

- No pain at rest
- Very little to no pain with increased activity
- Good scapulothoracic mobility and control
- Full glenohumeral motion
- If present, eliminate GIRD if patient is not an overhead athlete
- Core/trunk/pelvic stability, posture, and scapular kinesis need to have improved if the need was there
- Improved hip motion and symmetry

Phase II: Stability-Strengthening (weeks 4 to 8)

Volume/duration: Perform 10 to 15 reps, 1 to 3 sets per exercise, depending on quality of movement and

Note: Mobility/ROM are measured and assessed via goniometry measurement, so that right versus left extremities are within 10° of one another to achieve symmetry. Stability/postural control are measured via administrator's observation, so that movement quality is high and no compensatory/unwanted motion are observed during these movement patterns.

minimizing the presence of compensatory movement patterns. Exercise will be terminated when there is a decrease in movement quality and/or movement compensations noted.

Goals

- Continue to protect healing tissue; not ready to resume mechanics of the causation of injury
- Shoulder stretching needs to continue, most importantly the horizontal adduction and sleeper position stretching
- Begin to address rotator cuff strength deficits (isometrically, concentrically, and eccentrically) using low intensity, high-volume work, while simultaneously using correct scapular mechanics and good postural alignment
- Increase strength training (volume and intensity) throughout this phase but be sure adequate recovery between sets and between workouts is accomplished
- Maintain cervical, thoracic, lumbopelvic, and ankle mobility acquired in Phase I
- Advance scapular, cervical, thoracic, lumbopelvic/hip/lower extremity stability training
- Reinforce muscle memory of correct neuromuscular firing, going from conscious to unconscious control
- Advance and challenge cardiovascular fitness

Protection

- Do not sleep on shoulder; do not sleep with arm/shoulder in overhead position (prone, supine or side-lying). "Crimping the garden hose" affects the rate of flow of the water down the hose much like sleeping on the shoulder and squeezing the neurovascular structures and vessels that feed the arm and shoulder. One bad night can negatively affect the patient for a day or more.

Management of Pain and Swelling

- Electrotherapy (TENS, IFC, Russian) may be used if there is pain, spasm, and muscle guarding
- Oral NSAIDs and analgesics should be able to be discontinued in this phase
- Cryotherapy as needed

Techniques for Progressive Increase in Range of Motion

Manual Therapy Techniques

- Manual therapy techniques used in Phase I are also indicated in Phase II to not just maintain what has been accomplished, but to address any new issues that may arise or be uncovered.
- Take advantage of this time to periodically evaluate the patient's strength and range of motion, as well as the firing patterns of motor recruitment.

Soft Tissue Techniques

- The same soft tissue techniques listed in Phase I certainly can apply in Phase II to not only maintain what's been achieved soft-tissue wise, but also to evaluate the tissue as new issues and changes in tissue tension, capsular, and muscular tightness emerge.

Stretching and Flexibility Techniques for the Musculotendinous Unit

- Although the patient has moved on to Phase II, it is critical that both the therapist and patient remain aware and on top of the patients kinetic chain mobility.
- Many flexibility goals have been met up to this point, however the patient's body type, posture, sport, and genetics are still programmed to return that athlete to the state of flexibility the athlete was in before the injury occurring. That being said, working on stretching and being "routine" with it needs to continue well beyond this program, much less beyond Phase I.
- At this point identifying the few stretches to help maintain the patient's flexibility would be beneficial because it is probably a bit of overkill to perform all of the stretches every day.
- Commonly the horizontal adduction stretch and modified sleeper stretch need to be continued 3 to 5 times per week. More aggressive techniques (such as active assistive and active isolated stretching with the use of a band, tubing or towel) can be used.

Clinical Pearls

- As the athlete increases their function and gets closer to returning to their sport, it is important to get them on their feet and doing ground-based mobility and dynamic warmup activity geared specifically toward their sport as well as their own mobility needs.
- This also plays a significant role in keeping the athlete on task and keeps their head in the sport. Although a particular body part may be on the mend and out of commission, the rest of their body is not.

Other Therapeutic Exercises

- Aerobic/cardiovascular conditioning needs to continue. This is a good time to start cross-training, mixing in some anaerobic work and building opportunities into the program to increase the athlete's level of fitness using other types of conditioning equipment and surfaces (i.e., treadmill, StairMaster, Versaclimber, Jacob's Ladder, upper body ergometer, viper rope climb [machine], rowing ergometer, ski ergometer, elliptical, arc trainer, conditioning on artificial grass, the beach, playing field, hard court and more).
- Continue to improve and reinforce postural awareness
  - Be sure patient is aware of their "neutral spine" and the optimal position of the pelvis
  - Correct shoulder protraction, forward head posture, and thoracic hypomobility and kyphosis
  - Most exercises in this phase should be performed standing or while in upright posture (can be done in kneeling, half-kneeling or standing)
    - Low rows
    - Tubing two-arm diagonals

  - Straight arm shoulder extension from 90° flexion to 0° with scapular pinch throughout the exercise
  - Chin tucks
- "No Money": Standing with arms at side, palms up and elbows bent at 90°. Externally rotate, pinching shoulder blades together, and pulling them inferior (toward tailbone), hold for 5 to 10 seconds, then slowly return to starting position. Can be done with or without tubing.

- Begin Rotator Cuff Exercises
  - Isometrics: Abduction/adduction, flexion/extension, internal/external rotation
  - Prone I (flexion), Ts (horizontal extension), Ys (scaption), and Ws (90/90 external rotation exercises) (with palms down or thumbs up)
    - Have a 5-second hold at the top of the arm lift and slowly lower the arm to complete each repetition. As soon as the arm touches the table or bench begin the next rep, with no rest until the set is complete.
  - Side-lying
    - External rotation
    - Dynamic "4": Externally rotate, extend elbow pressing hand toward the sky. With a straight arm slowly lower the arm in a diagonal pattern toward contralateral hip, return elbow to starting position at side with elbow bent at 90°, and repeat
  - Standing: Internal/external rotation at 30° and 45° abducted
    - External rotation needs to be done slowly and under control with good cocontraction of the scapula stabilizers and moving slowly during the eccentric phase of the exercise.
  - Diagonal patterns can begin 1 to 2 weeks into Phase II
  - Standing "3"
    - Front raises
    - Lateral raises (with GH-ER to prevent iatrogenically impinging the shoulder)
    - Scaption/full can (thumb up position) raises
- Have a 1 to 2 second hold at the top and slowly lower the weight. Do not allow the patient to "rest" and relax at the end of each repetition; maintain an "active" shoulder and correctly positioned scapula and posture throughout the set
  - Bodyblade/perturbations can be done in many planes and with many of the exercises listed above in the rotator cuff exercise list
- Increase work on active scapular control, increasing strength and endurance
  - Back to corner external rotation isometrics
  - Back to corner wall slides
  - Wall angels (Figure 6-55)
  - Wax on/wax off (one arm and two arm: against wall, on slideboard, or on floor with sliding discs)
  - Robbery (begin with arms at side, with elbow bent at 90° and internally rotated with hands on abdomen. Finish with both arms externally rotated with humerus at side and elbow bent 60° to 90°)
  - Lawnmower (beginning from contralateral side, end with elbow flexed at side and scapula retracted)
  - Thumbtacks

FIGURE 6-55. Wall angels.

  - Lunge and punch (at 135° shoulder flexion, 120° shoulder abduction, bring arm overhead in a half circle pattern)
  - Kettlebell holds: "Pack the shoulder" and do 15 to 30 second holds
    - Supine punch position
    - Supine punch position with kettlebell bottom up
    - Side-lying 90° abduction
    - Side-lying 90° abduction with kettlebell bottom up
    - Move from supine to side-lying and back to supine
  - Dynamic hug
  - Supine punch: Retract and protract scapula
  - Prone row
  - Pushup plus
  - Pushups/wall pushups with various hand positions on wall
  - Plank to side plank (start in plank position, then rotate torso to left or right so unloaded forearm is pointing to sky, then rotate trunk back to prone plank position, then rotate in the opposite direction and repeat) (Figures 6-56 to 6-58)
  - Kneeling forearm physio ball slides
  - Standing forearm wall slides with Thera-Band around elbows and wrists
  - Lat pulldowns (never behind head)
  - Assisted pullups (do not hang at end of each rep, maintain active shoulders throughout set)

FIGURE 6-56. Prone plank on elbows.

FIGURE 6-57. Prone plank.

FIGURE 6-58. Side plank on elbows.

- Functional core stabilization exercises
  - Continue core stabilization exercises in Phase I
  - Upper extremity work (rotator cuff ex—IR/ER, D1/D2) while sitting on a physio ball
  - Stability "prone plank"
    - As the plank gets easier, then lift each elbow off the ground (1 to 5 seconds)
    - As the plank gets easier, then lift each foot off the ground (1 to 5 seconds)
  - Stability "side plank"
- Continue diaphragmatic/belly breathing
- Dynamic lower extremity exercises
  - Increase resistance and volume with all of the dynamic lower extremity exercises done in Phase I
  - Begin running/sprinting progression

Clinical Pearls

- It is critical that to have success strengthening a muscle or a group of muscles, their antagonist counterparts cannot be chronically tight and shortened.
- Using a foam roll, massage stick, and the other modalities listed in the soft tissue technique section will improve recovery, reduce muscle soreness, and help maintain joint ROM and mobility.

Sensorimotor Exercises

- Increase difficulty of sensorimotor exercises presented in Phase I
- Ideas to increase difficulty: Close eyes/add resistance/increase distance of excursions/add wobble board, DynaDisc or Airex pad/if performing a lower extremity exercise then add an upper extremity movement or exercise and vice versa

Neuromuscular Dynamic Stability Exercises

- Kneeling and half-kneeling (with narrow base) modified lifts and chops with or without resistance depending upon ability to stabilize hips and trunk while maintaining a narrow base
- Bodyblade/perturbations are done dynamically in this phase working to stabilize the glenohumeral, scapulothoracic, sternoclavicular, as well as postural muscles of the spine and pelvis while the arm is moving at different angles and at different speeds (IR/ER, abduction/adduction, flexion/extension, diagonal patterns, scaption)
- Lower extremity balance activities such as single leg stance, BOSU ball squats, star excursion, Y-balance
- Segmental upper and lower body rolling patterns[8]
  - The upper body rolling pattern from supine to prone is initiated by lifting and turning the head, and reaching with the opposite arm. The roll needs to occur in segmental fashion. (The movement begins by rotating the head, the shoulders rotate in the same direction, followed by the trunk, hips, and then the legs. If the patient is log rolling, corrections, either verbal and/or tactile, cues needs to be used.)
  - The upper body rolling pattern from prone to supine is initiated by turning the head and retracting the lead scapula to bring the arm around. Keep reaching and rotating, and again this need to happen in a segmental fashion from the head all the way down the spine to the lower extremities.
  - The lower body rolling pattern from supine to prone is initiated by flexing, adducting, and internally rotating the opposite hip. Reach the leg across the body and extend the knee as the hips, pelvis, and lumbar spine begin rotating over toward the prone position. The roll must be segmental in nature.
  - The lower body rolling from prone to supine is initiated by extending, adducting, and externally rotating the opposite hip. While rotating over to supine be sure the rotation occurs segmentally and not as a log roll.

Sport-Specific Exercises

- The patient should be able to increase the level of intensity and volume of the sport-related activity as long as the activity does not put the rehabilitating shoulder at risk. Other activities that do involve the affected shoulder can be considered (i.e., hitting, tossing underhand, swimming the breaststroke, or modified sidestroke).

Milestones for Progression to the Next Phase

- Glenohumeral range of motion is within normal limits with a firm end feel with joint mobility testing.
- Rotator cuff strength (MMT) has improved to within 1 to ½ grade right versus left.
- Maintained or improved spinal, hip/pelvis, and ankle mobility

Phase III: Power and Acceleration (weeks 8 to 12)

Volume/duration: Perform 10 to 15 reps, 1 to 3 sets per exercise, depending on quality of movement and minimizing the presence of compensatory movement patterns. Exercise will be terminated when there is a decrease in movement quality and/or movement compensations noted.

Goals

- Improve strength and power
- Maximize use of kinetic chain
- No signs or symptoms of impingement returning
- Improve dynamic neuromuscular control of scapula/trunk
- Begin mechanical work of the mechanism of injury

Management of Pain and Swelling

- Ice application postexercise as needed.

Techniques for Progressive Increase in Range of Motion

Manual Therapy Techniques

- Manual therapy techniques as previously stated in Phase II as needed to achieve full mobility in upper quarter.
- Joint mobilization grade III to IV as indicated for the glenohumeral joint, scapulothoracic joint, and thoracic spine.

Soft Tissue Techniques

- Continue soft tissue techniques in Phase II as indicated.

Stretching and Flexibility Techniques for the Musculotendinous Unit

Other Therapeutic Exercises

- Patients should be instructed in glenohumeral, scapulothoracic, and cervicothoracic stretching/flexibility techniques.
- Progress Phase II exercises with increased intensity, volume, and frequency as tolerated.

Activation of Primary Muscles Involved

- Progress Phase II exercises with progressive resistance as tolerated.

Open and Closed Kinetic Chain Exercises

- Advance exercises from Phase II
- Front planks and side planks, with and without weight shifts on stable surfaces and progress to unstable surfaces
- Slide board exercises in plank or quadruped position

Techniques to Increase Muscle Strength, Power, and Endurance

- Progress strength exercises in Phase II per tolerance
- Begin periodization program for strength training, which entails cycling or manipulating training variables to provide variation in volume and intensity to avoid overtraining.

Neuromuscular Dynamic Stability Exercises

- Advance exercises from Phase II
- Continue chops and lifts in half and tall kneeling and split squat positions
- The pushup progression leads to dynamic wall pushups to dynamic pushups to floor pushups

Clinical Pearl

> Stability exercises should be progressed from static to dynamic movements, bilateral to unilateral activities, and from a stable to unstable base of support.

Plyometrics

- Bilateral throwing patterns using chest pass movements into the rebounder progressing to single arm activities
- Overhead bilateral medicine ball slams

Functional Exercises

- Overhead strengthening is incorporated, such as kettlebell presses, pullups, etc.
- Lower extremity agility drills are added, such as higher speed cone/footwork, bounding, hurdles, and box jumping.

Sport-Specific Exercises

- Progression to a formal strength and conditioning program once athletes have full mobility/ROM, strength, and are pain free with upper quarter activity/movements.

Milestones for Progression to Advanced Sport-Specific Training and Conditioning

- Improve function, strength, endurance, and stability as well as improved neuromuscular control and coordination of the kinetic chain.
- Power tests may include overhead medicine ball throw and standing rotational medicine ball throw.

Note: Mobility/ROM are measured and assessed via goniometry measurement, so that right versus left extremities are within 10° of one another to achieve symmetry. Strength comparisons are measured via manual muscle testing (MMT) to assess symmetry right versus left. Stability, endurance, and power tests are measured by assessing symmetry right versus left with the absence of compensatory motion during observed movement patterns.

Phase IV: Return to Sport/ Competition (weeks 12+)

Note: Volume/duration: Perform 10 to 15 reps, 1 to 3 sets per exercise, depending on quality of movement and minimizing the presence of compensatory movement patterns. Exercise will be terminated when there is a decrease in movement quality and/or movement compensations noted.

Goals

- Return to sport symptom-free
- Normal kinematics: no scapular dyskinesis, no SICK scapula, improved neuromuscular control, and muscle firing patterns throughout kinetic chain
- Improved cardio and anaerobic function
- Patient has increased knowledge and understanding of their body, function, predispositions to injury, mechanical awareness, the need to build in recovery into their program, and have a "plan"
- Continue maintenance drills, exercises, movement patterns, correctives, stretching, and sport-specific training

Management of Pain and Swelling

- Ice application postexercise as needed

Techniques for Progressive Increase in Range of Motion

Manual Therapy Techniques

- Manual therapy techniques as previously stated in Phase III as needed.
- Additional joint mobilizations can be targeted toward hypomobile joints, including the glenohumeral joint (grade III to IV), scapulothoracic joint, and thoracic spine as needed.

Soft Tissue Techniques

- Patient instruction self-management techniques including the use of a foam roller, tennis ball, or lacrosse ball which can provide long-term treatment options.

Stretching and Flexibility Techniques for the Musculotendinous Unit

- Use of sustained end range stretching to achieve desired mobility goals.
- Pre- and postexercise stretching should focus on functional movement patterns.

Other Therapeutic Exercises

- Multijoint movements should be included in this phase including front squats, deadlifts, overhead press, pull-ups, and rows.

Activation of Primary Muscles Involved

- Focus should be establishing on returning to a level of preinjury function.

Sensorimotor Exercises

- D1/D2 movements with cables or bands
- Ball toss exercises in standing or split squat
- Medicine ball rotations

Open and Closed Kinetic Chain Exercises

- Advancing the previous exercises from Phase III in accordance with sport-specific demands
- Examples of progression may include kettlebell swings, push presses, snatch, and power cleans

Techniques to Increase Muscle Strength, Power, and Endurance

- Continue periodization to optimize recovery and return to sport.

Neuromuscular Dynamic Stability Exercises

- Resistance exercises in standing progress from symmetrical stance to asymmetrical stance to unstable surfaces as necessary. Exercises may include PNF movements, such as resisted chops and lifts.
- Kettlebell Turkish get-ups with added neck and shoulder rotations in each phase (Figure 6-59)

Clinical Pearl

> Dynamic stability exercises and strength training should duplicate the endurance, strength, and power demands that will be encountered closest to an athlete's chosen sport.

Plyometrics

- Advance level of dynamic pushups, plank walking up and down over a step, and overhead tossing activities/ movements

Sport-Specific Exercises

- Light sport-specific training including light throwing for pitchers and light overhead stroke movements for swimmers

Specific Criteria for Return to Sports Participation: Tests and Measurements

- Pain scale (VAS): 0/10, full shoulder ROM/mobility in all planes, strength/MMT 4+ to 5/5 in all planes, HHD: less than 5% to 10% right versus left.
- Upper extremity Y-balance test: less than 4 cm difference right versus left in all test directions.
- Closed kinetic chain upper extremity stability test.
- Functional movement screen (FMS): >14 total score with a ≥2–2 right to left symmetry on the shoulder mobility test component.

Multiple-Choice Questions

QUESTION 1. The goals of Phase I rehabilitation include all but:

A. Protect healing segment
B. Minimize effect of spinal immobilization
C. No signs or symptoms of instability
D. Return to sports

QUESTION 2. What are appropriate interventions for Phase III rehabilitation?

A. Manual therapy
B. Stretching exercises
C. Begin return to sport activity
D. All the above

QUESTION 3. The act of _____ has been shown to activate reflex contraction of the rotator cuff muscles?

A. Neck rotation
B. Gripping
C. Jaw clenching
D. Eye tracking

QUESTION 4. During which time frame does "return to sport" start?

A. Week 6
B. Week 8
C. Week 10
D. Week 12

QUESTION 5. What is not a criteria for progression of the patient to the next phase?

A. Increased AROM without pain
B. Able to perform sport-specific motion without pain
C. Able to tolerate improved activity without pain
D. Contact sports without physician clearance

Answer Key

QUESTION 1. Correct answer: **D** (see Phase I)

QUESTION 2. Correct answer: **D** (see Phase III)

QUESTION 3. Correct answer: **B** (see Phase I: third Clinical Pearl)

QUESTION 4. Correct answer: **D** (see Phase IV)

QUESTION 5. Correct answer: **D** (see Phase I-IV)

POSTOPERATIVE REHABILITATION AFTER TREATMENT OF INTERNAL IMPINGEMENT

Mark Rogow, ATC, CSCS, and Charles E. Rainey, PT, DSc, DPT, OCS, SCS, CSCS, FAAOMPT

Indications for Surgical Treatment

- Persistent activity-related pain and/or pain with instability with desire to continue in these sports/activities.
- This is typically experienced by throwing athletes, caused by the articular side of the insertion of the supraspinatus tendon impinging against the posterosuperior glenoid rim in the combined movement of abduction and extreme external rotation (overhead throwing position) (Figure 6-60).
- Prehabilitation failed: The preoperative rehabilitation protocol offered in this text is a quality example of the needs and goals of what should be accomplished. If this fails, then surgical treatment should be considered if the athlete has a strong desire to return to their sport at the level at which they were competing before their injury.
- In the nonathletic population, conservative treatment is recommended for a minimum of 3 to 6 months. Be sure to determine their level of symptoms and activities in which they are limited before deciding upon surgery.
- When pain and a positive relocation test persist after rehabilitation.
- Surgery may be recommended earlier in the athlete.

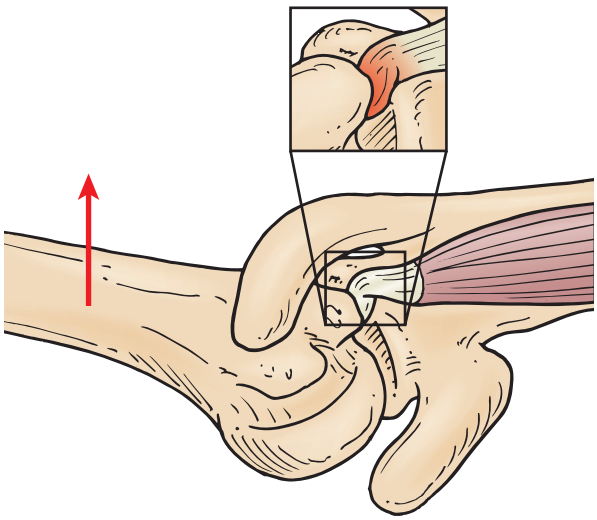

FIGURE 6-60. Articular side of the insertion of the supraspinatus tendon impinging against the posterosuperior glenoid rim in the combined movement of abduction and extreme external rotation.

Brief Summary of Surgical Treatment

Major Surgical Steps (Debridement Only)

- General anesthesia and shoulder arthroscopy, patient in lateral decubitus position
- Diagnostic arthroscopy to document all pathology (Figure 6-61)
- Glenohumeral joint explored through posterior portal to examine partial tears in the supraspinatus and infraspinatus tendon insertion and posterior labrum
- An anterior-superior instrument portal is used, just anterior to the acromioclavicular joint.
- Arm is positioned in abduction-extension-external rotation (the critical position) to ensure all pathology is detected and confirm diagnosis (demonstrating the tendon lesion impinged on the glenoid rim).
- Extensive debridement of the posterior labrum is performed with a motorized shaver, starting superiorly 15 to 20 mm posterior to the biceps insertion, removing all the pathologic tissue and precluding any labral reinsertion.
- Soft tissue debridement is often continued into the posteroinferior glenoid rim (seven o'clock position) to obtain a smooth posterior angle.
- Glenoidplasty performed with a motorized burr, removing all spurs present from the posterior glenoid rim.
- An additional instrumental portal is required many times to reach the posteroinferior glenoid rim more easily
- The arm is positioned in the critical position to ensure absence of internal (posterior) impingement

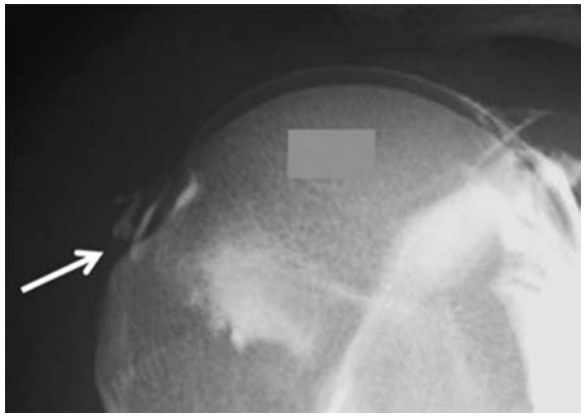

FIGURE 6-61. Partial tear of the articular side of the supraspinatus tendon (*arrow*) shown on arthrogram.

- Padded abduction sling postoperatively for patient comfort

Factors That May Affect Rehabilitation

Surgical

- If arthroscopic labral repair, rotator cuff repair or bicep tendon tendinosis are performed, the repaired structures will need to be protected for 6 weeks.
- This includes limited passive glenohumeral abduction and external rotation ROM, active shoulder ROM, and resistive bicep work.
- The sling may be discontinued at 4 to 5 weeks postoperatively depending on surgeon preference and patient compliance with ROM restrictions.

Before Surgery: Overview of Goals, Milestones, and Guidelines[1]

The prehabilitation outline is included in the nonoperative rehabilitation section of this chapter. We strongly recommend executing the program or at least a majority of it before choosing surgical intervention.

Goals to be Met Before Surgery

- Establish diagnosis: Identify if there is GIRD, posterior capsular hypomobility, a lack of rotator cuff and/or scapular strength and endurance, acquired glenohumeral anterior instability, labral and/or rotator cuff injury, or a combination of a number of these dysfunctions/pathologies. Establish a plan to address each of these conditions
- Optimize postural alignment
- Address SICK scapula and/or scapular dyskinesis
- Restore glenohumeral and scapulothoracic joint mobility
- Address any and all mobility issues and fascial restrictions from nose to toes
- Reestablish and enhance dynamic stability/muscle synergy (balance)/neuromuscular control of both glenohumeral and scapulothoracic joints
- Improve shoulder, trunk, lumbopelvic, and ankle stability
- Monitor progress closely and advance forward in the program as milestones are achieved. Moving forward in a program is less determined by time, rather than by goals attained. However, it is possible to be working in multiple phases given the performance of the entire kinetic chain is being rehabilitated and improved, not a single body part.
- Return to ADLs without pain.
- Increase strength, power, endurance, and myokinematics of entire kinetic chain.
- Failure to return to sport after goals above had been met.

[1]*Prehabilitation, if appropriate, is described in the Nonoperative Rehabilitation section of this chapter.*

Clinical Pearls

Jobe's clinical classification of internal impingement:
- Stage III (Advanced): Surgery is likely indicated for patients who have not responded to nonoperative treatment when pain localized to the posterior shoulder in the late-cocking and early acceleration phases of throwing, and/or have pain with activities of daily living.
- When pain and a positive relocation test persist after rehabilitation, Jobe feels that such patients require surgical repair of their rotator cuff and/or labral pathology as well as a modified anterior capsulolabral shift.

GUIDING PRINCIPLES OF INTERNAL IMPINGEMENT REHABILITATION

- Understand type(s) of surgical repair performed is critical
- Understand the anatomic structures and their rate of healing
- Understand positions and activities that stress the healing structures
- Proper selection of manual therapy intervention applied at the appropriate phase of healing
- Respect rate of ROM progression
- Because every surgical repair is different, respect that the rehabilitation progression needs to be customized to the individual, taking into account their sport, size of repair, age, type of repair, as well as their willingness and ability to comply with the protocol.

After Surgery—Postoperative Rehabilitation: Overview of Goals, Important Milestones and Guidelines

Factors Contributing to and Pathologies Resulting from Internal Impingement

- Poor scapular mechanics and movement patterns (dyskinesis)
- Weak scapular stabilizers and/or rotator cuff
- Lack of endurance of scapular stabilizers and/or rotator cuff
- Partial tear or complete tear of rotator cuff: Surgeons have identified undersurface tears of the anterior aspect of the infraspinatus tendon as well as undersurface tears on the posterior aspect of the supraspinatus
- Laxity of the anterior capsule: Acquired glenohumeral anterior instability
- Labral pathology: Most commonly superior-posterior labral tears
- GIRD: Significant loss of glenohumeral internal rotation
- Less than optimal posture
- Bony changes: Bennett's lesion (extra-articular ossification of the posterior capsule)
- Glenoid chondral erosion

- Chondromalacia of posteriosuperior humeral head
- Biceps tendon pathology

GUIDING PRINCIPLES OF INTERNAL IMPINGEMENT REHABILITATION

- Establish diagnosis: Identify if there is GIRD, posterior capsular hypomobility, a lack of rotator cuff and/or scapular strength and endurance, acquired glenohumeral anterior instability, labral and/or rotator cuff injury or a combination of a number of these dysfunctions/pathologies before surgery. Establish a plan to address each of these conditions following surgery in congruence with the patient's surgeon.
- Once the postoperative restrictions have been established, the rehabilitation protocol needs to be customized based on the patient's age, tissue quality, size of tear, security of repair, and additional procedures performed.
- Optimize postural alignment
- Address SICK scapula and/or scapular dyskinesis
- Restore glenohumeral and scapulothoracic joint mobility
- Address any and all mobility issues and fascial restrictions from nose to toes
- Reestablish and enhance dynamic stability/muscle synergy (balance)/neuromuscular control of both glenohumeral and scapula-thoracic joints
- Improve shoulder, trunk, lumbopelvic, and ankle stability
- Monitor progress closely and advance forward in the program as milestones are achieved. Moving forward in a program is less determined by time, rather than by goals attained. However, it is possible to be working in multiple phases given the performance of the entire kinetic chain is being rehabilitated and improved, not a single body part.
- Return to ADLs without pain
- Increase strength, power, endurance and myokinematics of entire kinetic chain
- Return to sport!

Phase I: Immediate Postoperative Period (days 0 to 14)

Volume/duration: Perform 10 to 15 reps, 1 to 3 sets per exercise, depending on quality of movement and minimizing the presence of compensatory movement patterns. Exercise will be terminated when there is a decrease in movement quality and/or movement compensations noted.

Clinical Pearl

- The rehabilitation program should move along a continuum. Its difficulty should increase over time with respect to the sport or desired activity[1] and evolve from bilateral to unilateral, supported to unsupported,[2] using active and passive movement, with and without load.[3]

Goals

- Protect the repaired structures
- Minimize the effects of immobilization
- Decrease pain and inflammation
- Retard muscle atrophy
- Restoring good posture
- Facilitating scapular mobility and control
- Initiate core stabilization exercise

If the athlete/patient is progressing without complications (with no signs of infection, no signs and symptoms of instability, or damage to the repair) progress to the next phase.

Protection

- Postoperative immobilization is achieved via sling use with the arm in slight abduction and neutral rotation.
- A sling with an abduction pillow is preferred due to patient comfort and proper glenohumeral positioning to prevent stress to the healing superior and posterior structures.
- Sling is to be used at all times, including sleep, unless directed by physician or therapist.
- Discuss proper sleep hygiene: Do not sleep on shoulder, do not sleep with arm/shoulder in overhead position (prone, supine or side-lying)
- If patient maintains kyphosis, forward head, forward shoulder posture, consider postural correction shirt or proprioceptive scapula taping.

Management of Pain and Swelling

- Oral pain medications as prescribed by surgeon
- Therapeutic modalities for pain and inflammation to include TENS, Hi-Volt and IFC e-stimulation
- TENS to control pain as well as inhibit muscular guarding and spasm
- Cryotherapy for pain and inflammation reduction
- Poly-mem/sports wrap and Kinesio taping (fan/weave technique) if postoperative swelling visible
- Patient education: Using pillows or bolsters to find a position of comfort to reduce stress on contractile structures of the shoulder as well as repaired structures while resting and sleeping

Techniques for Progressive Increase in Range of Motion

Manual Therapy Techniques

- ROM Precautions: IR 0°, humeral elevation in scapular plane 90° (precautions adjusted for other concurrent surgical repairs such as SLAP, Bankart repair, posterior capsule release, anterior capsule plication)
- PROM: Manual range of glenohumeral joint via oscillatory passive range of motion (per precautions) as well as affected elbow/wrist (flexion, extension), and scapula. Muscular guarding should be considered and manual therapy adjusted as necessary to facilitate relaxation to avoid undue stresses on the posterior capsulolabral complex. Additionally, stretching into

the end ranges should be avoided to prevent stressing the repair and limit any unnecessary increase in inflammation.[4]

Stretching and Flexibility Techniques for the Musculotendinous Unit

- Shoulder stretching not performed during this stage with the exception of the cervical musculature (i.e., levator scapula, upper trapezius) as needed.
- Grade I to II glenohumeral/scapulothoracic joint mobs

Clinical Pearl

- If SLAP repair or biceps tenodesis has been performed, NO biceps muscle activation should be performed for first 8 weeks.

Other Therapeutic Exercises

- Athletes/patients are encouraged to participate in low intensity cardiovascular conditioning activities such as stationary biking or treadmill walking. The sling must be worn during these activities and if there is increased pain or muscle guarding, the activity should be modified or ceased.
- Core stabilization exercises: Supine
  - Establish neutral pelvis
  - Draw-in maneuver
  - Partial crunch
  - Pelvic tilts
  - Bridging/single-leg bridge/bridge marching
  - Dead bugs (moving legs only)
  - Physio ball wall squats
- Evaluate for and treat deep neck flexor inhibition (may need tissue work on suboccipitals, cervical extensors, and scalenes)
  - Supine active chin tuck
  - Supine cervical flexion
- Properly instruct diaphragmatic breathing
  - The importance of breathing and the quality of each breath needs to be emphasized to the patient throughout their exercise program, so the volume dosage parallels their therapeutic exercise dosage. They should inhale and exhale fully on every repetition.
- Dynamic lower extremity exercises
  - Body weight squats
  - Lunges (in the sagittal, frontal and transverse planes)
  - Step-ups
  - Lateral step-ups
  - Step-downs
  - Trendelenburg exercise
  - Thera-Band walking (forward, backward, side-step)
  - Romanian dead lift (can use light weight with uninjured arm)
  - Good morning exercise (body weight only)
  - Single-leg stance/single leg excursions (in the sagittal, frontal and transverse planes)
  - Calf exercises

Clinical Pearls

- All exercises and stretches in this phase should be done pain free, slowly and under control.
- Reinforcement of quality movement and mechanics while working on posture and scapular control needs to be regular and routine.
- It is critical to achieve good scapular control before increasing volume and intensity of strength training or the underlying issue of scapular dyskinesis and poor scapular control will either slow the athlete's return to play or will significantly increase the athlete's predisposition to reinjury.

Activation of Primary Muscles Involved in Injury Area or Surgical Structures

- Postural Exercises
  - Reinforce proper scapular position
  - Sternal lifts
  - Scapular pinches (supine, side-lying)
- Codman's Pendulum exercises to maintain passive motion at the glenohumeral joint. Due to improper technique, which is often observed clinically, the use of assisted Codman's with the sound side support of the affected arm until the patient understands and regularly executes proper technique is recommended.
- UE ranger exercises (Figure 6-62)
  - Flexion/extension
  - Abduction/adduction from 0° to 45° abduction
  - Circumduction
- Hand gripping and active wrist flexion and extension range of motion activities initiated.

Clinical Pearl

- Establish or maintain good posture and good scapulothoracic position throughout the day. Using postural correction shirts, clavicle collars, as well as Kinesio-type tape, can help reinforce and/or reeducate critical postural and suprascapular muscles.

Sensorimotor Exercises

- Finger and wrist kinesthetic and strengthening exercises can be performed; however, no pronation or supination should be done, while the biceps is not to be exercised if a biceps tendinosis was performed.
- Active assistive ROM; cane/wand exercises after 7 to 14 days postoperatively

Open and Closed Kinetic Chain (CKC) Exercises

- Depending upon healing parameters and type of repair performed, patient may begin upper extremity CKC exercises versus the therapist.
- The hand of the patient needs to be gripping an object, either the therapist's hand or another object, to initiate the coupling and co-contraction of the scapulothoracic and glenohumeral musculature to prevent shear, increase joint stability, reproduce, or provide proprioceptive stimulation to joint mechanoreceptors (GTO,

FIGURE 6-62. UE Ranger. **A,B**, Shoulder flexion/extension with contralateral scapular retraction. **C,D,** Shoulder abduction/adduction with contralateral scapular retraction. **E,F,G,H,** Perform shoulder circumduction or write 'alphabet' with hand while contralateral scapula maintains retracted position.

muscle spindle, etc.) which helps to reorganize and reestablish normal muscle firing patterns.
- Submaximal isometrics can also begin after first week of healing.

Clinical Pearls

- The act of gripping has been shown to activate reflex contraction of the rotator cuff muscles which will stimulate glenohumeral mechanoreceptors.[5]
- This in turn increases joint compression and dynamic muscular cocontraction improving joint congruity, reduce shear forces, stimulates joint proprioceptors while enhancing dynamic stabilization.[6]

Techniques to Increase Muscle Strength, Power, and Endurance

- Resistance to lower body and core strengthening exercises should be light in resistance and in intensity throughout this phase. Begin to increase endurance (increase repetitions/volume) in the second half of this phase.

Neuromuscular Dynamic Stability Exercises

- Begin core/trunk stability exercises listed above.

Functional Exercises

- Discuss with patient shoulder/spine posture. Give home exercise program
- Initiate diaphragmatic breathing

Milestones for Progression to the Next Phase

- Minimal pain with PROM
- Decreased tenderness and swelling on and around incision
- Isometrics performed pain free
- Ready to move forward with active assistive range of motion (AAROM)
- Ready to begin active range of motion (AROM)

Phase II: Mobility (weeks 2 to 6)

Volume/duration: Perform 10 to 15 reps, 1 to 3 sets per exercise, depending on quality of movement and minimizing the presence of compensatory movement patterns. Exercise will be terminated when there is a decrease in movement quality and/or movement compensations noted.

Goals

- Protect repaired structure(s)
- Minimize effect of immobilization
- Retard muscle atrophy
- PROM glenohumeral elevation in scapular plane of 140°, ER 30°
- No marked pain globally about the glenohumeral joint
- No signs or symptoms of instability
- Restoring good posture
- Facilitating scapular mobility and control
- Continue core stabilization exercise

Protection

- Use of the sling is continued. If arthroscopic labral repair was performed without involvement of the rotator cuff musculature or bicep tendon, the sling may be discontinued at 4 to 5 weeks postoperatively depending on surgeon preference and patient compliance with ROM restrictions.
- Continue to use proper sleep hygiene, especially after the sling has been discontinued.

Management of Pain and Swelling

- Electrotherapy (TENS and IFC) is continued for pain and muscle guarding
- Hi-Volt E-stimulation/Russian helps muscle reeducation
- Oral pain medications are usually continued (per physician/surgeon)
- Cryotherapy with compression postexercise/treatment and at home if needed

Techniques for Progressive Increase in Range of Motion

Manual Therapy Techniques

- ROM precautions: IR 0°, ER 30°, horizontal adduction 0°, scapular plane elevation to 120° week 4, scapular plane elevation to 140° week 6, sagittal plane flexion 90° week 4, sagittal plan flexion 120° week 6.
- PROM: Manual ROM of the humerus (per above precautions) while ensuring quality of glenohumeral and scapulothoracic motion and avoidance of excessive/compensatory scapular mobility to impingement. Scapular elevation, depression, and abduction.
- Grade I and III glenohumeral joint mobilizations, with light traction, may improve available PROM and also contribute to pain management.

Soft Tissue Techniques

- Scar mobilization to postsurgical incisions once closed.
- Soft tissue massage/mobilizations, IASTM (instrumental assisted soft tissue mobilization), and trigger point dry needling are all indicated to reduce spasm, tightness, reset muscle tendon units, and improve joint restrictions.
- Be sure to look outside the glenohumeral joint to cervical, thoracic, scapulothoracic, acromio- and sternoclavicular restrictions all affect position and function of the glenohumeral joint

Stretching and Flexibility Techniques for the Musculotendinous Unit

- Patients may begin table slides or physio ball rolling for passive techniques within the ROM precautions.

- AROM: Scapular clocks are continued and scapular dumps are initiated to emphasize thoracic and lumbar mobility.
  - Scapular clocks: with elbow extended, hand is placed in either abducted position (at 90°), in scapular plane or with shoulder flexed to 90° at 0° abducted. Always with hand against fixed object, like a wall. Actively retract and protract scapula (9 to 3 o'clock), then elevate and depress scapula (12 to 6 o'clock). Note: Scapular dumps are equivalent to lawnmowers.
- Elbow and wrist ROM is encouraged and can be done as part of the Home Exercise Program.
- Pulleys for AAROM may begin after the second postoperative week (depending upon the type of repairs performed in surgery) as long as correct technique is demonstrated. As patients gain PROM to 120° in the scapular plane without guarding or pain, AAROM techniques are continued to include flexion and abduction via wands, wall walks and the UE ranger with cues to avoid compensatory shoulder shrugs.

TIMELINE 6-5: **Postsurgical Rehabilitation After Treatment of Internal Impingement**

PHASE I (weeks 1 to 2)	PHASE II (weeks 2 to 6)	PHASE III (weeks 6 to 10)
• Postop immobilization: wear sling at all times (including sleep) • Pain control: oral pain meds as prescribed • E-stimulation and cryotherapy for pain/inflammation • Patient education: proper sleep hygiene and positioning • PROM to glenohumeral, scapula, elbow, and wrist • Glenohumeral ROM precautions: IR 0°, scapular plane elevation 90° • Grade I/II mobs to glenohumeral and scapulothoracic joints • AAROM with can/wand exercises after 7–14 days postop • Sub-maximal isometrics can begin at 7 days postop • Cervical musculature (upper traps, levator scapulae) stretching as needed. • Low intensity cardiovascular activities (treadmill, stationary bike) • Core stabilization exercises in supine • Codman Pendulum exercises • UE ranger exercises • Hand gripping, active wrist flex/ext activities, finger strengthening • Diaphragmatic breathing in all exercise postures • Postural stabilization exercises (scapular pinches) • Dynamic lower extremity CKC exercises (squats, lunges, step-ups, lateral step-ups, etc.)	• Continue to wear sling. If repair performing without rotator cuff or bicep tendon repair, sling may be D/C at 4–5 per surgeon • Continue proper sleep hygiene and positioning • Oral pain medications continued per surgeon • E-stimulation and cryotherapy for pain/inflammation • Continue ROM to glenohumeral, scapula, elbow, and wrist • Wk 4: IR 0°, ER 30°, horizontal adduction 0°, scapular plane elevation to 120°, sagittal plane flexion 90° • Wk 6: scapular plane elevation to 140°, sagittal plan flexion 120° week 6 • Avoid horizontal adduction and shoulder extension beyond neutral/beyond the frontal plane with ALL exercises • Grade II/III to glenohumeral joint for ROM and pain management • Scar mobilizations to incisions once closed • Soft tissue mobilizations to upper quarter in include cervical, thoracic, scapulothoracic, acromio- and sternoclavicular restrictions • Pulleys for AAROM can begin at Week 2, progress to AROM per pt tolerance • Began light AROM movements (wall walks, seated towel slides behind back) • Continue scapular stability exercises (Is, Ys Ts, Ws) • Scapular AROM (scapular clocks) and PNF patterns in all planes • Moderate intensity cardiovascular exercise (treadmill. stationary bike, elliptical, StairMaster, etc.) • Kettle bell holds with shoulder packing (supine/side-lying) • Core stabilization in supine/prone (dead bugs, SL/DL bridges, etc.) • Continue dynamic lower extremity CKC exercises • Lower extremity balance activities (SL stance eyes open/closed, BOSU ball, Airex pad, balance beam) • Begin motor control exercises, such as PNF rhythmic stabilization and perturbations (physio ball oscillations with arm outstretched) • Begin quadruped upper extremity weight shifting if healing parameters and repair type is suitable • Pushup holds leaning into wall • Seated towel slides • Thumbtacks	• D/C sling • Oral analgesics prn per surgeon • E-stimulation and cryotherapy use as needed or use postexercise soreness • AAROM and AROM for glenohumeral and scapulothoracic joints performed in all planes (no ROM restrictions, per pt tolerance only) • Joint mobilizations (Gr I-IV) per capsule restrictions • Rotator cuff strengthening/stability exercises • Sleeper stretch/modified sleeper stretch • Side-lying horizontal adduction stretch • Bicep/triceps strengthening • Body blade/perturbations • Continue to advance scapular stability exercises (Is, Ys, Ts, Ws) • Continue scar mobilization, including cross-friction • Soft tissue mobilizations and self-stretching to upper quarter musculature (pectoralis major/minor, levator scapulae, upper trapezius, lats, rhomboids, rotator cuff muscles) • Pulleys or cable pulls • Viper (rope climbing machine) • Standing forearm wall slides • Wax on/wax off exercises • Dynamic 4 exercises • Quadruped weight shifts and pushups on knees • Seated press-ups at Week 10 • Cardiovascular endurance activities (light jogging, swimming, UBE) • Advanced core stabilization exercises (Supermans, quadruped diagonals/bird dogs, dead bugs) • Lower extremity balance activities • Low level lower extremity plyometrics (dot drills, jump rope, hops, skipping, low level bounding/box jumps)

- Careful observation for compensation and emphasis on restoring scapulohumeral mechanics is important while increasing ROM during this phase to avoid subacromial impingement.

Other Therapeutic Exercises

- Athletes/Patients should continue low to moderate intensity cardiovascular conditioning activities such as:
  - Stationary biking
  - Treadmill walking
  - Treadmill incline
  - Elliptical
  - Arc trainer
  - Stairmaster
  - Outdoor walking and/or up to moderate level hiking

Be sure that the potential need for upper body support and loading during the use of stairclimbers, elliptical and arc trainer activities restricts safe implementation of these conditioning options until 8 weeks postoperatively in most postsurgical cases. In this phase the sling may be

TIMELINE 6-5: Postsurgical Rehabilitation After Treatment of Internal Impingement (Continued)

PHASE IV (weeks 10 to 14)	PHASE V (weeks 14 to 24)	PHASE VI (weeks 24 to 52)
• Oral analgesics prn per surgeon • E-stim and cryotherapy use as needed or use postexercise soreness • PROM to full ROM • Glenohumeral joint mobilizations (Gr III-IV) as needed • Continue scar mobilization as needed • Continue soft tissue mobilizations to pec major/minor, subscapularis. Lats • End-range stretching of upper quarter musculature • IR stretching can begin at Week 12 postop (cross chest stretch, sleeper stretch) • Rotator cuff strengthening/stability exercises • Bent over rows • Jacob's ladder • TRX serratus hug exercise • Half/tall kneeling chops and lifts with narrow base (with and without resistance) • Glenohumeral PNF D1/D2 patterns • Pushups (wall pushups to standard floor pushups) • Lower extremity SL balance exercises progressed • Medicine ball front squats • Dynamic CKC activities with manual perturbation, tilt boards • Lower extremity plyometrics progressed • Upper extremity rebounder exercises (chest pass, ER/IR ball toss/catch) • Begin walk-jog progress at 12 weeks • Lower extremity sport-specific drills (hops, jumping, change in direction/agility drills)	• Continue joint mobilizations (Gr III-IV) and soft tissue mobilizations as needed • Continue scar mobilization as necessary • End-range stretching of upper quarter musculature • Progress lower extremity, gluteal, and hip stretch exercises • OKC: Upright rows, seated rows, lateral raises, front raises • OKC: ER/IR at 0° and 90° abduction, isotonic/resistance bands, PNFs, diagonal lift and chop exercises, pool resisted motions • CKC: side planks, front planks and weight shifts on stable and progress to unstable surfaces • CKC: BOSU ball for progression of pushups to uneven surfaces • Advance upper body strengthening • Pushup progression from single arm wall pushup to floor pushups • Upper body plyometrics using bilateral arm throwing patterns • Overhead bilateral medicine ball slams and catching drills • Rebounder IR/ER at 90° abduction • Overhead strengthening • TRX Exercises (SL squat, mountain climbers, split squat, prone runners, etc.) • Lower extremity agility program (ladder and hurdle drills) • Progress lower extremity balance activities • Running progression • Turkish get-up progression • Bear crawling • Inchworms/crabs • SFMA Rolling patterns (upper body/lower body) • Dynamic stability exercises (jumping jacks, walking lunges, skipping, hops, etc.) • Throwing athletes begin light tossing at short distances (avoid full wind-up until 20 wk postop)	• Cryotherapy postexercise • Joint mobilizations to glenohumeral, scapulothoracic, thoracic spine as needed • Self soft tissue mobilizations using tennis/racquet ball as needed • Home stretching for posterior capsule progression (supine horizontal stretch with IR, sleeper stretch) • Continue end range stretching for upper body musculature • Multijoint movements (front squats, power/hang cleans, clean and press) • Ball toss exercises in standing • D1/D1 exercises with cables • Medicine ball throwing activities (diagonals, woodchops, slams, Russian twists) • Advance upper body plyometrics (overhead toss, dynamic pushups, etc.) • Single arm dumbbell walks • Rock climbing wall • Tire flipping • Battle rope exercises • Wk 24: Throwing athletes begin short tossing (increase throwing intensity/volume) • Wk 24: Swimming athletes begin limited overhead stroke work • Return to sport: continue fitness/rehab exercises including total body strengthening program

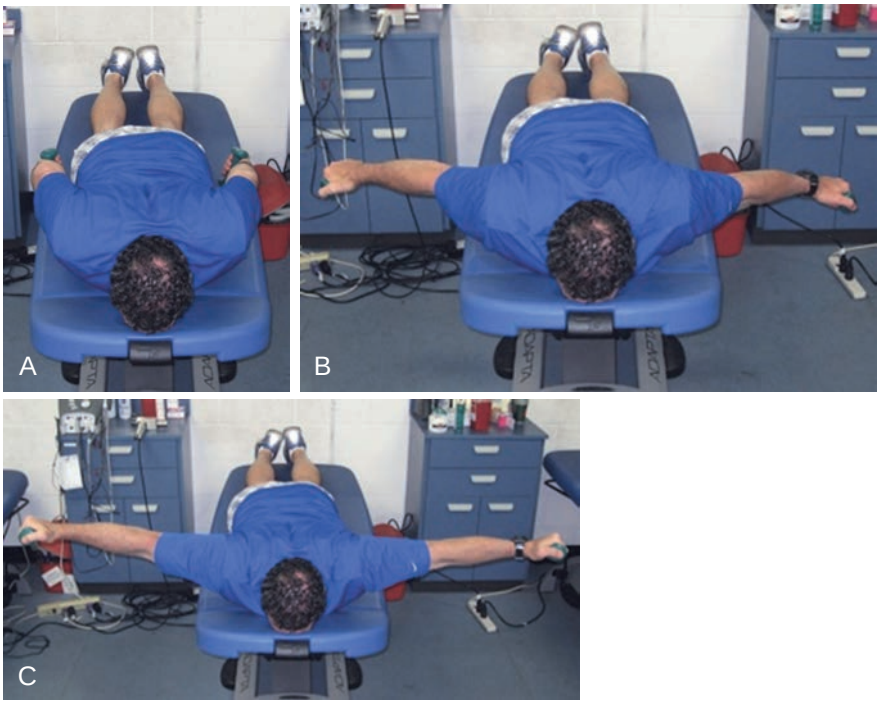

FIGURE 6-63. Prone I (**A**), V (**B**), T (**C**) light dumbbell or cuff weight exercise.

worn during these activities initially, however, will not be worn by the end of this phase.

- Core stabilization exercises (supine/prone)
  - Establish neutral pelvis
  - Draw-in maneuver
  - Partial crunch
  - Pelvic tilts
  - Bridging
    - Bridging in supine position, with knees bent, extend hips toward ceiling by pushing through heels and mid-foot.
  - Single-leg bridge
    - Single-leg bridge is performing this with only one leg while the other leg is extended.
  - Bridge marching
    - Bridge marching is maintaining hips in extended position and alternating each foot on and off the table (or floor).
  - Butterflies
    - Butterflies are the same as clamshells: Side-lying with hips and knees bent at 90° with Thera-Band around knees, keep bottom leg on table or floor while the top leg externally rotates and abducts.
  - Modified dead bugs (arms may begin to flex above 90° if pain free and allowable per the protocol/arms may also press against the ground or versus tubing (concentric or isometric shoulder extension)
  - Wall/table prone plank (on elbows against wall or table)
- Lower extremity exercises during this phase may include all those listed in Phase I. The volume of those exercises should be increased in this phase. Intensity/resistance should increase in the next phase. Can add:
  - Single leg Romanian Deadlifts (RDLs)
  - Machines: Leg extension, leg curl, abduction/adduction, multihip

Activation of Primary Muscles Involved in Injury Area or Surgical Structures

- Sub-maximal isometrics are begun in neutral rotation and less than 30° abduction with the elbow flexed to 90° with submaximal force (modified neutral):
  - Flexion/extension
  - Abduction/adduction
  - IR/ER
- Continue scapular squeezes/pinches and sternal lifts
- Modified prone (bilateral 5 second holds with slow and control eccentric lowering of arms) (Figure 6-63)
  - I
  - V/Y
  - T
- Unsupported Codman's are continued
- UE ranger exercises with ranger on floor and with ranger on wall
  - Flexion/extension
  - Abduction/adduction within protocol rom
  - Circumduction
- AROM may be initiated as to include:
  - Wall walks
  - Standing shoulder raises (shoulder flexion and scaption in the open can position)
- May begin low rows toward end of this phase
- Hydrotherapy
  - Front raises/scaption, lateral raises with foam bells (AAROM)
  - Scapular protraction/retraction with foam bells (Punches)
    - Foam bells are dumbbells made out of foam material.
  - IR/ER in modified neutral position
  - Rhythmic stabilization in any of these planes/exercises (sub maximal effort)
  - Bicep curls

FIGURE 6-64. Kettle bell holds. **A,B,** Supine (kettle bell bottom down and bottom up). **C,D,** Side-lying (kettle bell bottom down and bottom up).

- Triceps pressdowns
- Shrugs/reverse shrugs

- Patients are reminded to avoid horizontal adduction and shoulder extension beyond neutral/beyond the frontal plane with all exercises

If possible, use mirror for immediate visual feedback so patient can see compensations, uneven shoulder height, posture, and more!

Sensorimotor Exercises

- Begin active angular replication exercises, for motor control, in the range of 0° to 90° scaption
- Saluting exercise
  - Begin with arm at side, then move hand out in front of body, lightly placing the radial side of the index finger just above same ipsilateral eyebrow. Perform this while maintaining good upright posture and scapular retraction.
- Point, reach, and touch various points against the wall
- Using PNF (proprioceptive neuromuscular facilitation) for the scapula. Manually cue and resist the scapula to elevate/depress, upwardly rotate/downwardly rotate, retract/protract in seated, supine and prone positions
- Kneeling, half-kneeling or standing with hand of injured arm on physio ball on floor or against wall doing up-and-down, left-and-right movement patterns, circles, rhythmic stabilization, and perturbations.
- Kettle bell holds (Figure 6-64)
  - Supine
    - With shoulder at 90°, and extending arm toward ceiling, hold kettle bell with the bottom down. As the patient gets stronger, turn the kettle bell with its bottom up. Be sure to pack the shoulder consciously contracting all periscapular musculature as if to squeeze tight one's armpit. The latissimus must be tonic. Each repetition is to be done for 15 to 30 seconds. (Discontinue if painful and do not perform if surgical repair performed)
- Packing the shoulder: Performed by synergistically and simultaneously cocontracting all muscles about the shoulder complex, making sure that the posterior, suprascapular muscles are firing. They will often times either fatigue sooner or be overshadowed by the more dominant anterior musculature.
  - Side-lying
    - Move to side-lying with the arm extended toward the ceiling or sky and again pack the shoulder.
- Using devices like the Wii and MR Cube which should use little to no resistance in this phase will help increase kinesthetic awareness, sensorimotor function, and

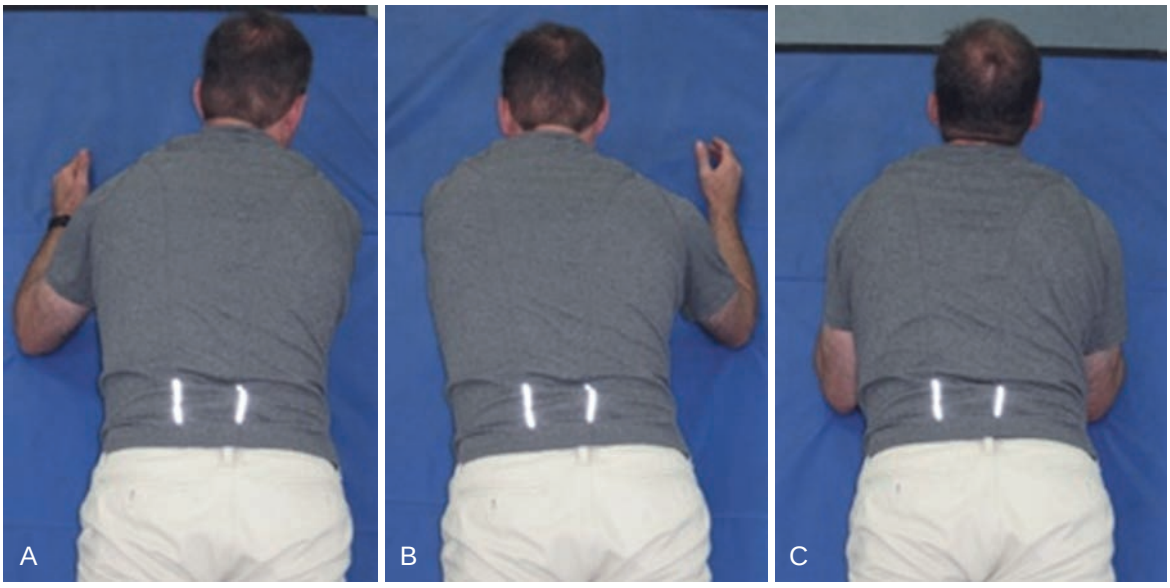

FIGURE 6-65. Quadruped weight shifts. Right (**A**), Left (**B**), Superiorly (**C**).

hand eye coordination. Parameters, which may include ROM limitations and speed of movement, need to be set by therapist.

Open and Closed Kinetic Chain Exercises

- Depending upon healing parameters and type of repair performed, patient may begin upper extremity weight shifting exercise. Begin in modified quadruped position (on elbows and on knees) control minor weight shift to left, right, up, down, and circular movements.
- Pushup position leaning into wall can also be performed if patient is able to have shoulder flexed slightly above 90° without pain or without scapular-thoracic compensation (Figure 6-65).
- Scapular clocks with arm extended against fixed surface with controlling movement of scapulo/glenohumeral joint clockwise and counterclockwise.
- Ball/physio ball oscillations with arm outstretched
- Seated towel slides protracting and retracting scapula while pressing down into table with sub-maximal effort
- Seated towel slides upwardly rotate and downwardly rotate scapula (putting contralateral hand behind neck and actively cocontracting the contralateral scapula usually yields improved dynamic scapular control) (Figure 6-66)
- Thumbtacks: In scapular plane only (Figure 6-67)
  - Imagine gripping a thumbtack on the wall with each hand, then upwardly and downwardly rotate humerus/scapulas and getting a scapular pinch at end range external rotation and repeat
- Pulley exercise: This is an active exercise, not a passive one. Be sure the patient is firing their humeral and scapular depressors throughout the entire exercise. If pain free above 90° can take shoulder through full available pain-free ROM.
  - Flexion/extension
  - Scaption
  - Abduction/adduction
- Total Gym exercises with bench angled from 5° to 30°
  - Low rows; 1 and 2 arm
  - Shoulder extension; seated and supine
  - Shoulder extension with back extension
  - Bicep curls
  - Triceps extensions
  - Seated torso twist with elbows flexed/with elbows extended

Clinical Pearl

- These closed chain exercises should be performed with sub-maximal effort. These exercises are geared more to achieve increased proprioceptive and kinesthetic awareness versus increasing strength.

Techniques to Increase Muscle Strength, Power, and Endurance

- Resistance to lower body and core strengthening exercises can and should increase in this phase; however, resistance shall not be applied on top of, around, or held by the surgical shoulder.
- Weighted vests may be considered depending upon type of surgery and postoperative week.

Neuromuscular Dynamic Stability Exercises

- Lower extremity balance activities may include but are not limited to:
  - Single-leg balance (eyes open and eyes closed 10 to 30 seconds)
  - BOSU ball
  - Star excursions
  - Airex pad/DynaDiscs/Thera-Band foam pad
  - Airex balance beam
- Manual rhythmic stabilization of trunk and core.

FIGURE 6-66. Seated towel slides. **A,** Scapular protraction. **B,** Retraction with contralateral scapula retracted. **C,** Scapular abduction. **D,** Adduction with contralateral scapula retracted.

FIGURE 6-67. A,B, Scapular thumbtacks.

Clinical Pearl

- A key premise of the Dynamic Neuromuscular Stability approach is that every joint position depends on stabilizing muscle function and coordination of both the local and distant muscles to ensure neutral or centered position of joints in the kinetic chain. The quality of this coordination is critical for joint function and influences not only local, but also regional and global anatomical and biomechanical parameters in the kinetic chain. (From Frank C, Kobesova A, Kolar P: Dynamic Neuromuscular Stabilization and Sports Rehabilitation. *Int J Sports Phys Ther* 8:62–73, 2013.)

Functional Exercises

- Seated and standing trunk rotation and trunk diagonals combined with flexion and extension while wearing sling may be performed to maintain thoracolumbar mobility
  - Shoulder dumps
  - Lawnmowers (beginning from contralateral side, end with elbow flexed at side and scapula retracted)
    - Begin the exercise with trunk flexed and rotated to the contralateral side with their hand at the level of their contralateral patella. Rotate the trunk toward the ipsilateral side as the arm that was reaching toward the patella, and extend the hip and trunk to a vertical orientation while simultaneously placing their arm at waist level and retracting their scapula so that the patient tries to place an elbow into their back pocket position.

Milestones for Progression to the Next Phase

- Minimal tenderness to palpation on and around incision
- PROM, AROM, and AAROM performed pain free
- Patient should have or nearly have full active range of motion via goniometer. ROM goals are based on surgeon's protocol.
- Good scapulothoracic joint mechanics/kinematics without compensation or substitution patterns measured qualitatively.

Phase III: Stability (weeks 6 to 10)

Volume/Duration: Perform 10 to 15 reps, 1 to 3 sets per exercise, depending on quality of movement and minimizing the presence of compensatory movement patterns. Exercise will be terminated when there is a decrease in movement quality and/or movement compensations noted.

Goals

- Achieve full pain-free AROM
- Attain normal glenohumeral and scapulothoracic mechanics and rhythm
- Initiate rotator cuff strengthening exercises
- Progress scapular stabilization exercises
- Achieve (if not yet acquired) and maintain cervical, thoracic, lumbopelvic, and ankle mobility
- Advance scapular, cervical, thoracic, lumbopelvic/hip/lower extremity stability training
- Reinforce muscle memory of correct neuromuscular firing going from conscious to unconscious control
- Advance and challenge cardiovascular fitness

Protection

- Sling use is discontinued
- Good sleep best practices continues
- Reinforce patient education as patient will be feeling more and more confident yet rotator cuff exercises are about to begin so it is easy to do too much too soon, especially if there was a rotator cuff repair involved

Management of Pain and Swelling

- Oral analgesic use is continued as needed (per the physician/surgeon)
- NSAIDs should be discontinued by this phase
- IFC E-stimulation for pain control PRN
- Hi-Volt E-stimulation/Russian: muscle re-education/may use with exercise
- Cryotherapy can continue to be used to mitigate postexercise inflammation and soreness if the shoulder does not recover within 24 to 48 hours from exercises

Techniques for Progressive Increase in Range of Motion

Manual Therapy Techniques

- AAROM and AROM should be able to be performed for scaption, ER in scaption, and forward flexion. Progress IR, ER, horizontal adduction, scapular plane elevation, sagittal plane flexion, and abduction.
- PROM: techniques continue in the scapular plane. Sagittal flexion and IR/ER at 45° of abduction are introduced while respecting pain complaints.
- Joint mobilizations: If adhesions are noted, capsular joint mobilizations may begin in reduced ranges such as oscillatory techniques grade I-III for inferior and posterior capsule if indicated per the procedure. Care must be taken when assessing posterior capsular structures. Scapular mobilizations in all planes continue including scapular lifts.

Clinical Pearl

- If multiple procedures were performed (i.e., rotator cuff repair, labral repair, capsular plication, Bankart repair, or others, which is often the case with internal impingement type of procedures), please refer to the more conservative ROM goals for each procedure which is available in this text.

FIGURE 6-68. A,B, Side-lying horizontal adduction self-stretch.

Soft Tissue Techniques

- Scar mobilization techniques including cross-friction are performed to assist with full tissue mobility around the shoulder region. This can also be performed by the patient at home with a little patient education.
- Soft tissue massage/mobilizations, IASTM (instrumental assisted soft tissue mobilization), and trigger point dry needling are all indicated to reduce spasm, tightness, reset muscle tendon units, and improve joint restrictions if needed.
- Low intensity friction massage is indicated for biceps tendon and teres minor tenderness/tendonitis, which are common secondary side effects of internal impingement and can be found postoperatively in some patients.

Stretching and Flexibility Techniques for the Musculotendinous Unit

- Patients should continue table slides and/or physio ball rolling for passive techniques within the ROM precautions.
- AROM: scapular clocks and scapular dumps are continued to emphasize thoracic and lumbar mobility.
- If limited, elbow and wrist ROM should be continued.
- Pulleys or cable pulls (on functional trainer, cable machines or with tubing) for AAROM should continue depending upon the type of repairs performed in surgery) as long as correct technique is demonstrated.
- The common muscle tendon units/soft tissue that tend to be hypomobile, lack pliability and/or joints that lack mobility following internal impingement surgery tend to be: pectoralis minor, levator scapulae, scalenes, upper trapezius, teres minor/infraspinatus, posterior capsule, scapulothroacic joint, and thoracic spine. Be sure to evaluate horizontal adduction, internal rotation, and the sleeper stretch position bilaterally within 6 weeks following surgery. While looking at horizontal adduction be sure the scapula is immobilized and in a neutral position (not retracted or protracted). The scapula needs to be fixed against the thorax before horizontally adducting the humerus. The 6- to 10-week postoperative phase is a critical time to address any and all soft tissue restrictions surrounding the shoulder as well as throughout the kinetic chain.
- Muscles that when tight affect can contribute to scapular dyskinesis:
  - Pectoralis minor
  - Levator scapulae
  - Upper/mid/lower trapezius
  - Rhomboids
  - Infraspinatus/teres minor
  - Latissimus dorsi
- Techniques to improve mobility/flexibility of the scapulothoracic and glenohumeral musculature include:
  - Inferior and posterior glides during horizontal adduction and internal rotation of the humerus on the glenoid (low grade end range mobilization glides to be performed by therapist)
  - Side-lying horizontal adduction stretch (self-stretch) (Figure 6-68)
  - Standing with scapula pinned against wall, horizontally adduct humerus (self-stretch)
  - Standing with scapula pinned against wall, internally rotate humerus with shoulder abducted at 70° and at 90° (self-stretch)
  - Supine horizontal adduction stretch (therapist assisted)
  - Corner stretch (self-stretch)
  - Doorway pectoralis major/pectoralis minor stretch (self-stretch)
  - Pectoralis minor on foam roll stretch (self and assisted technique)
  - Side-lying, supine and prone flexion stretch (therapist assisted)
  - Side-lying on foam roll and actively flexing and extending shoulder
  - Standing shoulder extension (self-stretch)
  - Supine shoulder extension (therapist assisted)
  - Backscratch/Apley's stretch (self-stretch with TheraBand or towel)
  - Subscapularis release (therapist assisted)
  - Standing latissimus/thoracolumbar fascia stretch

- Supine angular (diagonal) with rotation stretches (therapist assisted)
- Sleeper stretch/modified sleeper stretch at 70°, 90° and 110° (self and therapist assisted) (Figure 6-69)

If there is any anterior or subacromial pain while performing the sleeper stretch, modify the position by performing 1), 2) and/or 3) as the stretch should only be felt in the posterior and posterior-lateral shoulder:

1) Rotating torso away from elbow 10° to 20° then reattempt stretch.
2) Increase the angle of the elbow from 90° out to 120° to 135°.
3) Lower position of humerus from 90° abducted to 50° to 70°.

Clinical Pearls

- We have found better results using contract-relax techniques during both self-stretching and therapist assisted stretching alongside passive stretches versus passive stretching alone.
- The key is initiating the low intensity contraction at the first barrier, the first feeling of tissue tension, not taking it to its end range then giving a contraction.
- After contracting the muscle or muscle group the patient is trying to stretch, take the stretch to the next barrier and then repeat. This technique also keeps the patient engaged and on task by making them an active participant in the stretch.
- It forces them to pay attention and be in tune with where their extremity is and the direction it is going in, what angles are the most effective, tissue tension differences at different angles, and in the long run it forces them to become less dependent upon the therapist.
- Patients should be given a home exercise/stretch program and are told of its critical nature. Without executing the Home Exercise Program, the chances of them having a successful outcome are significantly decreased.

FIGURE 6-69. Sleeper and modified sleeper stretch. **A,B,** Sleeper stretch: humerus at 90°/elbow at 90° and 135°. **C,D,** Sleeper stretch: humerus at 45°/elbow at 90° and 135°. **E,F,** Sleeper stretch: humerus at 105°/elbow at 90° and 135°.

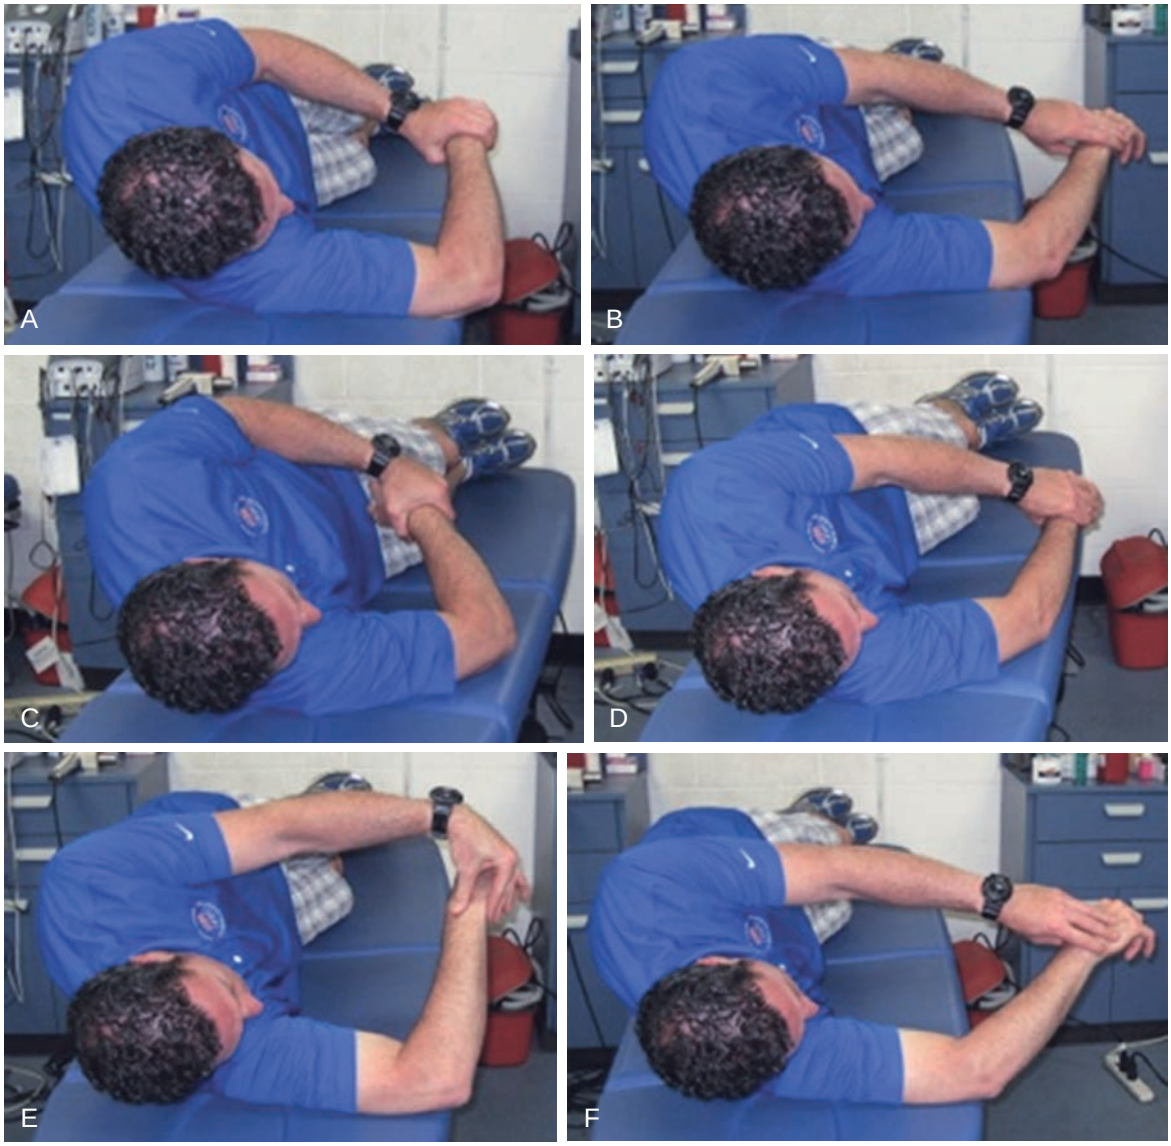

FIGURE 6-69 (cont'd). G,H, Modified sleeper torso lying on scapula: humerus at 90°/elbow at 90° and 135°. **I,J,** Modified sleeper torso lying on scapula: humerus at 60°/elbow at 90° and 135°. **K,L,** Modified sleeper torso lying on scapula: humerus at 105°/elbow at 90° and 135°

Other Therapeutic Exercises

- Patients should increase their intensity and duration times of cardiovascular conditioning. A variety of exercises are listed in Phase II. (Ensure the safe implementation of upper body support and loading during the use of stairclimbers, ellipticals, arc trainers and other conditioning activities until 8 weeks postoperatively for most cases.) Activities that can be added in this phase include:
  - Light jogging
  - Swimming (if indicated based upon having achieved full ROM, having adequate strength and per the parameters of the surgeon's protocol)
- Upper body ergometer (UBE) within pain-free ranges without resistance
  - Patient needs to maintain neutral scapular posture (scapula is not to be protracted or elevated)
  - Perform interval programs
  - Work in both directions (forward and backward/30 seconds: 1 minute in each direction is a good place to start).
  - Performing the UBE in standing position provides an integrated conditioning exercise involving upper body strengthening and endurance, torso, pelvis, and lower extremity stability work.
  - Within 1 to 2 weeks should be able to add resistance
- Viper (rope climb machine) (Figure 6-70)
  - Patient needs to maintain neutral scapular posture (scapula is not to be protracted or elevated)
  - Work by pulling down on rope, either two hands together or alternating
  - Usually start with humerus flexed no greater than 90° flexion and over next 1 to 2 weeks increase shoulder ROM

FIGURE 6-70. Viper machine (rope climb) with split stride (**A**) and contract core and trunk (**B**) to stabilize. Patient should focus on scapular involvement.

- Core stabilization exercises (Supine: establish neutral pelvis, partial crunch, pelvic tilts, bridging, modified dead bugs: arms may begin to flex above 90° if pain free and allowable per the protocol)
- Core stabilization exercises (supine/prone)
  - Continue exercises in Phase II
  - Superman (if pain free at end range shoulder flexion while prone)
  - Quadruped
    - Alternate arms
    - Alternate legs
    - Alternate arms and legs
  - Dead bugs (arms may begin to flex above 90° if pain free and allowable per the protocol. Arms may also press against the ground or vs. tubing; concentric or isometric shoulder extension)
    - Alternate arms
    - Alternate legs
    - Alternate arms and legs
  - Wall, table, floor prone plank
- Lower extremity exercises during this phase should increase in intensity/resistance. Dumbbells, kettle bells and weighted vests can be used to add resistance if the shoulder and shoulder girdle are ready and able to stabilize itself throughout the entire exercise. Exercises to add to those listed in Phase I and II include:
  - Single leg Romanian deadlift
  - Single-leg excursions (in the sagittal, frontal and transverse planes)

Clinical Pearl

- Although these stretching/flexibility exercises focus on ROM and mobility, cueing the depressors of the humeral head before initiating the movement pattern, as well as maintaining the depressed humeral head during the exercise can be critical for the patient.
- If unable to do this, there is often a premature and subconscious elevation of the humeral head and scapula when initiating forward flexion, abduction and scaption either during AROM and/or AAROM work.

Activation of Primary Muscles Involved in Injury Area or Surgical Structures

- Increase work on active scapular control: increasing strength and endurance
- Back to corner external rotation isometrics
- Back to corner wall slides
- Wall angels
- Wax on/wax off (1 arm and 2 arm, against wall, on slideboard, or on floor with sliding discs) (Figure 6-71)
- No money or robbery (begin with arms at side, with elbow bent at 90° and internally rotated with hands on abdomen, finishes with both arms externally rotated with humerus' at side and elbows bent 60° to 90°)
- Lawnmower (beginning from contralateral side,-end with elbow flexed at side and scapula retracted)
- Thumbtacks (in sagittal and scapular plane)
  - With hand simulating as though the hand is closed and the thumb is pushing a thumbtack into the wall, with elbow extended, hand is placed in either abducted position (at 90°), in scapular plane or with shoulder flexed to 90°at 0° abducted. Always with hand against fixed object, like a wall. Actively retract and protract scapula (9 to 3 o'clock), then elevate and depress scapula (12 to 6 o'clock),very similar to scapular clocks.
- Kettle bell holds, pack the shoulder for 15- to 30-second holds
  - Supine punch position
  - Supine punch position with kettle bell bottom up
  - Side-lying 90° abduction

FIGURE 6-71. Wax on/wax off. Scapular upward (**A**), downward (**B**) rotation with contralateral scapular retraction. Shoulder flexion (**C**), extension (**D**) movement pattern with contralateral scapular retraction.

  - Side-lying 90° abduction with kettle bell bottom up
  - Move from supine to side-lying and back to supine
- Dynamic hug
- Supine punch: Retract and protract scapula (with dumbbell, cuff weights, or tubing)
- Prone row
- Wall pushup plus
- Wall push-ups with various hand positions on wall
- Kneeling forearm physio ball slides
- Standing forearm wall slides with Thera-Band around elbows and wrists (Figure 6-72)
- Lat pulldowns (never behind head/begin with light weight)

The scapulohumeral muscles become the primary focus during this phase.

- In the previous phase we focused on middle and lower trapezius, rhomboids, and serratus anterior to create stability and foundational strength and stamina for the scapulothoracic joint and we added exercises before this section to advance their development.
- The rotator cuff musculature is the next critical element for successful rehabilitation as full ROM is established and a significant amount of healing has taken place.
- Most exercises in this phase should be performed standing or while in upright posture (can be done in kneeling, half-kneeling or standing) with tubing, cables, Keiser equipment, or with just the weight of the arm:
  - Low rows
  - No money exercise
  - Tubing two-arm diagonals
  - Straight arm shoulder extension from 90° flexion to 0° with scapular pinch throughout the exercise

FIGURE 6-72. A,B, Standing forearm wall slides with Thera-Band.

FIGURE 6-73. A-E, Dynamic 4 (side-lying diagonal eccentric exercise) with dumbbell, cuff weight, or tubing

- Rotator cuff exercises include:
  - Side-lying (with weight of arm, cuff weights, or light dumbbells)
    - External rotation
    - Dynamic 4: Externally rotate, extend elbow pressing hand toward the sky. With a straight arm slowly lower the arm in a diagonal pattern toward contralateral hip. Return elbow to starting position at side with elbow bent at 90°, then repeat. (Figure 6-73)
  - Standing: Internal/external rotation at 30° and 45° abducted
    - External rotation needs to be done slowly and under control with good cocontraction of the scapula stabilizers and move slowly during the eccentric phase of the exercise.
  - Diagonal patterns can begin 1 to 2 weeks into Phase III
  - Standing 3 (with weight of arm, cuff weights, or light dumbbells)
    - Front raises
    - Lateral raises
    - Scaption/full can (thumb up position) raises
- Have a 1- to 2-second hold at the top and slowly lower the weight. Do not allow the patient to rest and relax at the end of each repetition. Maintain an active shoulder and active and correctly positioned scapula and posture throughout the set.
  - Bodyblade/perturbations can be done in many planes and with many of the exercises listed above in the rotator cuff exercise list once some foundational rotator cuff strength has been established
- Continue scapular squeezes/pinches and sternal lifts. However, add resistance by leaning into wall, using manual resistance, or tubing.
- Continue Prone I, V and T began in Phase II (Figure 6-74)
  - Add prone Y and W (with palms down and/or thumbs up)
  - Continue bilateral 5-second holds with slow and controlled eccentric lowering of arms
- Discontinue Codman's
- Biceps and triceps strengthening with light resistance may begin (beginning 8 weeks postoperatively)

Sensorimotor Exercises

- Rhythmic stabilization and manual strengthening of the upper extremity while patient is supine, seated, or standing

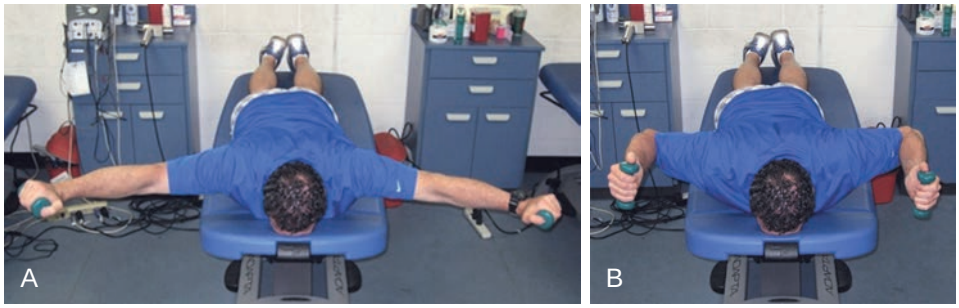

FIGURE 6-74. Prone Y (**A**) and W (**B**) light dumbbell or cuff weight exercise

- Isometric
- Concentric
- Eccentric

- The Bodyblade is an effective tool to incorporate (beginning at 8 weeks postoperatively) at 0° abduction as well as 90° scapular elevation.
- Upper extremity physio ball exercises. These can also be executed with the arm outstretched while kneeling, half-kneeling or standing depending upon the patient's ability to maintain good core/trunk stability while performing the exercise.
- UE ranger exercises with ranger on floor and on wall
  - Flexion/extension
  - Abduction/adduction
  - Circumduction
  - Write the alphabet with hand

Clinical Pearl

- A key component to successful PNF inclusion is patient education for proper positioning throughout; cue to stabilize the scapula before generating upper extremity motion or before accepting resistance.
- In addition, PNF is used to restore movement patterns common to athletes; this includes tracking the upper extremity movement with the eyes, as well as cervical and trunk rotation.
- This will also prepare the patient for more functional PNF patterns to be performed with tubing or cable resistance later in the treatment progression.
- PNF patterns are also performed on the nonaffected arm for crossover effect.
- Scapular PNF patters are continued throughout this phase progressing from side-lying to seated, and standing.

Open and Closed Kinetic Chain Exercises

- Closed chain proprioception activities: lightweight medicine ball rotations at 90° scapular plane elevation progressing to 90° forward flexion against a wall, and standing upper extremity weight bearing with weight shifting on a table with the hands at least 1.5 times the shoulder width to minimize direct posterior shear stresses through the GHJ.
- Quadruped weight shifts when able to load shoulder without discomfort or compensations per the surgeons protocol
- Quadruped with hand of injured arm on ball or wobble board (all exercises must not reproduce pain or compromise good scapular/postural position)
- Beginning at week 10: Seated press-ups for the latissimus dorsi as well as increased weight bearing/loading through the joint is added.
- Hydrotherapy
  - Similar volume dosage for hydrotherapy as other therapeutic exercises; however, caused by the decreased stress and benefit of movement, improving proprioception and muscle memory, there are times when reps and sets will be greater than normal volume dosage for therapeutic exercise.
    - Front raises/scaption, lateral raises with foam bells (AAROM)
    - Scapular protraction/retraction with foam bells (punches)
    - Horizontal abduction/adduction
    - IR/ER in modified neutral position
    - Rhythmic stabilization in any of these planes/exercises (sub max effort)
    - Bicep curls
    - Triceps press downs
    - Shrugs/reverse shrugs

Isokinetics

- Isokinetics can be initiated in this phase if patient can begin firing the rotator cuff
- IR/ER at modified neutral (in plane of scapula)
- Settings should be set for submaximal isometrics
- All exercises need to be supervised by the therapist

Techniques to Increase Muscle Strength, Power, and Endurance

- Progress biceps and triceps exercises in standing.
- Add light weights to shoulder flexion and scapular plane elevation in the open can position at 8 to10 weeks postop.
- Progress lower extremity strength training exercises.
- Progress to elliptical and stair stepper for cardiovascular conditioning at week 8.

Neuromuscular Dynamic Stability Exercises

- Progress manual rhythmic stabilization drills for upper extremity in neutral and advance in varying degrees of

abduction (0° to 90°) as ROM allows. Performing these exercises both sitting and standing will increase core recruitment and integrated work with the shoulder complex.

Clinical Pearl

The goals of neuromuscular rehabilitation according to Lephart et al.[7] are:
- To improve cognitive appreciation of the shoulder relative to position and motion.
- To enhance muscular stabilization of the joint in the absence of passive restraints.
- Restore synergistic muscular firing and coordinated movement patterns.

Plyometrics

- Low intensity lower extremity plyometrics may begin in the final 1 to 2 weeks of Phase III. Same volume dosage as therapeutic exercises.
  - Dot drills
  - Box drills
  - Cone/footwork drills
  - Jump rope
  - One- and two-legged hops
  - Skipping
  - Bounding
  - Box jumps

Functional Exercises

- Ground-based exercises for the lower extremities (that do not load, compromise or force the shoulder into flexion or abduction above 90°). Many are listed above; however, should add additional exercises that incorporate movement patterns specific to the athlete's sport but would not use the injured arm in the exercise.

Phase IV: Functional Strengthening (weeks 10 to 14)

Volume/Duration: Perform 10 to 15 reps, 1 to 3 sets per exercise, depending on quality of movement and minimizing the presence of compensatory movement patterns. Exercise will be terminated when there is a decrease in movement quality and/or movement compensations noted.

Goals

- Full pain-free ROM in all planes, both active and passive
- Improved scapular kinesis
- Normal scapulohumeral rhythm
- AROM WFL pain-free flexion and abduction
- Strength MMT 4/5 or better versus the scapulothoracic and scapulohumeral muscles
- Pain-free ADLs
- Normal soft tissue, T-spine and glenohumeral mobility
- Minimal to no pain with therapeutic exercise
- Progress rotator cuff strengthening

Management of Pain and Swelling

- Oral NSAIDs may be continued, however is likely unnecessary. If pain and/or inflammation continue to be a limiting factor to progress, the patient should return to the surgeon for reassessment.
- IFC E-stimulation may also be used to assist with pain and/or inflammation.
- Cryotherapy is used posttreatment sessions as needed to mitigate muscle soreness or reduce exercise-induced inflammation.
- Soft tissue massage can also be used to assist the reabsorption process of interstitial fluid, lactic acid, and other byproducts of exercise.

Techniques for Progressive Increase in Range of Motion

Manual Therapy Techniques

- AAROM, PROM, and AROM should be able to be performed through a full ROM.
- Joint mobilizations: If adhesions are noted, capsular joint mobilizations may continue along with oscillatory techniques grade I to IV for inferior and posterior capsule if indicated per the procedure as they may be incorporated to ensure full capsular mobility by the end of week 14.
- Care must be taken when assessing capsular structures that were compromised during surgery and those that were not within normal tissue pliability standards before surgery.
- Scapular mobilizations in all planes continue including scapular lifts.

Soft Tissue Techniques

- Assess the need for soft tissue mobilization to all muscles surrounding the scapulothoracic and glenohumeral joints, including but not limited to the pectoralis major/minor, subscapularis, and latissimus dorsi.
- Scar mobilizations are also indicated to minimize incisional adhesions.
- Monitor for development of biceps tendon inflammation and posterior rotator cuff tenderness and pain. Use direct soft tissue mobilization (many are listed in Phase III) to these tissues as indicated.

Stretching and Flexibility Techniques for the Musculotendinous Unit

- PROM if needed with end-range stretching.
- Latissimus dorsi, pectoralis major/minor stretching should be routine at this point.
- Hot packs may be used before stretching to facilitate muscle relaxation.
- Patient education on restoration of mobility, avoidance of pain, and reporting any feelings of shoulder instability are critically important through the final 4 stages of this protocol.

Other Therapeutic Exercises

- Aerobic/cardiovascular conditioning needs to continue. This is a good time to start cross-training, mixing in

FIGURE 6-75. Jacob's ladder.

some anaerobic work and building into the program opportunities to increase the athlete's level of fitness from other types of conditioning equipment and surfaces (i.e., treadmill, StairMaster, Versaclimber, Jacob's ladder [Figure 6-75], upper body ergometer, viper rope climb [machine], rowing ergometer, ski-ergometer, elliptical, arc trainer, conditioning on artificial grass, the beach, playing field, hard court, and more.)

- Upper body support and loading during the use of stairclimbers, elliptical, and arc trainer activities should not be an issue by the end of this phase.
- Continue to improve and reinforce good posture and postural awareness throughout all upper extremity, lower extremity, and trunk exercises:
  - Be sure patient is aware of what a neutral spine is and what is the optimal position of the pelvis
  - Correct shoulder protraction, forward head posture, and thoracic hypomobility and kyphosis
- Increase volume and intensity with:
  - Jogging/running
  - Swimming
  - Upper body ergometer (UBE) with resistance, in both directions, using interval programs from 5 to 15 minutes
  - Viper (rope climb machine)
- Core stabilization exercises (all those listed in Phase III) in addition to:
  - Wall, table, floor prone plank
  - Wall, table, floor side plank
  - Plank to side plank (start in plank position, then rotate torso to left or right so unloaded forearm is pointing to sky, then rotate trunk back to prone plank position, then rotate in the opposite direction and repeat)
  - Supine upper extremity trunk twists
  - Supine lower extremity trunk twists
  - Progress to performing core stabilizing exercises on a physio ball
- Lower extremity exercises during this phase should increase in resistance and volume; however, move towards being more functional and more sport-specific. If dumbbells, kettle bells, and weighted vests were not able to be used in the previous phase they should be able to be used in this phase. Exercises to add to those listed in Phase I to III include, but are not limited to:
  - Hamstring curls
  - Deadlifts
  - Squats
  - Leg press

Clinical Pearls

- Resistance is increased within pain tolerance and the precautions of avoiding certain end ranges may be indicated caused by type of surgical procedure.
- As an example, forced horizontal adduction and sagittal plane axial loading with the arm past neutral horizontal adduction at this stage is avoided if the patient had a posterior stabilization procedure.

Activation of Primary Muscles Involved in Injury Area or Surgical Structures

- Humeral IR/ER rotator cuff strengthening exercises are progressed to 90° abduction.
- Rotator cuff exercises (IR/ER) at 30° and 45° abducted should increase volume (up to 3 sets of 20 reps) then increase resistance (beginning with 3 sets of 8 to 10 reps).
- Review list of exercises in this section in Phase III. There is a good chance the patient was unable to perform all of the exercises listed so switch out some of the exercises to add variety and complexity otherwise be sure to increase volume (reps) first, then increase level of resistance before moving to new exercises.

Sensorimotor Exercises

- Glenohumeral joint PNF D1 and D2 while seated, standing, or supine.
  - Can be performed versus therapist, with tubing, cable, or Keiser machine
- Continue the rhythmic stabilization exercises
  - To increase difficulty, increase speed and amount of resistance
  - Be sure to change arm angles and include changes in pronation/supination, gripping versus open hand, elbow partially flexed versus bent to 90°.
  - Be cognizant of what the rest of the body is doing. Is the patient employing good posture? Maintaining good trunk stability? Is the patient continuing to breathe? Are they in an athletic position if standing? Are they engaging the contralateral side to increase stability, joint proprioception, power, and strength?
- The Bodyblade can continue to be used in this phase. If the smaller blade was used in the previous phase,

perhaps the patient is ready to move up to a larger blade. Change arm angles and be aware that the exercises can be performed supine, side-lying, prone, and standing in this phase.
- While performing an upper extremity exercise, perform a lower extremity exercise and vice versa.

Open and Closed Kinetic Chain Exercises

- Both open and closed kinetic chain exercises are listed throughout Phases III and IV.
- Additional CKC exercises include, but not limited to prone physio,ball walking, prone physio ball weight shifting, prone physio ball single arm balance with contralateral arm raises at various angles.
- Pushups on wall can be performed with hands in various positions.
- Continue quadruped weight shifts and with one arm and knee on unstable surface if still challenging to athlete.
- Athletes are encouraged to avoid locking-out the elbows during this phase to avoid excessive loading of the posterior capsule. Hand width during CKC exercises should remain slightly wider than the shoulder distance.

Isokinetics

- IR/ER at modified neutral in plane of scapula
  - Reps performed at 180°/s to 300°/s
- IR/ER at 90°/90° in plane of scapula
  - Reps performed at 180°/s to 300°/s.
- Settings can be set for concentric/eccentrics
  - 60° to 120°/s for rhythmic stabilization

Techniques to Increase Muscle Strength, Power, and Endurance

- If athlete is not challenged with a particular exercise and they are up to 20 reps, then increase the resistance, if reps and resistance have been increased then work to increase the speed, while in control of the movement pattern, to increase power.
- Increase number of reps and intensity of exercises performed in pool
  - Add pushups against edge of pool for power and endurance

Neuromuscular Dynamic Stability Exercises

- Lunge with trunk twist (can add holding on to medicine ball)
- Lunge and unilateral punch (Kibler's exercises)
  - Punch with one arm at 135° shoulder flexion while the other elbow is bent with fist on chest and scapula retracted and return to starting position with both fists on chest
  - Punch with one arm at 120° shoulder abduction while the other elbow is bent with fist on chest and scapula retracted and return to starting position with both fists on chest
- Kneeling and half-kneeling with chops and lifts with or without resistance depending upon ability to stabilize hips and trunk while maintaining a narrow base (Figure 6-76)
- TRX serratus hug exercise (Figure 6-77)
  - Place forearms into the TRX handles, lean forward keeping your elbows tucked by your sides
  - Bring both arms into shoulder flexion, keeping elbows bent and protract the scapulas
  - Push out and up until the elbows are close to eye level
  - Pause at the top of the movement while the shoulders are rounded and slowly return to the start position
- Perform UE exercises:
  - While sitting on physio ball
  - While standing on Airex pad or on any unstable surface
  - While in quadruped position
  - While on one leg
  - With eyes closed
- Rhythmic stabilization is progressed to standing and in positions with decreased base of support, open chain, or unstable surface.
- Axial compression drills: closed chain on unstable surfaces (i.e., Airex pad, weighted ball, tilt boards)
- Manual perturbation to the trunk while in dynamic closed chain loaded position

Plyometrics

  - Increase level of lower extremity plyometric drills (i.e., box jumps, dot drills, hopping, broad jump, landing drills, single leg hops, jump rope) if begun in Phase III, if not, then begin those listed in Phase III and progress to those listed earlier in this paragraph.
  - Upper extremity wall dribble (begin with two-handed drills)
- Side toss (facing perpendicular to wall)
- Side to side toss with ball at waist level (facing wall)
- Side to side toss with ball at shoulder height (facing wall)
- Side to side mini-toss with arms overhead (facing wall)
- Plyoback/rebounder exercises to include:
  - Chest pass
  - Overhead throws
  - Side to side throws
  - ER/IR ball toss and catch (focus on eccentric component)
    - With elbow at side
    - With elbow at 90°/90°
    - D2 pattern
    - Catch the ball over the shoulder for eccentrics with elbow at side, at 90°/90° and in D2 pattern

Clinical Pearl

- We strongly recommend performing a minimum of 4 weeks of plyometrics before beginning the throwing program, a high velocity overhead exercise, or beginning whatever activity led to the athlete's surgery.

Functional Exercises

- Progress the walk-jog progression.

FIGURE 6-76. A-F, Half-kneeling chops and lifts.

Sport-Specific Exercises

- Lower extremity sport-specific drills in a controlled environment at 3 months postoperatively (i.e., hopping, jumping, changes in direction, agility drills)
- Begin sport-specific upper extremity defensive type drills (blocking, catching, fielding, etc.)

Phase V: Power and Acceleration (weeks 14 to 24)

Goals

- Full pain-free uncompensated functional AROM
- Normal kinematics of scapulohumeral and scapulathoracic joints (no dyskinesis)
- No episodes of instability
- Pain free with all exercises
- MMT 5/5 strength of rotator cuff, shoulder, and scapular stabilizers
- Functional strength, power and endurance of rotator cuff and scapular stabilizers should be >75% to 80% before the injury
  - All strength, endurance, stability, and power tests are measured by assessing symmetry right versus left with the absence of observed compensatory motion during movement patterns
  - Power tests may include overhead medicine ball throw and standing rotational medicine ball throw
- Thorough clinical examination produces negative findings
- No tender to palpation/no subjective symptoms
- No compensations seen while performing functional movement patterns or while under moderate resistance/load
- Good trunk, pelvis, and ankle stability
- Isokinetic testing: IR/ER ratio: 66% to 70%/ER 98% to 105%/IR 105% to 115%. Side to side ratios should be within 75% to 85% for abduction and adduction.

FIGURE 6-77. TRX unilateral serratus hug. (Also can be done with both arms at the same time).

- Progressing with sport-specific skill training (throwing, swimming, racquet sport, sport-related overhead activities)
- Compliance with Home Exercise Program
- May require clearance from physician/surgeon to begin throwing/overhead activity progression toward end of Phase V depending upon sport and complexity of surgery

Management of Pain and Swelling

- Oral NSAIDs may be continued; however, they are likely unnecessary. If pain and/or inflammation continue to be a limiting factor to progress, the patient should return to the surgeon for reassessment.
- IFC E-stimulation may also be used to assist with pain and/or inflammation.
- Cryotherapy is used posttreatment sessions as needed to mitigate muscle soreness or reduce exercise-induced inflammation.
- Soft tissue massage can also be used to milk and assist the reabsorption process of interstitial fluid, lactic acid, and other byproducts of exercise.

Techniques for Progressive Increase in Range of Motion

Manual Therapy Techniques

- AAROM, PROM and AROM should be able to be performed through a full ROM.
- Continue as above to increase or maintain full capsular mobility.
- Joint mobilizations: If adhesions and restrictions are noted, capsular joint mobilizations may continue along with oscillatory techniques grade III-IV for inferior and posterior capsule.
- Scapular mobility in all planes should be evaluated periodically to insure the capability to maintain ROM throughout sport-specific training.

Soft Tissue Techniques

- Assess the need for soft tissue mobilization to all muscles surrounding the scapulothoracic and glenohumeral joints, including but not limited to the pectoralis major/minor, subscapularis, and latissimus dorsi, especially since sport-specific work has been introduced.

- Scar mobilizations could be indicated.
- Continue to monitor for development of biceps tendon inflammation and posterior rotator cuff tenderness and pain. Use direct soft tissue mobilization (many are listed in Phase III) to these tissues as indicated.

Stretching and Flexibility Techniques for the Musculotendinous Unit

- PROM if needed with end-range stretching.
- Athletes are instructed in full glenohumeral and scapulothoracic stretching techniques as well as how to maintain cervical, thoracic and lumbopelvic-hip mobility.

Other Therapeutic Exercises

- Progress with prone I, V, T, W and Y exercises, standing light dumbbell or cuff weight exercises and diagonal patterns with increased resistance and volume as tolerated.
- Progress lower extremity, gluteal and hip strength exercises.
- Progress walk, jog progression toward sprinting.
- TRX exercises
  - Single-leg squat
  - Mountain climbers
  - Split squat with single arm end range flexion resistance to TRX
  - Suspended knee tucks
  - Prone runners
  - Single-leg bridge + 2 arm row
- Advance core stability exercises
  - As the prone plank gets easier, lift each elbow off the ground (1 to 10 seconds)
  - As the prone plank gets easier, lift each foot off the ground (1 to 10 seconds)
  - As the side plank gets easier, lift the top leg up and lower leg slowly
  - As the side plank gets easier, lower hips toward ground and bring back up
- Can begin pullup program if have not done so. Begin with assistive pullups (on assistive pullup machine or use stretch bands to assist)
  - Do not hang at end of each repetition or at end of set; maintain active engaged shoulders throughout each set.

Clinical Pearls

- Remember it is critical that to have success strengthening a muscle or a group of muscles, their antagonist counterparts cannot be chronically tight and shortened.
- Using a foam roll, massage stick and other modalities listed in the soft tissue technique sections will improve recovery, reduce muscle soreness, and will help maintain joint ROM and mobility.

Activation of Primary Muscles Involved in Injury Area or Surgical Structures

- Refer to list in previous two phases and add progressive resistance.

Sensorimotor Exercises

- Glenohumeral joint PNF D1 and D2 while seated, standing, or supine.
  - Change speed and arm angles to increase difficulty.
  - Include eccentric exercises in the progression of the exercises.
- Continue rhythmic stabilization and Bodyblade exercises a minimum of 1 to 2 times a week.
- Vary the upper extremity exercises while performing lower extremity exercises and vice versa.

Open and Closed Kinetic Chain Exercises

- OKC: Continue progression of UE weight room exercises listed above.
- OKC: Pool resisted movement patterns should continue. Can use pool for recovery and flush.
- The BOSU ball can be used for progression of pushups to uneven surfaces for CKC activities.
- CKC may also include slide board exercises in quadruped or pushup position.

Isokinetics

- Isokinetics can be initiated in this phase.
- IR/ER at modified neutral in plane of scapula, reps performed at 180°/s to 300°/s.
- IR/ER at 90°/90° in plane of scapula, reps performed at 180°/s to 300°/s.
- Settings can be set for concentric/eccentrics 60° to 120° per second/rhythmic stabilization.
- Testing at 180°/s and 300°/s.
  - Following a minimum of 2 weeks of work on the isokinetic device
  - Expected Biodex results: ER/IR ratio at 180°/s: male 66; female 71
  - Peak T/BW range for IR at 180°/s: male 17 to 23; female 13 to 17
  - Peak T/BW range for ER at 180°/s: male 11 to 15; female 8 to 12

Techniques to Increase Muscle Strength, Power, and Endurance

- Advance endurance sets to strength exercises (repetitions of 6 to 10 per set).
- Implement an undulating periodization model for strength training

Neuromuscular Dynamic Stability Exercises

- The pushup progression leads to dynamic bilateral upper extremity wall pushups, then to single arm dynamic pushups on the wall; progression then leads to dynamic floor pushups.
- Bear crawling
  - In prone position with only feet and hands on the floor, butt should be raised higher than any other body part. Maintain hands and feet shoulder and hip wide respectively. Then move slowly and deliberately forward. (Can be performed crawling backwards as well as to left and right as patient progresses)
- Inchworms
  - With hands and feet on ground, walk each foot, one foot at a time, toward the hands while keeping

elbows and knees extended. As feet has gotten as close as they can to the hands, the hands begin to walk out away from the feet to a distance the patient feels comfortable supporting their own weight, then repeat.
- Renegade row (pushup position, then perform single arm row, alternate arms)
- Bow and arrows (standing with arms together out in front of body holding tubing or pulley handles in each hand, then rotate legs and torso 90° and get hands in a bow and arrow position then return to the starting point)
- Segmental upper and lower body rolling patterns[8]
  - The upper body rolling pattern from supine to prone is initiated by lifting and turning the head, and reaching with the opposite arm. The roll needs to occur in segmental fashion. (The movement begins by rotating the head, the shoulders rotate in the same direction, followed by the trunk, hips, and then the legs. If the patient is log rolling, corrections, either verbal and/or tactile cues, need to be used.)
  - The upper body rolling pattern from prone to supine is initiated by turning the head and retracting the lead scapula to bring the arm around. Keep reaching and rotating and again this needs to happen in a segmental fashion from the head all the way down the spine to the lower extremities.
  - The lower body rolling pattern from supine to prone is initiated by flexing, adducting, and internally rotating the opposite hip. Reach the leg across the body and extend the knee as the hips, pelvis, lumbar spine begin rotating over toward the prone position. The roll must be segmental in nature.
  - The lower body rolling from prone to supine is initiated by extending, adducting, and externally rotating the opposite hip. While rotating over to supine be sure the rotation occurs segmentally and not as a log roll.
- Turkish get-up progression: Work through all seven Turkish get-up stages with added neck and shoulder rotations in each phase to ensure adequate movement quality and overall stability in each phase.
- Dynamic stability warmups exercises that can be integrating into the daily routine are:
  - Jumping jacks
  - Jumping twists
  - Walking lunges
  - Walking side lunges
  - Walking lunge with twist and/or with upward reach
  - Walking quad stretch
  - Walking glut stretch
  - Leg swings: hip flexion/ext and hip abd/adduction
  - Skipping
  - Skip hops
  - High knees
  - Butt kicks
  - Side stepping
  - Carioca
  - Backpedals
  - Backpedal and rotate right/rotate left
  - Bounding
  - Spiderman crawls
  - Inchworms

Plyometrics

- Plyometrics were initiated in Phase IV using two-handed technique, then after two weeks of using two hands can progress to one hand if no compensations seen or pain experienced by patient.
  - Chest pass
  - Overhead throws
  - Side to side throws
  - ER/IR ball toss and catch (focus on eccentric component)
    - With elbow at side
    - With elbow at 90°/90°
    - D2 pattern
    - Catch the ball over the shoulder for eccentrics with elbow at side, at 90°/90° and in D2 pattern
- Overhead bilateral medicine ball slams and overhead medicine ball catching is also added.
- Pushup plyometrics can be initiated: begin against wall, then progress to counter, then to floor.

Clinical Pearls

- If anterior structures of the shoulder were repaired surgically, and/or anterior structures were injured before rehab, be conscious of volume, intensity and mechanics of anterior shoulder work (i.e., pressing movements).
- If anterior structures had been compromised, six to eight weeks or longer of pressing exercises should probably only be permitted to go to frontal plane only.
- It is the authors experience that allowing the humerus to horizontally abduct and go beyond the midline of the torso increases the likelihood of soft tissue irritation and inflammation.
- Be cognizant and educate your patients on the best exercise mechanics for them

Functional Exercises

- Overhead strengthening is incorporated as well as lower extremity agility drills including ladder and hurdle drills as well as running progression (intervals, sprints).
- Resistance exercises in standing progress from double-leg to single-leg stance, asymmetrical resistance and unstable surfaces continue.
- Continue lower extremity agility program.
- May add resistance sled, resistance bands or parachute to running/sprinting drills.

Sport-Specific Exercises

- Throwing athletes may begin light tossing at shorter distances (45 feet) after a minimum of four weeks of upper extremity plyometrics.
  - The patient needs to demonstrate relatively normal throwing mechanics.

  - Throwing should be closely monitored and discontinued if the athlete exhibits any compensatory movement patterns or shoulder girdle discomfort. Be conscious of what is going on with their lower extremity, length of stride, and position of landing leg and foot.
  - How does the follow-through look? Are they finishing the throw out in front of their body or does it look like they are cutting off the throw?
  - Throwing 3 times a week for the first 4 weeks is adequate and can progress to 4 times a week in week 8 to 12.
  - Begin with 10 tosses to warmup, then begin tossing at prescribed distance, initially 45 feet for 15 throws. Need to be at each distance a minimum of 3 to 6 sessions depending upon how the athlete is progressing and the complexity of surgery. The distances increase by 15 feet with of 60 feet and beyond including a step and throw. At 60 feet, 10 additional throws are added for a total of 25 throws at this distance. For athletes 18 years and over, a maximum distance of 150 feet is adequate and should only be performed if there are no compensations or poor mechanics exhibited.
  - Athlete needs to have been throwing for a minimum of 8 weeks and reached a distance of 120 feet before throwing off a mound. Mound work should be performed 2 times a week for the first 3 to 4 weeks, can then progress to 3 times a week.
  - Breaking pitches and off speed pitches do not begin until athlete has begun mound work.
- Other overhead activities such as swimming, racquet sports, serving in volleyball, shot putting, throwing a javelin, and others should have a warmup period before beginning the official count.
- Begin at a relatively low intensity and progress over the next month to increase volume and intensity with days of active rest/recovery in between.
- Be sure that the athlete is able to recover in between each training session before increasing volume or intensity.
- Four weeks of plyometrics should be performed before beginning the sport-specific overhead activity.

Milestones for Progression to the Next Phase

- Goal is for strength to be at least 80% of unaffected side before beginning sport-specific overhead activity

Phase VI: Return to Sport/ Competition (weeks 24 to 52)

Note: Volume/duration: Perform 10 to 15 reps, 1 to 3 sets per exercise, depending on quality of movement and minimizing the presence of compensatory movement patterns. Exercise will be terminated when there is a decrease in movement quality and/or movement compensations noted.

Goals

- Full pain-free uncompensated functional AROM.
- Normal upper extremity/scapular kinematics.
- Mobility and ROM geared to athlete's sport and position.
- Approximately 90% strength, power, and endurance required for sport.
- Pain free with all exercises and activities.
- MMT 5/5 strength of rotator cuff, shoulder, and scapular stabilizers.
- Maintain good trunk, pelvis, and ankle stability.
- Progressing with sport-specific skill training.
- To be in better physical condition, have increased athleticism, decreased likelihood to reinjure surgical shoulder or another body part, improved body control and sport-specific (i.e., throwing, serving, swimming) mechanics.
- Athlete's increased knowledge, understanding, and application of best practices to prepare to play, maintain good health, achieve a higher level of performance, and know how to build in recovery into their program.
- May need clearance from physician/surgeon to return to the playing field/arena at end of throwing or overhead activity program.
- Build in extended period of recovery following competitive season. Can continue to be active, however allowing 4 to 8 weeks of limited overhead activity after the season is over is recommended.

Management of Pain and Swelling

- Oral NSAIDs may be continued however is likely unnecessary. If pain and/or inflammation continue to be a limiting factor to progress, the patient should return to the surgeon for reassessment.
- IFC E-stimulation may also be used to assist with pain and/or inflammation.
- Cryotherapy is used posttreatment sessions to mitigate muscle soreness or reduce exercise-induced inflammation.
- Soft tissue massage can also be used to milk and assist the reabsorption process of interstitial fluid, lactic acid, and other byproducts of exercise.
- Do not sleep on shoulder ever! This will cause a reduction of blood flow and lymphatic drainage in both directions to the shoulder and upper extremity and will negatively affect the athlete's ability to recover from work and exercise.

Techniques for Progressive Increase in Range of Motion

- Should have full AROM by 6 months

Manual Therapy Techniques

- Continue as above to increase or maintain full capsular mobility if not yet achieved.
- Joint mobilizations: If adhesions and restrictions are still noted, capsular joint mobilizations may continue along with oscillatory techniques grade III to IV for inferior and posterior capsule.
- Scapular mobilizations in all planes should be evaluated periodically to be sure able to maintain throughout sport-specific training.

Soft Tissue Techniques

- Assess the need for soft tissue mobilization to all muscles surrounding the scapulothoracic and glenohumeral joints.
- Educating and reinforcing the patient to take ownership in self-management of monitoring and treating soft tissue tension issues, capsular and joint restrictions with the use of stretch bands, foam rolls, myofascial release balls and implements will provide a vehicle for long term self-treatment.
- Scar mobilizations could be indicated.
- Continue to monitor for development of biceps tendon inflammation and posterior rotator cuff tenderness and pain. Use direct soft tissue mobilization (many are listed in Phase III) to these tissues as indicated.

Stretching and Flexibility Techniques for the Musculotendinous Unit

- Athletes are instructed in full glenohumeral and scapulothoracic stretching techniques as well as how to maintain cervical, thoracic, and lumbopelvic-hip mobility.
- Home stretching for posterior capsule progression: supine horizontal stretch, supine horizontal stretch with IR, sleeper stretch, modified sleeper and sleeper stretch with rollover.
- Continued use of sustained end range stretching to achieve desired symmetrical or required mobility.
- Preperformance/exercise stretching should focus on functional movement patterns and dynamic warmup versus static stretching to prepare the athlete for sport.
- Postexercise and postcompetition cool down stretching should be incorporated into the program to address muscles, tendons, and joints that have a propensity to get tight following training or sport activity.

Other Therapeutic Exercises

- Integrated conditioning at this stage should include dynamic multijoint movements, predominately closed chained.
- Many of the total body, core stability, total arm, and total leg strengthening exercises can be continued; however, we recommend building in extended periods of active rest from many of these exercises following 6 months of rehabilitation. This ensures recovery, both physical as well as mental, a chance for the patient's body to regroup, and usually causes a reinvigoration of energy and enthusiasm by the athlete when it is time to resume strengthening exercises.

Clinical Pearls

- Where the athlete is on the competitive season calendar is very important in determining the plan from months 6 to 12. So following the sixth month of rehabilitation, consider the following:
  - If their season is getting ready to begin or has already begun, in most cases, surgeons and rehabilitation specialists do not expect pitchers to be game ready until at least month 8 or 9; however, it is often stated that 12 months is a more realistic timetable to expect a pitcher to return to live games.
  - It usually pays to lean toward the conservative side than the aggressive side of returning to game speed on the calendar; however, it is not uncommon for successful postoperative rehabs to take 15+ months to return.
  - Treat your athlete as an individual.
- Because position players typically do not throw as hard and as frequently with the volume of pitchers, they can typically return to games once they have completed the 120 to 150 feet in their throwing program and have spent 2 to 4 weeks throwing to bases, throwing on the infield if an infielder, and throwing to the bases from the outfield if they are an outfielder.
- If it is midseason following the sixth month of rehabilitation, rushing to get the pitcher in a game before the season is over is possible. However, be sure to listen to the athlete and pay close attention to how the pitcher's arm is feeling in between their mound work.
- If it is the end of the season and they have completed their throwing/overhead program, it's a good time to actively rest and not throw for the next 6 to 8 weeks. Take a break from formal conditioning for 4 to 6 weeks then resume by beginning with a cardio and mobility program. Work toward a strength building phase, then towards a power phase with 4 to 6 weeks of spring training/practice/preseason workouts.

Activation of Primary Muscles Involved in Injury Area or Surgical Structures

- If preinjury levels of function, strength, stamina, power, and mobility have been achieved or exceeded then consider a maintenance phase for the primary muscles involved in the surgery.
- Those involve both the scapulothoracic and scapulohumeral muscles, so performing exercises that can incorporate this large group of muscles reducing the volume and intensity of the exercises need to be done.
- Selecting exercises that combine both groups 2 to 3 days/wk may be best to be able to maintain what the athlete has acquired to this point.

Sensorimotor Exercises

- Ball toss exercises in standing; to add difficulty, toss the ball on one leg
- D1/D2 movements with cables; to add difficulty, change angles of the pulley, change the athlete's base and foot position
- Medicine ball
  - Diagonals
  - Rotate left/rotate right
  - Woodchops
  - Slams
  - Wall ball drills
  - Russian twists
  - Supine upper extremity twists/supine lower extremity twists
  - Progression to slosh balls

- Slosh balls are different sized balls filled with water or other fluid. The movement of the fluid within the ball makes it more challenging to the patient while performing drills/exercises with the ball.
- Rapid repositioning drills and reaction movement drills
- Sport-specific balance/body control exercises

Open and Closed Kinetic Chain Exercises

- Advancing the previous exercises in accordance with sport-specific demands while also identifying exercises that will address the athlete's weaknesses

Techniques to Increase Muscle Strength, Power, and Endurance

- Isokinetic training is usually significantly reduced or eliminated at this point
- Refine and integrate the undulating periodization model to optimize recovery as the athlete prepares in the several months leading up to their playing season.

Neuromuscular Dynamic Stability Exercises

- Resistance exercises in standing progress from a double- to single-leg stance, asymmetrical resistance, and unstable surfaces as necessary to replicate anticipated performance demands.
- Single arm dumbbell walks
- Monster rope throws and drags
- Rope, pole, ladder, and rock wall climbing
- Obstacle courses
- Tire flipping
- Battle rope exercises

Clinical Pearl

- Reinjury is more likely to occur when the athlete is fatigued. To optimally prepare the athlete for full return to sport, dynamic stability exercises and strength training must be taken to a sufficient level of stress to closely replicate the strength, power, and endurance demands that will be encountered.

Plyometrics

- Advance the plyometric exercises in Phases IV and V to increasing level of difficulty with the use of the plyoback, wall, and ground.
- Medicine ball exercises need to include catching/receiving the ball to gain the physiological effect of eccentric and decelerating work.

Sport-Specific Exercises

- By 24 weeks postoperative athletes may have begun light sport-specific training to include short tossing for throwing athletes and limited overhead stroke work for swimmers, tennis, as well as other racquet sports, and volleyball players.
- A progression of throwing volume, distance and intensity continues during much of this phase.
- A progression of overhead swings, as well as freestyle and other overhead swimming strokes should increase in volume and intensity during much of this phase.
- Wrestlers and mixed martial arts athletes should progress toward more sport-specific drills (i.e., in quadruped and prone positions, grappling, boxing and striking objects).
- For football and rugby players introducing and increasing the volume and intensity of the position specific drills (i.e., punches, swim techniques, push off drills) should be done over 1 to 3 months depending upon the surgeon's expectations, type of procedure, and how well the rehab process is going to this point.
- Preparticipation CKC testing may include the CKC upper extremity stability test and/or the upper extremity Y-balance test (as well as isokinetic testing). Goniometric measurements, isometric dynamometers, MMT can also be used.
- Preparticipation power tests may include the vertical jump, broad jump, standing backward overhead medicine ball throw, and standing rotational medicine ball throw. Preinjury test values would provide the best measure of functional recovery as sport/position specific normative data is limited.

Clinical Pearl

- Do not learn the hard way; you may not be a subject matter expert on being able to identify and teach the best throwing mechanics, sport and position specific kinematics of the athlete so reach out to the athlete's coaches or a local coach who you know and respect to have them lend a hand with aiding in providing expert advice as the athlete begins their long awaited sport-specific rehabilitative (throwing, swimming, overhead exercise, etc.) program.

Criteria for Return to Sport

General

- Normal scapulothoracic and glenohumeral kinematics via qualitative assessment. Full AROM without instability or scapular dyskinesis.
  - This is a subjective, objective and functional way of determining return to sport. Does the athlete report any symptoms of looseness or instability while performing sport-specific tasks? Assess scapular mechanics/stability through a variety of movement patterns at various speeds and versus a variety of different resistances. Could be done manually (using mirror) and/or while athlete is performing sport-specific activity. The use of video to review mechanics can also be helpful.
- Minimum of 90% (side to side) symmetry on isokinetic testing of muscular strength, power, and endurance. ER to IR ratio at least 70%.
- CKC testing and integrated power tests with good quality of motion, maintenance of scapulothoracic and core stability throughout the tests with no report of shoulder pain or instability.
  - Upper extremity power tests may include, but are not limited to: plyo-pushups, plyoback (one and two

arm throws into mini-tramp), bilateral manual testing (IR/ER at 30°, 45° and 90°, D2 pattern, movement pattern specific to sport).
- Medical clearance from surgeon.

Sport-Specific

- Implementation of return to sport criteria must include a demand/needs analysis of the chosen sport.
- The rehabilitation specialist should be able to analyze the demands on the shoulder complex and create a sufficient series of tests and exercises to ensure readiness for return to preinjury levels of activity.
- Pain free during and after sport-specific training and recovery within normal timeframe so as to be able to repeat the program in an expected and acceptable timeframe.

After Return to Sport

- Continue total body fitness and rehabilitation exercises.
- Typically these exercises are referred to as maintenance exercises; however, if some of the exercises are not challenging to the rehabilitative shoulder and to the athlete, then the athlete will usually lose strength and stamina over the course of their playing season.
- Be aware of this and conduct period checks of their ROM and strength each month throughout their season.

Exercises and Other Techniques for Prevention of Recurrent Injury

- Prevention of recurrence requires continued maintenance of dynamic neuromuscular control (strength, mobility, kinesthetic awareness, and proprioception). Degradation in any of these areas could put the athlete at risk for reinjury if they continue to place a high degree of physical demands on the surgically repaired glenohumeral joint.
- Although sport-specific training is essential to ensure readiness for return to sport, a training program that does not include reactive drills and a diversity of training modalities can result in a shoulder complex unable to adapt to the ever changing demands of athletic competition.

Multiple-Choice Questions

QUESTION 1. If arthroscopic labral repair was performed without involvement of the rotator cuff musculature or bicep tendon, when typically may the sling be discontinued?

A. 2 to 3 weeks
B. 4 to 5 weeks
C. 7 to 8 weeks
D. 9 to 10 weeks

QUESTION 2. If SLAP repair or biceps tenodesis has been performed, there should be NO biceps muscle activation performed during what time frame?

A. 0 to 2 weeks
B. 0 to 4 weeks
C. 0 to 8 weeks
D. 0 to 12 weeks

QUESTION 3. _____ has shown to activate reflex contraction of the rotator cuff muscles which will stimulate glenohumeral mechanoreceptors?

A. Gripping
B. Scapular elevation
C. Abdominal bracing
D. Neck retraction

QUESTION 4. Which phase has a goal of full pain-free AROM?

A. Phase I (0 to 2 weeks)
B. Phase II (2 to 6 weeks)
C. Phase III (6 to 10 weeks)
D. Phase IV (10 to 14 weeks)

QUESTION 5. Which phase has a goal of 5/5 MMT of rotator cuff, shoulder, and scapular stabilizers?

A. Phase II (2 to 6 weeks)
B. Phase III (6 to 10 weeks)
C. Phase IV (10 to 14 weeks)
D. Phase V (14 to 24 weeks)

Answer Key

QUESTION 1. Correct answer: **B** (see Brief Summary of Surgical Treatment)

QUESTION 2. Correct answer: **C** (see Phase I: Immediate Postoperative Period, Clinical Pearl #2)

QUESTION 3. Correct answer: **A** (see Phase I: Immediate Postoperative Period, Clinical Pearl #5)

QUESTION 4. Correct answer: **C** (see Phase III: Immediate Postoperative Period, Goals)

QUESTION 5. Correct answer: **D** (see Phase V)

POSTOPERATIVE REHABILITATION FOLLOWING ARTHROSCOPIC ROTATOR CUFF REPAIR

Todd S. Ellenbecker, DPT, MS, SCS, OCS, CSCS, and David S. Bailie, MD

Indications for Surgical Treatment

- Failure of nonoperative treatment of rotator cuff tear
- Severe impact on functional activities and presence of shoulder pain at night and at rest
- Significant weakness of the shoulder and upper extremity limiting functional performance

Brief Summary of Surgical Treatment

Major Surgical Steps

- Place patient in beach chair position with arm draped free with use of assistant to hold arm or articulated arm holder

- Examine under anesthesia to evaluate for any loss of motion as early frozen shoulder can occur with RCT
- Inflate joint with 20 to 30 ml of elaine from a posterior approach using an 18G spinal needle
- Enter joint from posterior approach using 30° arthroscope
- Swelling can be minimized by running inflow through the arthroscope at low pressure (40 to 45 mmHg)
- Perform complete diagnostic arthroscopy and establish surgical plan, including confirming size, location, and tear pattern of RCT
- Treat intraarticular pathology as needed
- Place arthroscope in subacromial space and confirm burial side tear pattern
- Establish accessory working portals: lateral in mid-clavicle line and anterior at level of AC joint using cannulas
- Perform subacromial decompression if needed (limit to only downward projecting bone anterior medial to anterolateral from the clavicle forward).
- Perform distal clavicle excision if warranted based on clinical symptoms and anatomy.
- Prepare cuff insertion site using a shaver, burr, and/or an arthroscopic rasp. Do not fully decorticate as this will weaken the bone but insure good bleeding surface.
- Perform margin convergence of any longitudinal splits or delaminated portions of the RCT using arthroscopic suture passers and #2 high tensile strength suture.
- Authors prefer offset single row repair technique: Place triple loaded anchors (typically one or two for most tears and three for large to massive tears) in a slightly offset pattern within the middle of the RC footprint. Authors prefer biocomposite anchors but any modern cuff anchor is satisfactory.
- Create small accessory portal (no cannula) either anterolateral or posterolateral or both to allow for suture management. Pull all sutures into these portals keeping them organized with hemostats. Pull suture to be passed through tear edge into lateral portal alone so it does not tangle with other sutures.
- Start repair by passing sutures in divergent simple pattern, or a combination of horizontal mattress and simple (modified Mason-Allen or rip-stop) depending on tissue quality and tear pattern. Begin either posteriorly and move anteriorly or vice-versa watching suture spacing as you progress.
- Once all sutures are passed, begin tying from posterior to anterior in order of suture passing. Be sure to only have the two limbs of sutured to be tied in the working portal while other sutures are housed in the accessory portals
- Complete the repair by tying all sutures. If there appears to be a dog ear while tying, simply repass the suture from the anchor OR pass an additional free suture and anchor.

Factors That May Affect Rehabilitation

- Patient pain levels may be elevated if an acromioplasty is performed along with the rotator cuff repair; this will be noticed during initial postoperative rehabilitation during shoulder elevation (both actively and passively) caused by pain generated during subacromial contact.
- Patient pain levels will be elevated with cross arm adduction if a distal clavicular excision is performed (Mumford procedure) and noticed by the clinician during early range of motion activity following rotator cuff repair.
- Slower progression of range of motion and initiation of resistive exercise for large and massive rotator cuff tears.

Before Surgery: Overview of Goals, Milestones, and Guidelines[2]

GUIDING PRINCIPLES OF POSTOPERATIVE REHABILITATION

- Protection of tissue repair
- Early passive range of motion to prevent capsular adhesions and glenohumeral joint stiffness
- Gradual progression of resistive exercise from multiple angle isometrics, to manual resistance to isotonics, isokinetics, plyometrics, and functional exercise
- Balance and optimize muscular force couples
- Prevent scapular compensatory patterns (shrug sign) through the use of proper resistive exercise sequence and optimal loading strategies

Postoperative Rehabilitation Protocol

Initial postsurgical rehabilitation focuses on a range of motion to prevent capsular adhesions while protecting the surgically repaired tissues. Some postsurgical rehabilitation protocols have specific range of motion limitations to be applied during the first 6 weeks of rehabilitation. Several basic science studies have been published that provide rationale for the safe application of glenohumeral joint range of motion and the movements allowing joint excursion, and capsular lengthening, yet safe and protective inherent tensions produced in the repaired tendon. Hatakeyama et al.,[1] using a cadaveric model, repaired 1 × 2 cm supraspinatus tears and studied the effects of humeral rotation range of motion on the tension in the supraspinatus in 30° of elevation in the coronal, scapular, and sagittal planes. Results showed that, compared to tension in a position of neutral rotation, 30° and 60° of external rotation actually showed a decrease in the tension within the supraspinatus muscle tendon unit. In

[2]*Prehabilitation, if appropriate, is described in the Nonoperative Rehabilitation section of this chapter.*

contrast, 30° and 60° of internal rotation showed increases in tension within the supraspinatus tendon. This study provides important insight into the ability to perform early passive range of motion into the directions of external rotation following rotator cuff repair. Additionally, since most patients are placed in positions of internal rotation following surgery during the period of immobilization, movement of the shoulder into internal rotation is performed despite the increased tension identified by Hatakeyama et al.[1] One final aspect of clinical relevance in the study by Hatakeyama et al.[1] was the comparison of the intrinsic tensile load in the repaired supraspinatus tendon between the frontal or coronal plane, scapular plane, and the sagittal planes during humeral rotation. Significantly higher loading was present in the supraspinatus tendon during humeral rotation in the sagittal plane as compared to both the frontal and scapular planes. Therefore, based on this important basic science study, early passive range of motion is performed into the directions of both external and internal humeral rotation using the scapular plane position to minimize tensile loading in the repaired tendon.[1]

One additional basic science study provides guidance for range of motion application in the early postoperative phase. Muraki et al.[2], studied the effects of passive motion on tensile loading of the supraspinatus tendon in cadavers similar to the study by Hatakeyama et al.[1] They found no significant increases in strain during the movement of cross-arm adduction in either the supraspinatus or infraspinatus tendons at 60° of elevation. However, internal rotation performed at 30° and 60° of elevation did place increased tension in the inferior most portion of the infraspinatus tendon over the resting or neutral position. This study provides additional guidance to clinicians for the selection of safe range of motion positions following surgery. It also shows the importance of knowing the degree of tendon involvement and repair as posteriorly based rotator cuff repairs (those involving the infraspinatus and teres minor) may be subjected to increased tensile loads if early internal rotation is applied during postoperative rehabilitation. Therefore, communication between the surgeon and treating therapist is of vital importance to ensure that optimal range of motion is performed following repair.

One area of initial concern in the rehabilitation process following rotator cuff repair lies in the progression from passive based range of motion applications to active-assistive and active range of motion. Some disagreement as to the degree of muscular activation occurring during commonly used rehabilitation activities exists that can be clarified by a review of the appropriate literature. Research by McCann et al.[3] provides clear delineation of the degree of muscular activation of the supraspinatus during supine assisted range of motion and seated elevation with the use of a pulley. Although both activities arguably produce low levels of inherent muscular activation in the supraspinatus, the upright pulley activity produces significantly more muscular activity as compared to the supine activities studied by McCann and colleagues.

Additionally, research by Ellsworth et al.[4] has quantified levels of muscular activation during Codman's pendulum exercise. Their study shows minimal levels of muscular activation in the rotator cuff musculature during Codman's pendulum exercise; however, the exercise cannot be considered passive as the musculature is truly activated, especially in individuals with shoulder pathology. Additionally, although many therapists, including the authors of this chapter, do not recommend the use of weight application in the hand during pendulum exercises caused by the potential for unwanted anterior translation, Ellsworth et al.[4] found that muscular activity in the rotator cuff musculature was not changed between the performance of pendulum exercise with and without weight application. Pendulum exercises without weight have the same effect on muscular activity as weight application, questioning the use of pendulum exercises in the early postsurgery phase in cases where only passive movements may be indicated.

These studies give objective guidance for the early application of assisted range of motion activities that can be applied safely in the early postsurgical rehabilitation following rotator cuff repair. As further research becomes available, clinicians will be able to make evidence based decisions regarding the appropriateness of specific rehabilitation exercises based on their inherent muscular activation. Rehabilitation in the first 2 to 4 weeks following rotator cuff repair typically consists of the use of truly passive, as well as several minimally active or active-assistive, exercises for the rotator cuff such as active assisted elevation, overhead pulleys, and pendulums. Additionally, the use of the balance point position (90° of shoulder flexion) in the supine position where the patient is queued to perform small active motions of flexion/extension from the 90° starting position to recruit rotator cuff and scapular muscular activity. These exercises coupled with early scapular stabilization via manual resistance techniques emphasizing direct hand contacts on the scapula to bypass force application to the rotator cuff and optimize trapezius, rhomboid, and serratus anterior muscular activation are recommended (see Figure 6-78). Kibler et al.[5] have published EMG quantification of low-level closed chain exercise such as weight-shifting on a rocker board and highlighted the low levels (<10%) activation of the rotator cuff and scapular musculature during application.

FIGURE 6-78. Side-lying manual scapular resistance applied by the physical therapist to improve scapular stabilization.

Phase I: Immediate Postoperative Period (days 0 to 14)

Clinical Pearls

- Early scapular exercise via manual contacts on the scapula to protect healing rotator cuff and allow for initial activation of scapular force couple components (Figure 6-78)
- Progression using submaximal isometrics (step-outs) (Figure 6-79) and manual resistive IR and ER by the physical therapist (Figure 6-80) 4 to 6 weeks postoperatively to begin early contraction of the rotator cuff and scapular stabilizers.

FIGURE 6-79. External rotation step-outs (dynamic isometrics) using elastic resistance.

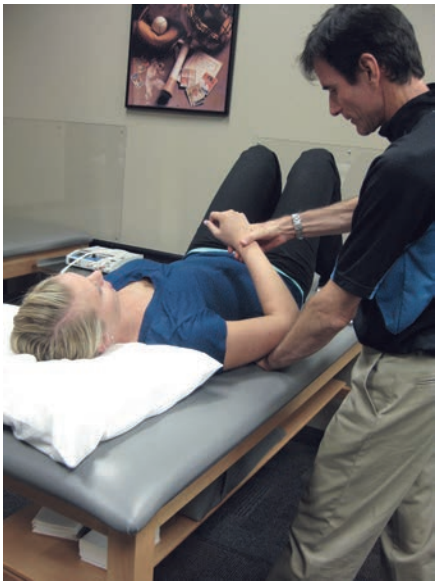

FIGURE 6-80. Manual external rotation resistance performed by the physical therapist early in the first phase to activate the posterior rotator cuff.

Goals

- Initiate passive range of motion to prevent range of motion loss of the glenohumeral joint
- Initiate scapular stabilization exercise with protection of the rotator cuff repair
- Minimize disuse atrophy of the upper extremity kinetic chain through the use of distal upper extremity exercise such as grip squeezes and wrist and hand exercise
- Provide patient with home exercise program and immediate postoperative care

Protection

- Sling with abduction pillow (DonJoy Ultrasling) worn for first 4 to 6 weeks postoperatively especially in precarious situations (outside the home)

Management of Pain and Swelling

- Use of electrical stimulation to affected area for pain reduction and before treatment coupled with moist heat to improve circulation and promote healing response.

Techniques for Progressive Increase in Range of Motion

Manual Therapy Techniques

- Accessory and physiological mobilization in all planes of motion and directions based on restrictions encountered during initial evaluation and subsequent reevaluations

Soft Tissue Techniques

- As needed to provide pain control

Stretching and Flexibility Techniques for the Musculotendinous Unit

- Physiologic range of motion in all planes of glenohumeral joint and scapular thoracic joint

Other Therapeutic Exercises

- TAS activity including wrist f/e curls, forearm pron/sup and ball squeezes to minimize effects of disuse atrophy in distal upper extremity

Activation of Primary Muscles Involved in Injury Area or Surgical Structures

- Exercises to begin submaximal contraction of the rotator cuff (primarily the infraspinatus and teres minor and subscapularis following a supraspinatus repair, as well as the serratus anterior, trapezius, and rhomboids.)

Sensorimotor Exercises

- Joint mobilization in addition to rhythmic stabilization to promote coactivation and challenge proprioception

Open and Closed Kinetic Chain Exercises

- A combination of open and closed kinetic chain exercises are used in the early phase, most notable closed

FIGURE 6-81. Ball approximation exercise performed with a physio ball to support the extremity and allow patient to perform safe active range of motion.

FIGURE 6-82. Supine rhythmic stabilization exercise in 90° of shoulder flexion.

chain exercises are gentle weight shifts with hands on plinth or countertop as well as ball approximation exercise (weightbearing or supported Codman's exercise) (Figure 6-81). This minimizes joint distraction for patients with anterior instability as well as promoting relaxation caused by the patient's extremity being supported on top of the ball.

Techniques to Increase Muscle Strength, Power, and Endurance

- Submaximal rotator cuff and scapular exercise is initiated during this stage using exercise movement patterns emphasizing short lever arms, minimal resistance loading, and high numbers of repetitions to promote muscular fatigue. Movement patterns with known muscular activation levels of the rotator cuff (Reinold et al.[6], Townsend et al.[7] and scapular musculature: Moesley et al.[8], Kibler et al.[5] are used). These include side-lying external rotation, low row, shoulder extension to neutral, serratus punch, robbery.

Neuromuscular Dynamic Stability Exercises

- Rhythmic stabilization is used in the 90° elevated balance point position initially (Figure 6-82) with the therapist providing submaximal provocations to induce dynamic stabilization.

Milestones for Progression to the Next Phase

- Glenohumeral joint range of motion progression in all planes of movement beginning initially with rotational range of motion in the 60° to 90° abducted position (for IR and ER range of motion).

TIMELINE 6-6: **Postoperative Rehabilitation after Open or Arthroscopic Posterior Shoulder Stabilization**

PHASE I (weeks 1 to 2)	PHASE II (weeks 3 to 6)	PHASE III (weeks 6 to 10)
• Sling • PT modalities • ROM-scapular plane elevation to 90° • Active assistive Codman's exercises • TBS/TAS/TLS activities as recommended & tolerated	• Sling • PT modalities • ROM-wk-4-scapular plane elevation to 120° • ROM-wk-6-scapular plane elevation to 160° • ROM-wk-4-Start flexion to 90° • ROM-wk-6-ER to 30° • ROM-wk-6-IR to 0° • TBS/TAS/TLS activities as recommended & tolerated • Scapular exercises • Week 4- AAROM exercises • Week 4- submax isometrics for GH joint muscles • Week 6- submax isometrics for ER	• DC sling • PT modalities as needed • PROM-full • Mobilizations as needed • TBS/TAS/TLS activities as recommended & tolerated • Scapular exercises—PREs • TAS—biceps/triceps PREs • Glenohumeral exercises—PREs • Rotator cuff exercises—PREs • Limit IR exercises to minimize strain to posterior capsule • PNF exercises • OKC rhythmic stabilization exercises • CKC exercises • Week 10 seated press-ups and increased weightbearing through joint • CKC manual perturbation exercises

- Tolerance of submaximal rotator cuff and scapular exercise using movement patterns and exercise listed in stage 1 of this program.

Phase II (weeks 6 to 12)

Clinical Pearls

- When applying strengthening progression for rotator cuff musculature in the elevated position, it is recommended that the scapular plane be used due to its functional implications and optimal bony congruency characteristics.[9] This position (scapular plane) is also better tolerated symptomatically than the coronal plane position which places greater anterior capsular tension during rotational exercise.

Goals

- Continue with range of motion in all planes/all positions
- Initiate and progress rotator cuff and scapular strengthening program
- Progress to 80° to 90° abducted position for rotator cuff and scapular strengthening at 10 to 12 week time period
- Initiate uncompensated elevation exercise to improve functional capacity of postoperative extremity

Protection

- Sling is typically discontinued at 4 to 6 weeks for many activities and situations, with sling use for up to 12 weeks for massive rotator cuff repairs or in repairs of nonoptimal tissue/fixation.

FIGURE 6-83. Cross arm adduction stretching using scapular stabilization to address posterior capsule and posterior muscle tendon tightness.

Management of Pain and Swelling

- Continued use of modalities are recommended such as interferential electrical stimulation and/or ultrasound to increase local blood flow and provide pain control particularly in patients following acromioplasty and distal clavicular excision who often present with continued increases in pain secondary to those bone-based procedures.

Techniques for Progressive Increase in Range of Motion

Manual Therapy Techniques

- Continued use of mobilization and passive stretching techniques to achieve terminal ranges of motion in all planes. Important use of scapular stabilization (Figure 6-83) during both cross arm adduction and internal

TIMELINE 6-6: **Postoperative Rehabilitation after Open or Arthroscopic Posterior Shoulder Stabilization** (Continued)

PHASE IV (weeks 10 to 14)	PHASE V (weeks 14 to 24)	PHASE VI (weeks 24 to 52)
• PT modalities as needed • PROM-full • Mobilizations as needed • Week 12- IR sleeper stretch • TBS/TAS/TLS activities as recommended & tolerated • Scapular exercises—PREs • TAS—biceps/triceps PREs • Glenohumeral exercises—PREs • Rotator cuff exercises—PREs • Thrower's Ten • Limit IR exercises to minimize strain to posterior capsule • PNF exercises • OKC rhythmic stabilization exercises • CKC exercises • CKC manual perturbation exercises	• PROM—maintain full motion • Mobilizations as needed • TBS/TAS/TLS activities as recommended & tolerated • Scapular exercises—PREs • TAS—biceps/triceps PREs • Glenohumeral exercises—PREs • Rotator cuff exercises—PREs • Thrower's Ten progress intensity • PNF exercises • OKC rhythmic stabilization exercises • CKC exercises • CKC manual perturbation exercises • Plyometrics—2 arm progressing to 1 arm • Overhead strengthening exercises • Sport-specific exercises begin • Overhead throwing athletes can begin with an easy interval throwing program • 20 weeks—begin full windup throwing	• PROM—maintain full motion • Mobilizations as needed • TBS/TAS/TLS activities as recommended & tolerated • Scapular exercises—PREs • TAS—biceps/triceps PREs • Glenohumeral exercises—PREs • Rotator cuff exercises—PREs • IR/ER exercises at 90° • Thrower's Ten progress intensity • PNF exercises • OKC rhythmic stabilization exercises • CKC exercises • CKC manual perturbation exercises • Plyometrics—2 arm chest passes progressing to 90/90 1 arm plyos • Overhead strengthening exercises • Sport-specific exercises progressed • Overhead throwing athletes progress through an interval throwing program

FIGURE 6-84. Internal rotation stretch with the extremity placed in the scapular plane in 80° of abduction coupled with a posterior glide stabilization force provided by the therapists hand placed upon the anterior aspect of the glenohumeral joint.

rotation stretches (Figure 6-84). Note the humeral position in the internal rotation stretching in Figure 6-84, where the therapist's upper leg is used to place the shoulder in the scapular plane position, allowing both of the therapist's hands to be available to provide a posterior glide and scapular stabilization as well as provide internal rotation overpressure.

Soft Tissue Techniques

- As needed based on periscapular muscular spasm secondary to overuse of these muscles during compensatory ADL usage.

Other Therapeutic Exercises

- Continued use of total arm strengthening techniques are recommended during this stage through the use of distal wrist and forearm strengthening such as wrist curls, ball dribbling, and bicep and tricep curls performed in positions with the glenohumeral joint in neutral resting (at the side) positions so as not to overload the rotator cuff during execution of these accessory exercises.

Activation of Primary Muscles Involved in Injury Area or Surgical Structures

- At 6 weeks postoperation, muscular activation of the supraspinatus is initiated using known patterns of rotator cuff activation such as prone horizontal abduction[6] via a pain-free range of motion. This particular movement pattern is favored over the classic empty can exercise which was previously advocated and has since been found to produce activation levels similar to the prone horizontal abduction exercise[10]. Recent research by Thigpen et al.[11] has shown that the empty can places the scapular in positions of increased anterior tilting and internal rotation which can aggravate the impingement process.

FIGURE 6-85. Ball on wall exercise performed in the scapular plane with 90° of elevation.

Sensorimotor Exercises

- Exercises such as rhythmic stabilization (Figure 6-82) are continued to be used in this phase of rehabilitation with increased intensity application for the perturbation.

Open and Closed Kinetic Chain Exercises

- Open kinetic chain exercise for the rotator cuff and scapular musculature predominate in this phase of training with the traditional Jobe exercises all using open kinetic chain environments. However, closed chain exercises like the ball on the wall (Figure 6-85) and step-up exercise for serratus anterior activation both use the closed kinetic chain environment for the exercise and are recommended during this phase of rehabilitation.

Techniques to Increase Muscle Strength, Power, and Endurance

- Progression to exercises to improve strength, power, and endurance are followed during this phase and at approximately 12 to 14 weeks postoperatively for small to large rotator cuff repairs, isokinetic exercise is initiated. The modified base or Davies 30-30-30 position is advocated for initial introduction of isokinetic exercise for internal and external rotation using 30° of elevation in the scapular plane[12] (Figure 6-86). Speeds of 120° to 240° per second are used with progression to speeds ranging between 180° and 300° per second in athletic individuals. Multiple sets of 15 to 20 repetitions are used to increase rotator cuff strength and provide an accommodating resistance overload to the patient to improve strength and endurance of the rotator cuff musculature. Isokinetic testing occurs at 12 to 14 weeks postoperation to determine strength levels and the continuation of rehabilitation. Moderate strength deficiencies are typically encountered in the posterior rotator cuff (external rotators) at 12 weeks following rotator cuff repair of tears ranging in size between small to large.[13]

FIGURE 6-86. Isokinetic modified base Davies 30/30/30 position to improve internal and external rotation strength and muscular endurance on the Biodex isokinetic dynamometer.

Milestones for Progression to the Next Phase

- Isokinetic ER/IR strength within 15% to 20% of contralateral side
- Isokinetic ER/IR ratios of 60% to 66% or greater
- Pain-free range of motion within 10° of contralateral side
- Negative impingement and provocation tests (i.e., subluxation/relocation test, empty can test, O'Brien's test)

Phase III (weeks 12 to 16)

Clinical Pearls

- Imperative to use and incorporate functional movement simulation into the clinical rehabilitation program to prepare the patient for entry into an interval sport return program.
- The use of very light medicine balls, 0.5 to 1 kg to perform single arm plyometric movements for deceleration and control are an important precursor to returning to throwing activity.
- Two hand plyometric exercises are also important for golf and other sport functional return programs.

Goals

- Advance overhead function in the 90° abducted scapular plane position
- Achieve terminal range of motion in all planes
- Increase muscular strength and endurance (fatigue resistance)
- Begin interval sport return programming
- Initiate and progress upper extremity plyometric program
- Prepare for discharge from formal physical therapy with detailed home exercise program if applicable (large and massive tears often require additional in-clinic rehabilitation to gain full strength in elevation

Protection

- No sling or brace is used during this stage

Management of Pain and Swelling

- Typically patients are weaned from any modality care at this time; however, the use of heat before rehabilitation and exercise is advocated, and continued use of ice following treatment, exercise, or functional return programming is followed.

Techniques for Progressive Increase in Range of Motion

Manual Therapy Techniques

- Continued use of the previously mentioned ROM and mobilization techniques is applied to achieve terminal ROM. Continued emphasis and development of independent stretching techniques for the patient is recommended. The sleeper stretch and cross-arm stretch are advocated to improve and maintain internal rotation ROM.[14,15]

Other Therapeutic Exercises

- Total arm strength activities continue through the use of the rehabilitation program of rotator cuff and scapular strength as well as a continued emphasis for the throwing and racquet sport athlete on distal forearm and wrist strengthening to ensure competence of those important muscles upon the return to activity phase.

Sensorimotor Exercises

- Continued use of rhythmic stabilization and closed chain (ball on wall) exercises continues during this phase to provide proprioceptive, and kinesthetically enriched, activity to the shoulder complex

Techniques to Increase Muscle Strength, Power, and Endurance

- The paradigm of multiple sets of 15 to 20 repetitions coupled with time based exercises of 30 seconds or more during external rotation oscillation exercise or body blade exercises continues in this later stage of rehabilitation due to the importance of establishing local muscular endurance in the rotator cuff and scapular musculature to provide glenohumeral compression and stabilization[16]. Additionally, the use of the isokinetic and plyometric exercises moves toward establishing and improving muscular power in the upper extremity.

Neuromuscular Dynamic Stability Exercises

- The use of closed chain rhythmic stabilization exercise (quadruped) and tripod positions (Figure 6-87) enable the patient to work both core and scapular stabilization and can also be used for functional progressions

FIGURE 6-87. Quadruped rhythmic stabilization exercise to improve scapular stabilization and begin to implement functional weightbearing activity.

to weightbearing and sport-specific activities (diving and landing).

Plyometrics

- Several plyometric exercises can be used starting with very light medicine balls (0.5 to 1.0 kg in weight). The side-lying ball drop/catch, and side-lying partner catch are two exercises that can be used to provide an overload stress for the posterior rotator cuff and scapular musculature before the initiation of any upper extremity sport activity. (Figures 6-88 and 6-89) Multiple sets of this exercise using 15 to 20 repetitions of the catches and working toward 20 to 30 second sets of catch and drop activity are recommended.

FIGURE 6-88. Side-lying plyometric external rotation drop exercise.

Functional Exercises

- In addition to the use of plyometric exercises that do mimic the functional movement patterns of overhead

FIGURE 6-89. A-D, Side-lying plyometric external rotation catch exercise with partner.

sports, interval sport return programs are followed before the patient is allowed back to any sport activity. These programs start with simulation of the activity without a ball or implement, and progress to very low levels of activity at shorter distances, or lower intensities to allow for a gradual return. The reader is directed to programs referenced here in Chapter 8 of this text. (Box 6-1)

Criteria for Return to Sport

General

- See Chapter 11 for an interval throwing program.
- Isokinetic ER/IR strength within 15% to 20% of contralateral side
- Isokinetic ER/IR ratios of 66% or greater
- Pain-free range of motion within 10° of contralateral side
- Pain-free IR and ER ROM endpoints that allow for uncompensated simulation of sport specific movement patterns after appropriate warmup and preparation.
- Negative impingement and provocation tests (i.e., subluxation/relocation test, empty can test, O'Brien's test)

After Return to Sport

Continuing Fitness or Rehabilitation Exercises

- Need for continued adherence to the rotator cuff and scapular exercise programming used in earlier rehabilitation phases
- Key to continue maintenance exercise for posterior rotator cuff as patients often discharged from therapy following rotator cuff repair with lower than optimal ER/IR ratios and require balancing via specific exercises
- A return to traditional lifting and sport activity most often is characterized by a dependence on internal rotation dominant activities. This can lead to increases in internal rotation strength without concomitant external rotation increases if diligent maintenance programs for rotator cuff and scapular exercise are not maintained.

Exercises and Other Techniques for Prevention of Recurrent Injury

- As in section above for strength
- Use of range of motion and stretching exercise particularly for internal rotation for those patients who return to throwing type activities after surgery and rehabilitation

BOX 6-1 Rehabilitation Protocol Following Arthroscopic Rotator Cuff Repair

General Guidelines:

- Progression of resistive exercise and ROM is dependent on patient tolerance.
- Resistance exercise should not be performed with specific shoulder joint pain.
- A sling is provided to the patient for support as needed with daily activities and to wear at night. The patient is weaned from the sling as tolerated and as directed by the referring physician.
- Early home exercises given to the patient following surgery including stomach rubs, sawing, and gripping activity.
- Progression to AROM against gravity and the initiation of resistive exercise are predicated by the size of the rotator cuff tear, and quality of the tissue and fixation.

Postop Weeks 1 & 2:

1. Early PROM to patient tolerance during the first 4 to 6 weeks:
   - flexion
   - scapular plane abduction
   - IR/ER with 90° to 45° scapular plane elevation
2. Mobilization of the glenohumeral joint and scapulothoracic joint. Passive stretching of elbow, forearm, and wrist to terminal ranges.
3. Side-lying scapular protraction/retraction resistance to encourage early serratus anterior and lower trapezius activation and endurance.
4. Home exercise instruction:
   - Instruction in PROM and AAROM home exercises with T-bar, pulleys, or opposite arm assistance in supine position using ROM to patient tolerance.
   - Weightbearing (closed chain) Codman's exercise instruction over a ball or counter-top/table.
   - Theraputty for grip strength maintenance

Postop Week 3:

1. Continue above shoulder PROM with progression to AAROM to patient tolerance.
2. Add upper body ergometer (UBE) if available.
3. Begin active scapular strengthening exercises and continue side-lying manual scapular stabilization exercise:
   - scapular retraction
   - scapular retraction with depression

Continued on following page

BOX 6-1 Rehabilitation Protocol Following Arthroscopic Rotator Cuff Repair *(Continued)*

4. Begin resistive exercise for total arm strength using positions with glenohumeral joint completely supported including:
   - bicep curls
   - tricep curls
   - wrist curls—flexors, extensors, radial and ulnar deviators
5. Begin submaximal rhythmic stabilization using the balance point position (90°-100° of elevation) in supine position to initiate dynamic stabilization.

Postop Weeks 5 & 6:

1. Initiate isotonic resistance exercise focusing on the following movements:
   - side-lying ER
   - prone extension
   - prone horizontal abduction (limited range to 45°)

   A low resistance/high repetition (i.e., 30 reps) format is recommended using no resistance initially (i.e., weight of the arm).
2. Progression to full PROM and AROM in all planes including ER and IR in neutral adduction progressing from the 90° abducted position used initially postop.
3. External rotation oscillation (resisted ER with towel roll under axilla and oscillation device) and Bodyblade to encourage local muscular endurance.
4. Home exercise program for strengthening the rotator cuff and scapular musculature with isotonic weights and/or elastic tubing (Thera-Band).

Postop Week 8:

1. Begin closed chain step-ups and quadruped rhythmic stabilization exercise.
2. Initiate upper extremity plyometric chest passes and functional two-hand rotation tennis groundstroke or golf swing simulation using small exercise ball progressing to light medicine ball as tolerated.

Postop Week 10:

1. Initiation of submaximal isokinetic exercise for IR/ER in the modified neutral position.
   Criterion for progression to isokinetic exercise:
   - Patient has IR/ER ROM greater than that used during the isokinetic exercise
   - Patient can complete isotonic exercise program pain-free with a #2 to #3 weight or medium resistance surgical tubing or Thera-Band
2. Progression to 90° abducted rotational training in patients returning to overhead work or sport activity.
   - prone external rotation
   - standing external/internal rotation with 90° abduction in the scapular plane
   - statue of liberty (external rotation oscillation)

Postop Week 12 (3 months):

1. Progression to maximal isokinetics in IR/ER and isokinetic testing to assess strength in modified base 30/30/30 position. Formal documentation of AROM, PROM, and administration of shoulder rating scales.
2. Begin interval return programs if criterion has been met below:
   - IR/ER strength minimum of 85% of contralateral extremity
   - ER/IR ratio 60% or higher
   - Pain-free range of motion
   - Negative impingement and instability signs during clinical exam

Postop Week 16 (4 months):

1. Isokinetic reevaluation, documentation of AROM, PROM, and shoulder rating scales.
2. Progression continues for return to full upper extremity sport activity (i.e., throwing, serving in tennis, etc.)
3. Preparation for discharge from formal physical therapy to home program phase.

Evidence

Ellenbecker TS, Elmore E, Bailie DS: Descriptive report of shoulder range of motion and rotational strength 6 and 12 weeks following rotator cuff repair using a mini-open deltoid splitting technique. *J Orthop Sports Phys Ther* 36:326–335, 2006.

This study followed patients 6 and 12 weeks postoperation following rotator cuff repair with a mini-open deltoid splitting technique and provided objective measure of range of motion and rotational strength. At 12 weeks postoperatively, patients' range of motion compared to their contralateral extremity showed 5° to 7° deficits in abduction, internal and external rotation and 9° great forward flexion than their contralateral side. Deficits in isokinetically documented strength for external rotation were 5% to 7% on the operative extremity and 2% to 11% greater internal rotation strength was measured on the operative extremity at 12 weeks postoperatively. The subjective portion of the ASES rating scale was 38/45 points for these patients at 12 weeks postop. (Level IV evidence)

Galatz LM, Charlton N, Das R, et al: Complete removal of load is detrimental to rotator cuff healing. *J Shoulder Elbow Surgery* 18:669–675, 2009.

This studied used a rat model and consisted of three groups following rotator cuff repair. These groups consisted of either botox injection, botox injection with complete immobilization, or saline injection with cast immobilization. The saline casted group had greater amounts of scar volume and greater cross sectional area as compared to the groups treated with botox and botox with immobilization. This study shows the detrimental effects of paralysis and immobilization on the healing and response of the tendon following rotator cuff repair. The complete removal of stress from the tendon resulted in a lower ultimate load to failure and decreased scar volume which jeopardizes healing and full function from the repair construct. (Level IV evidence)

Koo SS, Parsley BK, Burkhart SS, et al: Reduction of postoperative stiffness after arthroscopic rotator cuff repair: Results of a customized physical therapy regimen based on risk factors for stiffness. *Arthroscopy* 27:842–848, 2011.

This study reviewed results of rotator cuff repair surgery and identified several concomitant factors that led to stiffness and ROM complications following rotator cuff repair. These factors included calcific tendonitis, PASTA lesions, SLAP repairs, and single tendon RTC repairs. For patients with these characteristics, this study then implemented an additional rehabilitation intervention that consisted of a closed chain table slide exercise which places the patient's shoulder into a forward flexed position and can be done independently at home. This procedure was used in patients with risk factors for glenohumeral joint stiffness after rotator cuff repair and found to minimize range of motion complication in these patients. It is recommended that specific interventions be applied to patients with these stiffness risk factors to optimize recovery following rotator cuff repair. (Level IV evidence)

Lee BG, Cho NS, Rhee YG: Effect of two rehabilitation protocols on range of motion and healing rates after arthroscopic rotator cuff repair: Aggressive versus limited early passive exercise. *Arthroscopy* 28:34–42, 2012.

This prospective randomized trial examined two rehabilitation protocols for medium and large size rotator cuff repairs. Patients in the aggressive rehabilitation group had immediate early passive range of motion performed by a therapist two times per day along with unlimited patient self ROM with no ROM limitations. Patients in the limited passive range of motion rehabilitation group had continuous passive range of motion devices used without the assistance of the therapist to 90° of elevation only and limited self ROM during the first 6 weeks following surgery. At 3 months, the patients in the aggressive passive range of motion group had significantly great ROM in all planes than those patients in the group with only CPM use. By 1-year postop, however, there was no significant difference between groups. From a healing rate perspective, there were no significant differences in MRI documented retears of the rotator cuff at 7.6 months postop, with rates of retear of 23% in the aggressive passive rehabilitation group and 9% in the limited passive range of motion group. This study shows that early range of motion does lead to significantly great range of motion following arthroscopic rotator cuff repair. (Level IV evidence)

Namdari S, Baldwin K, Ahn A, et al: Performance after rotator cuff tear and operative treatment: A case-control study of major league baseball pitchers. *J Athletic Training* 46:296–302, 2011.

This study examined, via public records and statistics, the performance characteristics of professional baseball pitchers (n = 33) who underwent operative treatment for rotator cuff tears in their dominant pitching shoulder. These pitchers were compared to an age matched control population (n = 117) who did not have documented rotator cuff tears. This study showed that pitchers who had rotator cuff tear surgery did not return to baseline values of preoperative status. Characteristics of pitchers who needed rotator cuff surgery were that they were more experienced and had better earned run averages than pitchers studied who did not have rotator cuff tears. This study does show a return to presurgical performance levels in professional pitchers who undergo surgery for rotator cuff tears. (Level IV evidence)

Multiple-Choice Questions

QUESTION 1. According to Hatakeyama et al.[1], what ranges of motion are considered safe following rotator cuff repair based on their cadaveric study?

A. All ranges of motion are safe
B. Humeral rotation of up to 90° in internal rotation is safe
C. Humeral rotation in the scapular plane of up to 60° of external rotation is safe
D. Scapular plane rotational motion is more stressful to the repaired supraspinatus tendon than the sagittal plane

QUESTION 2. Which of the following statements about early scapular stabilization exercise is/are true?

A. Manual scapular stabilization is recommended with direct contacts on the scapula to minimize stress to the repaired tendon
B. The movements of scapular protraction and retraction are important for inclusion
C. Multiple sets of 15 to 20 repetitions are recommended to improve strength and endurance of the scapular stabilizers
D. All of the above are correct

QUESTION 3. What statement is not true about the empty can exercise?

A. Increased anterior tilting of the scapular is inherent in this exercise compared to the full can exercise position
B. The empty can exercise is superior with respect to muscle activation of the supraspinatus compared with the prone horizontal abduction Blackburn exercise
C. The combined movements of internal rotation and elevation in the empty can exercise can produce impingement
D. Increased internal rotation of the scapula has been reported in the empty can position as compared to the full can position

QUESTION 4. What exercises are not indicated in postoperative rehabilitation following rotator cuff repair?

A. Side-lying external rotation
B. Rowing
C. Pushup and military press
D. Prone horizontal abduction

QUESTION 5. What are key indicators used to determine a patient's readiness to return to sport activity following rotator cuff repair?

A. ER/IR ratios above 60% to 66%
B. Pain-free range of motion
C. Negative impingement and labral tests
D. All of the above are key indicators

Answer Key

QUESTION 1. Correct answer: **C** (see Phase I)

QUESTION 2. Correct answer: **D** (see Phase I)

QUESTION 3. Correct answer: **B** (see Phase II)

QUESTION 4. Correct answer: **C** (see Phase II)

QUESTION 5. Correct answer: **D** (see Phase III)

BEYOND BASIC REHABILITATION: RETURN TO TENNIS AFTER ROTATOR CUFF REPAIR

Neal M. Berger, MD, Jeremy Vail, PT, OCS, ATC, and Seth C. Gamradt, MD

Epidemiology and Mechanism of Injury

- The game of tennis imparts great physiologic and mechanical stresses on the shoulder.[1]
- Consequently many recreational and competitive tennis players suffer from shoulder pain. The incidence of shoulder pain in tennis athletes has been studied. Safran and Hutchinson reported a 35% prevalence of shoulder pain in 370 girls playing in the National Hard Court Championships 16 and under division and a 24% prevalence of shoulder pain in 480 boys playing in the National Hard Court Championships 16 and under and 18 and under division.[1,2]
- Lehman reported a 24% incidence of shoulder pain in younger players, ages 12 to 19, and as high as a 50% incidence in middle age players.[3]

- The high incidence of shoulder complaints in even young athletes underscores the demand placed on the shoulder for a lifelong tennis player.
- For the older athlete, increasing shoulder pain and a decreased ability to play tennis can be a sign of rotator cuff pathology. Most shoulder pain in tennis players is attributed to overuse and involves the rotator cuff and/or biceps tendon.[1]
- More specifically, rotator cuff injuries in tennis can be caused by repetitive microtrauma, a single episode of macrotrauma, or degeneration associated with aging.
- In younger athletes, microtrauma and overuse are believed to be the most common cause of pain. Fortunately, it is very unusual for athletes less than 35 years of age to have full-thickness rotator cuff tears.[4]
- As such, tennis players in this younger age group can most often be successfully treated conservatively with physical therapy, rest, and nonsteroidal antiinflammatory agents (NSAIDs).
- However, with aging, the rotator cuff is susceptible to partial and full thickness tears that can jeopardize pain-free participation in tennis.
- It is well accepted that the incidence of rotator cuff tears increases with age in both athletes and nonathletes. Many individuals continue to play tennis into their 5th and 6th decades when there is a dramatic increase in the incidence of rotator cuff tears.
- The cause of tears in this age group is often hypothesized to be caused by a combination of extrinsic compression from subacromial impingement and intrinsic rotator cuff degeneration.
- Microtrauma secondary to subacromical impingement during the overhead movements in tennis can certainly contribute to tearing the degenerative rotator cuff of older tennis players.[4]

Surgical Outcomes

- Bigliani et al. reported on a series of rotator cuff tears in tennis players aged 50 and 70 and found an inciting traumatic event as the cause of rotator cuff tear in 11 of 23 players. Six of the eleven reported injury while playing tennis.[5]
- Bertand, in his series of 51 surgically treated rotator cuff tears in tennis players age 39 to 67 years old, reported that 22 of the 51 patients had a specific traumatic episode. Two of his patients had a concomitant anterior shoulder dislocation.[4]
- Although these studies show there may have been a specific inciting event in which these tennis players suffered their rotator cuff tears, the acute tears probably occurred in a rotator cuff weakened by degenerative changes that are almost universal with aging.
- When a significant rotator cuff tear occurs in a tennis player, tennis can become very difficult to play without pain, particularly the serving motion.
- For a chronic rotator cuff tear, a trial of rest, NSAIDs, injection, and physical therapy is most often attempted to restore a pain-free shoulder with activities of daily living. This is followed by a gradual return to sporting activity.
- When this trial of nonoperative therapy fails (3–6 months), surgical repair of the rotator cuff is often performed to restore function and relieve pain.
- In patients with an acute traumatic event and full thickness rotator cuff tear, surgical repair is often performed acutely. Many of these patients state that besides the obvious goals of improving pain and restoring strength, one of the main goals of rotator cuff surgery is to restore function including sporting activities such as tennis.
- Several studies have reported on the results of rotator cuff repair specifically in tennis players. Bigliani et al., reported on 23 patients with full thickness rotator cuff tears that prevented them from playing tennis. The average age of the patients was 58 years (range, 39 to 71). The patients were largely recreational tennis players who averaged 3 days per week playing tennis preoperatively. These patients were surgically treated with an open rotator cuff repair and anterior acromioplasty. At average follow-up of 42 months, 83% of the patients were pain-free and were playing tennis at their preinjury level. Thirteen percent of the patients had some residual weakness and were playing tennis, but at a lower level than before the surgery. One patient was unable to play tennis and had pain with activities of daily living. All four of the patients who did not return to their preinjury playing level had massive tears. Although four other patients with massive tears had successful outcomes, the authors concluded that tennis players with massive rotator cuff tears should be made aware preoperatively that they may not return to their preinjury level. More importantly, they concluded that the majority of patients with symptomatic rotator cuff tears preventing them from playing tennis could return to tennis after open rotator cuff repair and acromioplasty.[5]
- Sonnery-Cottet et al. reported the results of a retrospective review where 51 tennis players, with an average age of 51 years, underwent surgical treatment for a rotator cuff tear. Thirty-two of the patients were recreational tennis players and 19 competed in tournaments on a national level at least in their age group. Overall, the patients averaged 3.5 hours of tennis per week. Patients varied in pathology from partial or full thickness tears of the supraspinatus, infraspinatus and/or subscapularis. Treatments varied from arthroscopic debridement (9 patients) to open repair (42 patients). Concomitant procedures were also performed in some patients and included bursectomy, coracoacromial ligament release, acromioplasty, and biceps tenodesis. They reported that 78% of the patients returned to playing tennis after surgery, with 61% returning to play at their preinjury level or higher. There is very little literature specifically examining the rehabilitation for tennis after rotator cuff repair. Rehabilitation specifically for tennis is demanding caused by the significant role the rotator cuff plays in tennis and its various strokes.[4]

EMG Analysis of Tennis Strokes

- Before developing an advanced rehabilitation protocol for returning to tennis, it is crucial to understand the

contribution each muscle makes during each tennis stroke.

- Jobe et al. investigated muscular activity during tennis strokes using electromyogram (EMG) and measured percentages of maximum voluntary isometric contraction (MVIC) of the shoulder musculature during forehand, backhand, and serve. The important work of Jobe's group deserves detailed mention here because it highlights the huge differences that occur in muscle activity during different strokes and during different phases of each stroke.
- During the cocking stage of serve, which involves shoulder abduction and external rotation while flexing the elbow, the percentages of MVIC were 53% for the supraspinatus, 41% for the infraspinatus, 25% for the subscapularis, 39% for the biceps brachii, and 70% for the serratus anterior.
- During the acceleration stage of serve, there is internal rotation and adduction of the shoulder with MVIC percentages of 113% for the subscapularis, 115% for the pectoralis major, and 74% for the serratus anterior.
- In the follow-through stage there was 63% of MVIC for the subscapularis and 53% of MVIC for the serratus anterior.[6]
- Forehand produces powerful internal rotation and adduction, with high activity of the subscapularis, biceps brachii, and serratus anterior.
- The follow-through had an increase in activity of the infraspinatus and a decrease in activity of the biceps brachii, subscapularis, and serratus anterior.
- The acceleration phase of the backhand consists of external rotation and abduction with high activity seen in the middle deltoid, supraspinatus, and infraspinatus.
- In the follow-through phase, there is decreased but continued moderate activity in the supraspinatus and infraspinatus.[6]
- Jobe's data quantifies the demand placed on specific muscle groups during tennis and allows the surgeon and physical therapist to tailor the patients' advanced rehabilitation activities based on what rotator cuff muscles were repaired. More importantly, a patient who is having difficulty with a particular stroke would benefit by strengthening the major muscles used during that stroke.

Rehabilitation Protocol

- After rotator cuff repair, both athletes and nonathletes proceed through rotator cuff rehabilitation protocols that are commonly subdivided into four phases: immediate postoperative, range of motion, early strengthening, and advanced strengthening.[7]
- However, many patients undergo rotator cuff repair to return to sporting activities, such as tennis. Thus, rehabilitation of a tennis player requires an advanced rehabilitation protocol that will increase the probability that the patient will be able to return to tennis without jeopardizing the structural integrity of the repair and the success of the surgery.
- After completing the standard rehabilitation and clearance by the surgeon, the patient can begin tennis specific exercises, drills, and activities. This is generally not before 4 or 5 months postrepair.
- These sport-simulating exercises are then slowly progressed until the therapist feels that the athlete is ready for an interval sports program.[8]
- The basic rehabilitation protocol shown in Box 6-2 must be completed and tolerated by the patient to progress to the advanced rehabilitation stages.

Return to Sports Program

- Reinold et al. highlight certain key points in developing a rehabilitation approach for return to sport. Applying these concepts to returning to tennis, the interval sports program should: 1) prepare the whole body for return to tennis with upper extremity, lower extremity, and core ROM and strengthening, 2) slowly

BOX 6-2 Rehabilitation Protocol

Phase I. Postoperative (0 to 6 weeks)

GOALS

- Edema control
- Protect repair
- Avoid shoulder stiffness in safe range

PRECAUTIONS

- Sling with abduction pillow at all times except showering (until week 4)
- No lifting
- No supporting body weight
- No AROM against gravity

WEEKS 0 TO 2 POSTOPERATIVE

- PROM-forward elevation in the scapular plane to 90°
- Passive ER to neutral
- Cryotherapy until swelling is diminished then after therapy and as needed
- Modalities PRN
- Hand, wrist, elbow AROM 3 times per day

BOX 6-2 Rehabilitation Protocol *(Continued)*

WEEKS 2 TO 4 POSTOPERATIVE

- Start pendulums.
- Passive supine elevation, passive ER (Goals: FE 120, ER 30, IR hip).
- Pulley exercises for flexion, as tolerated. Use cane for ER; IR in scapular plane.
- Begin scapular strengthening program, in protective range.
- Deltoid and rotator cuff isometrics, submaximal and pain free.

WEEKS 4 TO 6 POSTOPERATIVE

- Joint mobilization & gentle PROM as necessary to restore near full PROM by week 6 (passive supine elevation, passive ER and IR in scapular plane at 45° abduction)
- Continue scapular strengthening
- Brace may be weaned at week 4 for small and medium size tears

Phase II. Protection and Range of Motion (6–12 weeks)

PRECAUTIONS:

- Avoid lifting and carrying
- No sudden shoulder movements
- Avoid supporting bodyweight

GOALS:

- Reestablish dynamic shoulder stability
- Avoid stressing healing rotator cuff
- Establish pain-free AROM

6 TO 8 WEEKS POSTOPERATIVE

- Initiate AAROM activities
- Flexion, unlimited, use arm support in supine position
- Progress to AROM in scapular plane, ER/IR at 45° and 90° of abduction
- Deltoid isotonics in plane of scapula
- Continue with modalities prn
- Joint mobilization for inferior humeral glide
- Manual therapy techniques to the posterior cuff and shoulder complex to ensure normal accessory motion, specifically with overhead movements
- Incorporate cardiovascular exercise, conditioning, and lower extremity work.

WEEKS 8 TO 12 POSTOPERATIVE

- Restore full AROM by 10 to 12 weeks
- Continue with scapular strengthening exercises
- Begin isotonic IR/ER in adduction with tubing, emphasize eccentrics (week 10)
- Continue with flexibility activities to maintain PROM
- Proprioceptive neuromuscular facilitation (PNF) patterns
- Manual resistance/assistance
- Rhythmic stabilization beginning in mid-range and progressing through entire range as able.

Phase III. Early Strengthening (12–18 weeks postoperative)

PRECAUTIONS:

- Lifting: 5 lbs.
- No overhead lifting

GOALS:

- Full active ROM
- Return to low level functional activities
- Improve muscular endurance
- Restore normal glenohumeral and scapulothoracic rhythm.

12 TO 18 WEEKS POSTOPERATIVE

- Continue extremity PREs to maintain full PROM
- Initiate rotator cuff strengthening protocol
  - IR/ER isotonic tubing exercises
  - Lateral raises

Continued on following page

BOX 6-2 Rehabilitation Protocol *(Continued)*

- Full can
- Prone rowing
- Prone abduction
- Side-lying ER
- Biceps/triceps
- Scap pushups (pushup plus)
- Step-up with overhead reach
- Multidirectional lunges with reach

Phase IV. Advanced Strengthening/Sport-Specific Training (18 weeks+)

- The advanced strengthening phase of any rehabilitation program must be undertaken with great care and caution
- The potential for complication and accumulation of tissue stress increases as the volume and load of exercise increases
- To ensure the appropriate training effect is applied to the athlete's body and specifically the integration of the lower body, core and upper body, the following guidelines for progression should be observed.

Guidelines for Progression to Advanced Strengthening

- Full AROM and PROM of glenohumeral joint
- Normalized and symmetrical scapulohumeral and scapulothoracic rhythm. This is measured by evaluating the contralateral uninjured shoulder.
- Normalized thoracic spine extension and coupled extension/rotation. This is measured by evaluating the contralateral uninjured shoulder.
- Normalized age-specific cervical spine stability and AROM, with specific emphasis on the coupled motions of bilateral lateral flexion/rotation.
- Tolerates standard rotator cuff strengthening (Phase 3).
- Specific components of the advanced strengthening phase of rehabilitation should seek to improve both muscular strength as well as power development, and with respect to the tennis swing, key emphasis must be placed on the efficient transfer through the kinetic chain to the racket head.
- This efficient transfer is a combination of both acceleration and, more importantly, deceleration of the hips, trunk, and shoulders to pass to the racket head with maximal velocity at impact with the ball.
- Program design should take into account the staging of sets, reps, and appropriate load to address muscular hypertrophy, strength and ultimately power development, but keeping at the forefront the concept that the rotator cuff, and specifically the surgically repaired cuff is not the principal generator of the forces that swing the tennis racket, but function to center the humeral head in the glenoid fossa during the swing.
- Additionally, given the specific demands, multitude of swings (forehand, backhand, overhead, serve) and techniques (i.e., double vs. single hand forehand/backhand) and the repetitive nature of the sport, an estimated or projected 1 Repetition Maximum would be appropriate to determine loads for the above mentioned training cycles specific to the shoulder.
- Ultimately, these loads must be adjusted to ensure that during performance of the exercises, there is correct maintenance of posture and technique, to include proper stability through the hip complex and appropriate respiratory patterns that avoid development of a high-threshold strategy compensation.
- Prior to progression to the power development portion of a return to play program, it would be appropriate to administer a form-of-movement screen or functional assessment to evaluate not only the repaired shoulder but the entire kinetic chain's preparedness to initiate this type of training and conditioning.
- It is well documented that the contribution of the rotator cuff to power generation during the tennis swing varies with each phase of the swing.[6]
- Given this fact, tennis-specific exercises should focus on strengthening the shoulder muscles as a group and identify any underlying dysfunction elsewhere in the kinetic chain that contributed to the initial injury.
- Tennis-specific exercises performed in addition to traditional advanced strengthening may include the following:
  - Half-kneeling chop and lift—bar (Figures 6-90 and 6-91)
  - Half-kneeling chop and lift—rope (Figures 6-92 and 6-93)
  - Half-kneeling chop slam (Figure 6-94)
  - Half-kneeling deceleration ball toss (Figure 6-95)
  - Concentric/eccentric ball toss (Figure 6-96)
  - Wide stance trunk rotations (Figure 6-97)
  - Standing side toss (Figure 6-98)
  - Lunge and side toss (Figure 6-99)
- These exercises can be performed in the advanced strengthening phase of the rehabilitation program initially one set of 8 to 10 repetitions 2 to 3 times per week, advancing to two sets of 8 to 10 repetitions every other day. When this protocol is tolerated, the interval return to tennis program can be initiated. Typically, this portion of the rehabilitation program lasts for 1 to 2 months depending on progression before starting the interval tennis protocol (Table 6-2).
- Return to the sport of tennis, specifically at the higher levels of competition have been discussed in this chapter and cited in multiple studies.
- To ensure that all aspects of the athlete's return to play are addressed, there must be considerable attention paid to the cardiovascular as well as the above mentioned power development.

BOX 6-2 Rehabilitation Protocol *(Continued)*

- Inherent in this development are Olympic-style lifts and plyometric training programs. These are keys to the development of whole body power that is essential to maximize the athlete's return. They require a considerable amount of proper coaching, supervision and occasional modification where appropriate given the specific athlete's needs and goals.
- As such, a properly educated strength and conditioning expert well versed in the specifics of the sport of tennis should be consulted.
- Lastly, given the aforementioned overhead, repetitive nature of the game of tennis, avoidance of overhead pressing, straight bar bench press, barbell snatch lifts and upright rowing is considered prudent.
- The use of the power clean should be used judiciously, with caution given to the stress placed on the athlete's wrist.
- Coinciding with the power development portion of the program, the interval sport program must be instituted and progressed through before final clearance from the surgeon and return to unrestricted play.
- It is critical to keep in mind that compensations, or biomechanical inefficiencies, that had played a role in the initial injury most likely will continue to be present as the athlete works through the interval sport program and if still present after recovery can lead to reinjury.
- A qualified coach/instructor is an excellent adjunct at this phase of the rehabilitation as the competitor returns to competitive or recreational tennis.

increase forces on the surgically repaired shoulder, 3) incorporate a tennis specific warmup program and regimen of regular exercises, and 4) focus on proper stroke technique to lessen the chance of reinjury or new injury.[8]

Surgical Considerations for the Rehabilitation Program

- In developing an advanced tennis rehabilitation program, the surgeon must consider the individualized aspects of each patient's pathology, surgical repair, and goals. With respect to pathology, the surgeon must consider the size of the tear, the location of the tear, the quality of the rotator cuff preoperatively, the associated shoulder pathology, and the quality of fixation. These factors will affect the basic rehabilitation, the progression of the advanced rehabilitation, and the timeline for return to tennis.
- Generally, larger tears require a slower, more conservative rehabilitation. In addition, these patients can often take closer to a year to return to sport as opposed to 6 months for smaller tears.
- Also, as shown from the work of Bigliani et al., patients with massive tears may return at a lower level of play or not at all.[5]
- With respect to tissue quality, preoperative MRIs will allow the surgeon to assess the amount of fat atrophy versus muscle in the affected rotator cuff muscles. Patients with more fat atrophy will likely be progressed

TIMELINE 6-7: **Postoperative Rehabilitation after Rotator Cuff Repair**

PHASE I (weeks 0 to 6)	PHASE II (weeks 6 to 12)
Weeks 0–2	**Weeks 6–8**
• Cryotherapy until swelling is diminished then after therapy and as needed • Modalities PRN • Hand, wrist, elbow AROM 3 times per day	• Initiate AAROM activities • Flexion, unlimited, use arm support in supine position • Progress to AROM in scapular plane, ER/IR at 45° and 90° of abduction • Deltoid isotonics in plane of scapula • Continue with modalities prn • Joint mobilization for inferior humeral glide • Manual therapy techniques to the posterior cuff and shoulder complex to ensure normal accessory motion, specifically with overhead movements • Incorporate cardiovascular exercise, conditioning, and lower extremity work
Weeks 2–4	**Weeks 8–12**
• Joint mobilization & gentle PROM as necessary to restore near full PROM by week 6 (passive supine elevation, passive ER and IR in scapular plane at 45° abduction) • Continue scapular strengthening • Brace may be weaned at week 4 for small and medium size tears	• Restore full AROM by 10–12 weeks • Continue with scapular strengthening exercises • Begin isotonic IR/ER in adduction with tubing, emphasize eccentrics (week 10) • Continue with flexibility activities to maintain PROM • Proprioceptive neuromuscular facilitation (PNF) patterns • Manual resistance/assistance • Rhythmic stabilization beginning in mid-range and progressing through entire range as able

FIGURE 6-95. Half-kneeling deceleration ball toss. (**A**) Ball is tossed from behind patient into (**B**) patient's dominant hand. (**C**) Patient then decelerates ball into (**D**) finishing position.

more slowly in rehabilitation and will have a more conservative prognosis for time to return to play.
- The strength of the surgical fixation will also affect the speed of progression of the rehabilitation. The stronger the repair, the more quickly the rehabilitation can be advanced.
- Several investigations have reported improved time-zero biomechanical strength of double row and transosseus equivalent repairs, but it is unclear if these repairs will allow an earlier return to athletics.[9]

Preoperative Goals

- The patient's preoperative goals will also have to be considered prior to initiation of the advanced rehabilitation. Many highly competitive athletes will have unrealistic timelines for return to tennis.
- In addition, these patients may have a tendency to progress their own rehabilitation without the clearance of their therapist or surgeon. These patients will need preoperative and postoperative education and guidance to understand the duration of rehabilitation and the character of pain acceptable during rehabilitation.
- It is well accepted that patients may have dull, sore, or aching pains in their muscles or tendons during advanced rehabilitation which is not necessarily a sign of reinjury. However, sharp pain, worsening ROM, and/or new onset weakness should prompt cessation of athletic activity and a reassessment by the physical therapist and surgeon.[8]

TIMELINE 6-7: **Postoperative Rehabilitation after Rotator Cuff Repair** (Continued)

PHASE III (weeks 12 to 18)

- Continue extremity PREs to maintain full PROM
- Initiate rotator cuff strengthening protocol
  - IR/ER isotonic tubing exercises
  - Lateral raises
  - Full can
  - Prone rowing
  - Prone abduction
  - Side-lying ER
  - Biceps/Triceps
  - Scap pushups (pushup plus)
  - Step-up with overhead reach
  - Multidirectional lunges with reach

PHASE IV (weeks 18+)

- Begin advanced strengthening phase with great care and caution
- Full AROM and PROM of glenohumeral joint
- Normalized thoracic spine extension and coupled extension/rotation
- Normalized age-specific cervical spine stability and AROM
- Tolerates rotator cuff strengthening protocol (Phase III)
- Tennis-specific exercises
  - Half-kneeling chop & lift—bar
  - Half-kneeling chop & lift—rope
  - Half-kneeling chop slam
  - Half-kneeling deceleration ball toss
  - Concentric/eccentric ball toss
  - Wide stance trunk rotations
  - Standing side toss
  - Lunge and side toss

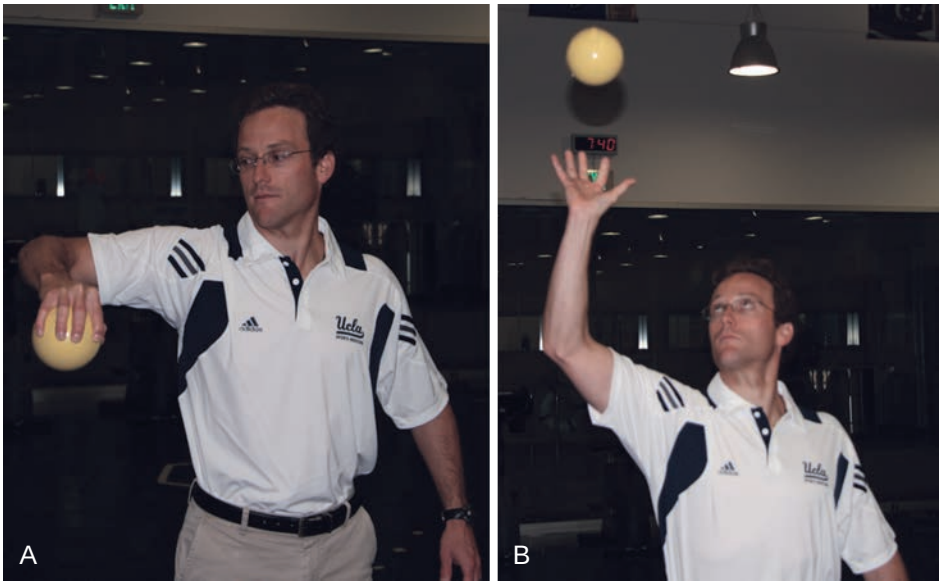

FIGURE 6-96. Concentric/eccentric ball toss. **A,B,** Ball is tossed concentrically using external rotation, caught, and eccentrically decelerated into starting position to repeat exercise.

Physician-Therapist-Patient Communication

- Lastly, the surgeon and physical therapist must communicate concerning the timing of progression to advance rehabilitation, the design of the program, and the timeline for return to tennis.
- The surgeon will often base their rehabilitation restrictions on the clinical factors described above, whereas the physical therapist is critical in assessing progression through the phases of rehabilitation while evaluating milestones for safe advancement.
- An effective surgeon/physical therapist relationship will increase the likelihood that patients will return to sport after rotator cuff repair.
- In this chapter, we present an abbreviated version of our complete rotator cuff rehabilitation protocol with an emphasis on the fourth phase of rehabilitation (advanced strengthening) and beyond, during which we incorporate tennis-specific functional exercises in preparation for the interval sport program described by Reinold et al.[8]

Evidence

Andrews J, Wilk KE: The Athlete's shoulder, New York, 1999, Churchill Livingstone.

An older but classic book describing the treatment of all types of athletic shoulder injuries.

Bigiliani LU, Kimmel J, McCann PD, et al: Repair of rotator cuff tears in tennis players. *Am J Sports Med* 20:112–117, 1992.

Twenty-three patients (average age 58 years) with full thickness rotator cuff tears that prevented them from playing tennis underwent open repair and acromioplasty. At average

follow-up of 42 months, 83% of the patients were pain-free and were playing tennis at their preinjury level. All four of the patients who did not return to their preinjury playing level had massive rotator cuff tears.

Ghodadra NS, Provencher MT, Verma NN, et al: Open, mini-open, and all-arthroscopic rotator cuff repair surgery: indications and implications for rehabilitation. *J Orthop Sports Phys Ther* 39:81–89, 2009.

This is one of the best and most detailed review papers for surgeons and physical therapists discussing rehabilitation and timelines after rotator cuff repair. (Level IV evidence)

Lehman RC: Shoulder pain in the competitive tennis player. *Clin Sports Med* 7:309–327, 1988.

Shoulder pain in the competitive tennis player ranges from 24% in the young player to 50% in the middle aged player. (Level IV evidence)

Millett PJ, Wilcox RB, 3rd, O'Holleran JD, et al: Rehabilitation of the rotator cuff: an evaluation-based approach. *J Am Acad Orthop Surg* 14:599–609, 2006.

An outstanding rotator cuff rehabilitation review that divides the rehabilition of the repaired shoulder into four phases: immediate postoperative, range of motion, early strengthening, and advanced strengthening. (Level IV evidence)

Reinold MM, Wilk KE, Reed J, et al: Interval sport programs: guidelines for baseball, tennis, and golf. *J Orthop Sports Phys Ther* 32:293–298, 2002.

This paper provides a timeline for tendon healing in and helps guide rehabilitation milestones based on biology of tendon repair and healing. (Level IV evidence)

Ryu RK, McCormick J, Jobe FW, et al: An electromyographic analysis of shoulder function in tennis players. *Am J Sports Med* 16:481–485, 1988.

Jobe et al. investigated muscular activity during tennis strokes using electromyogram (EMG) and measured percentages of maximum voluntary isometric contraction (MVIC) of the shoulder musculature during forehand, backhand, and serve. This study highlights the huge differences in muscle activity that occur during different strokes and during different phases of each stroke. (Level II evidence)

Safran MR, Hutchinson HM: *Unpublished Data*, 1995.

Unpublished data reporting a 35% prevalence of shoulder pain in 370 girls playing in the National Hard Court Championships 16-and-under division and a 24% prevalence of shoulder pain in 480 boys playing in the National Hard Court Championships 16-and-under and 18-and-under division. (Level IV evidence)

Sonnery-Cottet B, Edwards TB, Noel E, et al: Rotator cuff tears in middle-aged tennis players: results of surgical treatment. *Am J Sports Med* 30:558–564, 2002.

Fifty-one tennis players with an average age of 51 years who underwent surgical treatment for a rotator cuff tear were evaluated. Treatments varied from arthroscopic debridement (9 patients) to open repair (42 patients). Seventy-eight percent of the patients returned to playing tennis after surgery, with 61% returning to play at their preinjury level or higher.

Multiple-Choice Questions

QUESTION 1. Based on retrospective, level-IV evidence, which of the following preoperative patient factors carries a high risk of poor outcome and failure to return to tennis after rotator cuff tear?

A. Full thickness rotator cuff tear
B. Age greater than 50
C. Concomitant acromioplasty
D. Massive rotator cuff tear

QUESTION 2. Based on observational and epidemiological data, what percentage of tennis players experience shoulder pain?

A. Less than 5%
B. 10%
C. 15%
D. More than 20%

QUESTION 3. Regarding EMG of the shoulder during tennis serve, forehand, and backhand, which of the following is an incorrect statement

A. During EMG of the shoulder during serving, the highest values of shoulder maximum voluntary isometric contraction (MVIC) occurred during the acceleration phase of serve.
B. The MVIC values of rotator cuff activity were similar regardless of stroke being evaluated.
C. Rotator cuff muscles remain active in the follow through phase of forehand and backhand.
D. The amount and location of muscle activity changes depending on which stroke is being evaluated.

QUESTION 4. Criteria to proceed with advanced strengthening and sport-specific exercises include all of the following except:

A. Full active shoulder range of motion
B. Full passive shoulder range of motion
C. Restoration of scapula-humeral rhythm
D. Continued mild pain with rotator cuff strengthening

QUESTION 5. An acceptable rehabilitation timeline for

restoring full active range of motion in a shoulder after rotator cuff repair is:

A. 2–4 weeks
B. 6–8 weeks
C. 10–12 weeks
D. 24 weeks

Answer Key

QUESTION 1. Correct Answer: **D** (see Surgical Outcomes of Rotator Cuff Tear in Tennis)

QUESTION 2. Correct Answer: **D** (see Epidemiology)

QUESTION 3. Correct Answer: **B** (see the EMG Analysis of Tennis Stroke)

QUESTION 4. Correct Answer: **D** (see Rehabilitation Timeline)

QUESTION 5. Correct Answer: **D** (see Rehabilitation Timeline)

BEYOND BASIC REHABILITATION: RETURN TO GOLF AFTER ROTATOR CUFF REPAIR

Seth C. Gamradt, MD, Jeremy Vail, PT, OCS, ATC, and Neal M. Berger, MD

Introduction

- Shoulder injuries are one of the most common injuries in both amateur and professional golfers; injuries to the shoulder rank third in frequency behind wrist/hand injuries and lumbar spine injuries in professional golfers.[1–3]
- Although not commonly thought of as an overhead sport, 30% of the golf swing is spent with the arms elevated above 90° (Figure 6-100).
- Further, golf involves an asymmetric attainment of extremes of shoulder range of motion at the top of the backswing and at the end of the follow-through that can exacerbate impingement and rotator cuff disease.

Epidemiology

- Jobe reviewed 412 patients with golf injuries and found the incidence of shoulder pain to be 20%, with the majority of shoulder pathology being impingement or rotator cuff disease.[4]

EMG Analysis of Golf Swing

- Jobe et al evaluated the activity of eight muscles during the asymptomatic golf swing using electromyography and high-speed motion cameras.[4]
- Surprisingly, the rotator cuff and deltoid were relatively inactive during the golf swing. The pectoralis major and latissimus dorsi muscles were the most active and provided power for downswing, acceleration, and follow-through. The deltoid was active in the lead shoulder just before ball contact and the supraspinatus fired at a low level in both shoulders throughout the swing but was more active in the lead shoulder. The subscapularis was the most active of the three rotator cuff muscles tested.[4] These EMG results have clinical implications for returning to golf after rotator cuff repair.

FIGURE 6-100. Stages of the golf swing.

Return to Sport

- Return to sport after repair of full or partial thickness rotator cuff tears has been unpredictable in overhead athletes (particularly pitchers), and many authors therefore advocate for debridement of rotator cuff tears alone in this population unless the tear involves greater than 50% of the thickness of the footprint.[5]
- It is possible that a higher percentage of golfers could return to sport after rotator cuff repair caused by the comparatively low demand (at least by EMG) on the rotator cuff in golf.
- Unfortunately, there is very limited evidence to evaluate the success or failure of rotator cuff repair in return to golf. Only one study has specifically evaluated rotator cuff repair in golfers; a 2001 retrospective study by Vives et al. reported excellent success after mini-open or open rotator cuff repair with a high level of satisfaction in a group of 29 recreational golfers with an average age of 60 years. They found that all but two golfers were able to return to their previous level of golf without detriment to driving distance or handicap.[6] Although this study shows excellent results, the results are certainly not applicable across all sizes of rotator cuff tear and level of golfing ability.
- Because golf is played by millions of Americans and is popular in the older age groups in which rotator cuff disease is common, designing an advanced rehabilitation protocol that will predictably return an athlete to golf is an important goal of surgeons and therapists alike.
- Often, the main impetus for a patient undergoing a rotator cuff repair is to return to an active lifestyle without shoulder pain, including golf. The ideal advanced rehabilitation protocol should be tailored to each patient/athlete with respect to the type and severity of injury and also the athletic goals.

Postoperative Rehabilitation

- Postoperative rehabilitation for return to sport after rotator cuff repair follows a stepwise progression to safely restore range of motion (ROM) followed by return of muscle strength and endurance.[7]
- Dynamic neuromuscular training with function and sport-specific drills then precedes an interval training program which transitions an athlete into full return to competition.[8]
- There are several key factors to consider when designing a rehabilitation protocol for return to golf after rotator cuff repair:
  1) Size and location of tear: Rotator cuff tears vary in size and location. A larger tear is generally rehabilitated more slowly than a large tear. Precautions are different depending on the location of the tear (e.g., protect against external rotation with a subscapularis repair).
  2) Tissue quality: Rotator cuff tears vary in tissue quality and tissue mobility. This affects the security of the repair and can limit the speed and eventual success of rehabilitation.
  3) Security of fixation: Double row fixation theoretically should allow for an accelerated rehabilitation protocol.
  4) Concomitant pathology: Subacromial impingement, acromioclavicular joint osteoarthritis, long head biceps pathology, and adhesive capsulitis are often all treated in the setting of rotator cuff repair.
  5) Skill level and goals of athlete: A high-level golfer desiring a maximal exertional swing will differ in rehabilitation needs from a recreational golfer.
  6) Short game: Chipping and putting can often be allowed relatively early in the rehabilitation program caused by the low demand on the cuff.

TIMELINE 6-8: **Postoperative Rehabilitation after Rotator Cuff Repair**

PHASE I (weeks 0 to 6)

Weeks 0 to 2

- PROM-forward elevation in the scapular plane using the opposite hand to 90°.
- Cryotherapy 15–20 min 4–6 times per day until swelling is diminished then after therapy and as needed.
- Modalities PRN
- Hand, wrist, elbow AROM 3 times per day

Weeks 2 to 4

- Start pendulums
- Passive supine elevation, passive ER (Goals FE 120, ER 30, IR hip)
- Pulley exercises for flexion, as tolerated. Use cane for ER; towel to increase IR
- Begin scapular strengthening program, in protective range
- Deltoid and rotator cuff isometrics, submaximal and pain free

Weeks 4 to 6

- Joint mobilization and gentle PROM as necessary to restore near full PROM by week 6
- Begin submaximal IR/ER isometric exercises in neutral, arm at side (week 4)
- Continue scapular strengthening
- Brace may be weaned at week 4 for small and medium size tears

PHASE II (weeks 6 to 12)

Weeks 6 to 8

- Initiate AAROM activities
- Flexion, unlimited, use arm support in supine position
- Progress to AROM in scapular plane, ER/IR at 45° and 90° of abduction
- Deltoid isotonics in plane of scapula
- Continue with modalities as needed
- Joint mobilization for inferior humeral glide
- Incorporate cardiovascular exercise, conditioning, and lower extremity work with lunge matrix followed by lunge-reach matrix

Weeks 8 to 12

- Restore full AROM by 10–12 weeks
- Continue with scapular strengthening exercises
- Begin isotonic IR/ER in adduction with tubing, emphasizing eccentrics (week 10)
- Continue with flexibility activities to maintain PROM
- Proprioceptive neuromuscular facilitation (PNF) patterns
- Manual resistance/assistance
- Rhythmic stabilization beginning in mid-range and progressing through entire range as able

Physician-Therapist-Patient Communication

- Obviously, surgeon/therapist communication is critical at the initiation of the rehabilitation protocol to obtain the details regarding tear size, location, tissue quality, and security of repair.
- This will allow the therapist or athletic trainer to implement the correct precautions as well as the pace of advancement.
- Also, a line of communication must remain open between the physical therapist and surgeon regarding progression through the sequence of rehabilitation phases.

Rehabilitation Protocol

- Any publication describing a rehabilitation protocol for rotator cuff repair is subject to debate and scrutiny regarding the initiation of key facets of rehabilitation progression.
- Formal recommendations are difficult to make using level-one clinical evidence comparing the success or failure of rotator cuff repair protocols caused by a paucity of high quality randomized comparative trials. Furthermore, in vivo studies in humans assessing the true rate and progression of enthesis restoration and healing are also not available.
- Therefore, the healing rate of the rotator cuff has been extrapolated from animal models of tendon-bone healing. It must be noted that animal models may not replicate the clinical situation of rotator cuff healing in humans as young animal models do not take into account the dysvascularity and degeneration often present in the aging rotator cuff in humans.
- From animal models, it is commonly thought that fibrous scar is present at 6 weeks and that progression to a mature repair takes 3 months.[9]
- These studies are referenced as evidence to refrain from active range of motion for 6 weeks postrepair and from strengthening until 3 months.
- Lastly, some surgeons prefer an accelerated rehabilitation protocol with early advancement of active ROM/strengthening and others prefer a decelerated protocol, especially in larger tears.
- Detailed rotator cuff repair rehabilitation protocols are described elsewhere in this text and in the literature.[10–12]
- Preceding return to sport, rotator cuff rehabilitation protocols are commonly subdivided into four phases: immediate postoperative, range of motion, early strengthening, and advanced strengthening.[12] Box 6-3 presents an abbreviated version of the complete rotator cuff rehabilitation protocol with an emphasis on the fourth phase of rehabilitation (advanced strengthening and functional rehabilitation) during which golf-specific functional exercises were incorporated in preparation for the interval sport program described by Reinold[8] (Table 6-3).

Summary

- Return to golf after rotator cuff repair is a goal of many rotator cuff patients.
- Successful rehabilitation of the repaired cuff relies on restoration of normal glenohumeral motion and strength prior to the institution of sports-specific exercises.
- When sports-specific exercises are tolerated with repetition pain-free, the interval sports program can be instituted.
- Careful attention must be paid to individual patient factors such as tear size, repair type, tissue quality, and patient goals. Each rehabilitation program can therefore be individualized to maximize the potential for the patient to return to golf.

TIMELINE 6-8: **Postoperative Rehabilitation after Rotator Cuff Repair** (Continued)

PHASE III (weeks 12 to 18)	PHASE IV (weeks 18+)

• Continue extremity PREs to maintain full PROM
• Initiate rotator cuff strengthening protocol
  • IR/ER isotonic tubing exercises
  • Lateral raises
  • Full can
  • Prone rowing
  • Prone abduction
  • Side-lying ER
  • Biceps/triceps
  • Scap pushups (pushup plus)
  • Chipping and putting is permitted at this point. Even light swings should be off a tee or without a divot to protect the newly repaired shoulder
  • Hitting fat places tremendous stress on the shoulder and can lead to reinjury
	• Begin advanced strengthening phase with great care and caution
	• Full AROM and PROM of glenohumeral joint
	• Normalized and symmetrical scapula-humeral and scapula-thoracic rhythm
	• Normalized thoracic spine extension and coupled extension/rotation
	• Normalized cervical spine stability and AROM, with specific emphasis on the coupled motions of bilateral lateral flexion/rotation.
	• Tolerates rotator cuff strengthening protocol (Phase 3)
	• Golf-specific exercises
	  • Half-kneeling chop & lift—bar
	  • Half-kneeling chop & lift—rope
	  • Half-kneeling chop slam
	  • Golf stance—Bodyblade stabilization through swing
	  • Standing chop slam
	  • Standing side toss

BOX 6-3 Rehabilitation Protocol for Return to Golf

Phase I. Postoperative (0–6 weeks)

GOALS:

- Edema control
- Protect repair
- Avoid shoulder stiffness in safe range

PRECAUTIONS:

- Sling with abduction pillow at all times except showering (until week 4)
- No lifting
- No supporting body weight
- No AROM against gravity

0 TO 2 WEEKS

- PROM-forward elevation in the scapular plane using the opposite hand to 90.
- Passive ER to neutral.
- Cryotherapy 15 to 20 minutes 4 to 6 times per day until swelling is diminished, then after therapy and as needed.
- Modalities PRN
- Hand, wrist, elbow AROM 3 times per day

2 TO 4 WEEKS

- Start pendulums
- Passive supine elevation, passive ER (Goals FE 120, ER 30, IR hip)
- Pulley exercises for flexion, as tolerated. Use cane for ER; towel to increase IR.
- Begin scapular strengthening program, in protective range
- Deltoid and rotator cuff isometrics, submaximal, and pain-free.

4 TO 6 WEEKS

- Joint mobilization and gentle PROM as necessary to restore near full PROM by week 6 (passive supine elevation, passive ER and IR in scapular plane at 45° abduction)
- Begin submaximal IR/ER isometric exercises in neutral, arm at side (week 4)
- Continue scapular strengthening
- Brace may be weaned at week 4 for small and medium size tears

Phase II. Protection and Range of Motion (6–12 weeks)

PRECAUTIONS

- Avoid lifting and carrying
- No sudden shoulder movements
- Avoid supporting bodyweight

GOALS

- Reestablish dynamic shoulder stability
- Avoid stressing healing rotator cuff
- Establish pain-free AROM

6 TO 8 WEEKS

- Initiate AAROM activities
- Flexion, unlimited, use arm support in supine position
- Progress to AROM in scapular plane, ER/IR at 45° and 90° of abduction
- Deltoid isotonics in plane of scapula,
- Continue with modalities as needed
- Joint mobilization for inferior humeral glide
- Posterior cuff tissue work
- Incorporate cardiovascular exercise, conditioning, and lower extremity work with lunge matrix followed by lunge-reach matrix

8 TO 12 WEEKS

- Restore full AROM by 10 to 12 weeks
- Continue with scapular strengthening exercises
- Begin isokinetic IR/ER in adduction with tubing, emphasize eccentrics (week 10)
- Continue with flexibility activities to maintain PROM
- Proprioceptive neuromuscular facilitation (PNF) patterns
- Manual resistance/assistance
- Rhythmic stabilization beginning in mid-range and progressing through entire range as able

BOX 6-3 Rehabilitation Protocol for Return to Golf *(Continued)*

Phase III. Early Strengthening (12–18 weeks)

PRECAUTIONS:

- Lifting: 5 lbs
- No overhead lifting

GOALS:

- Full active ROM
- Return to low level functional activities
- Improve muscular endurance
- Restore normal glenohumeral and scapula-thoracic rhythm

12 TO 18 WEEKS

- Continue extremity PREs to maintain full PROM
- Initiate rotator cuff strengthening protocol[7]
  - IR/ER isotonic tubing exercises
  - Lateral raises
  - Full can
  - Prone rowing
  - Prone abduction
  - Side-lying ER
  - Biceps/triceps
  - Scap pushups
  - Pushup plus exercises
  - Chipping and putting is permitted at this point. Even light swings should be off a tee or without a divot to protect the newly repaired shoulder.
  - Hitting fat places tremendous stress on the shoulder and can lead to reinjury.

Phase IV. Advanced Strengthening/Sport-Specific Training (18 weeks+)

- The advanced strengthening phase of any rehabilitation program must be undertaken with great care and caution.
- The potential for complication and accumulation of tissue stress increases as the volume and load of exercise increases.
- To ensure the appropriate training effect is applied to the athlete's body and specifically the integration of the lower body, core and upper body, the following guidelines for progression should be observed:

Guidelines for Progression to Advanced Strengthening

- Full AROM and PROM of glenohumeral joint
- Normalized and symmetrical scapulohumeral and scapulothoracic rhythm
- Normalized thoracic spine extension and coupled extension/rotation
- Normalized cervical spine stability and AROM, with specific emphasis the coupled motions of bilateral lateral flexion/rotation.
- Tolerates standard rotator cuff strengthening (Phase 3)
- Specific components of the advanced strengthening phase of rehabilitation should seek to improve both muscular strength as well as power development, and to ensure the efficient transfer of this power through the kinetic chain to the club head.
- This efficient transfer, commonly referred to as the kinematic sequence as it relates to the golf swing, is a combination of both acceleration and more importantly, deceleration of the hips, trunk, and shoulders to pass to the club head with maximal power at impact with the ball.
- Program design should take into account the staging of sets, reps, and appropriate load to address muscular hypertrophy, strength, and ultimately power development, but keeping at the forefront the concept that the rotator cuff, and specifically the surgically repaired cuff, is not the principal generator of the forces that swing the golf club, but merely to aid in the centration of the humeral head in the glenoid fossa during the swing.
- Additionally, given the specific demands of the golf swing and its repetitive nature, an estimated or projected 1 repetition maximum derived from a 10 repetition performance would be appropriate to determine loads for the above mentioned training cycles.
- Ultimately, the load must be adjusted to ensure that during performance of the exercises, there is correct maintenance of erect or golf stance posture, to include proper stability through the hip complex and appropriate respiratory patterns that avoid development of a high-threshold strategy compensation.
- Additionally, at this point in the rehabilitation program it would be appropriate to administer a form of movement screen or assessment to evaluate not only the repaired shoulder but the entire kinetic chain.
- It is well documented that the contribution of the rotator cuff to power generation during the golf swing varies with each phase of the swing.[4]
- Given this fact, golf-specific exercises should focus on strengthening the shoulder muscles as a group and identify any underlying dysfunction elsewhere in the kinetic chain that contributed to the initial injury.
- Golf-specific exercises that are performed in addition to traditional advanced strengthening include the following:

BOX 6-3 Rehabilitation Protocol for Return to Golf *(Continued)*

- Half-kneeling chop and lift—bar (Figures 6-101 and 6-102)
- Half-kneeling chop and lift—rope (Figures 6-103 and 6-104)
- Half-kneeling chop slam (Figure 6-105)
- Golf stance—Bodyblade stabilization (Figure 6-106)
- Standing chop slam (Figure 6-107)
- Standing side toss (Figure 6-108)

- These exercises can be performed in the advanced strengthening phase of the rehabilitation program initially one set of 8 to 10 repetitions 2 to 3 three times per week, advancing to two sets of 8 to 10 repetitions every other day. When this protocol is tolerated, the interval return to golf program can be initiated. Typically, this portion of the rehabilitation program lasts for 1 to 2 months depending on progression before starting the interval golf protocol).
- Once these exercises are tolerated with repetition, the interval sport program can be instituted.
- It is critical to keep in mind that specific swing faults should be avoided or corrected, as these swing flaws could have been contributors to the initial injury and if still present after recovery can lead to reinjury.
- These flaws are:
  1. Steep swing plane
  2. Fat divots (use a tee)
  3. Casting
  4. Vertical trail arm (without adequate ER and scapular retraction)
  5. Limited follow-through
- A qualified swing instructor is an excellent adjunct at this phase of the rehabilitation as the competitor returns to competitive or recreational golf.

Table 6-3 Interval golf program

	Monday	Wednesday	Friday
Week 1	10 putts 10 chips 5 min rest 15 chips	15 putts 15 chips 5 min rest 25 chips	20 putts 20 chips 5 min rest 20 putts 20 chips 5 min rest 10 chips 10 short irons
Week 2	20 chips 10 short irons 5 min rest 10 short irons 15 medium irons (5-iron off tee)	20 chips 15 short irons 10 min rest 15 short irons 15 chips Putting 15 medium irons	15 short irons 20 medium irons 10 min rest 20 short irons 15 chips
Week 3	15 short irons 20 medium irons 10 min rest 15 short irons 15 medium irons 5 long irons 10 min rest 20 chips	15 short irons 15 medium irons 10 long irons 10 min rest 10 short irons 5 long irons 5 wood	15 short irons 15 medium irons 10 long irons 10 min rest 10 short irons 10 medium irons 10 long irons 10 wood
Week 4	15 short irons 15 medium irons 10 long irons 10 drives 15 min rest Repeat	Play 9 holes	Play 9 holes
Week 5	Play 9 holes	Play 9 holes	Play 18 holes

Chips, Pitching wedge; *short irons*, wedge, 9-iron; *medium irons*, 7-iron, 6-iron, 5-iron; *long irons*, 4-iron, 3-iron, 2-iron; *woods*, 3-wood, 5-wood; *drives*, driver

Evidence

Andrews JR, Wilk KE: *The athlete's shoulder*, 1994, New York, 1994, Churchill Livingstone.

An older but excellent book describing the treatment of all types of athletic shoulder injuries.

Drakos MC, Rudzki JR, Allen AA, et al: Internal impingement of the shoulder in the overhead athlete. *J Bone Joint Surg Am* 91:2719–2728, 2009.

An outstanding review of the pathophysiology and current thinking in shoulder dysfunction of the overhead athlete. (Level IV evidence)

Ekdahl M, Wang JH, Ronga M, et al: Graft healing in anterior cruciate ligament reconstruction. *Knee Surg Sports Traumatol Arthrosc* 16:935–947, 2008.

This paper provides a timeline for tendon healin, and helps guide rehabilitation milestones based on biology of tendon repair and healing. (Level IV evidence)

Ghodadra NS, Provencher MT, Verma NN, et al: Open, mini-open, and all-arthroscopic rotator cuff repair surgery: indications and implications for rehabilitation. *J Orthop Sports Phys Ther* 39:81–89, 2009.

This is one of the best and most detailed review papers for surgeons and physical therapists discussing rehabilitation and timelines after rotator cuff repair.

Gosheger G, Liem D, Ludwig K, et al: Injuries and overuse syndromes in golf. *Am J Sports Med* 31:438–443, 2003.

An excellent review of golf injuries not limited to the shoulder.(Level IV evidence)

Jobe FW, Moynes DR, Antonelli DJ: Rotator cuff function during a golf swing. *Am J Sports Med* 14:388–392, 1986.

An excellent article discussing EMG of the shoulder during the golf swing. The rotator cuff is relatively inactive during the golf swing. The most active muscles are the pectoralis major and latissimus dorsi. The most active rotator cuff muscle is the subscapularis. (Level II evidence)

McCarroll JR: The frequency of golf injuries. *Clin Sports Med* 15:1–7, 1996.

Injuries to the shoulder are third most common among golfers after injuries to the hand/wrist and lumbar spine. (Level IV evidence)

Millett PJ, Wilcox RB, 3rd, O'Holleran JD, et al: Rehabilitation of the rotator cuff: an evaluation-based approach. *J Am Acad Orthop Surg* 14:599–609, 2006.

Another outstanding rotator cuff rehabilitation review that divides the rehabilition of the repaired shoulder into four phases: Immediate postoperative, range of motion, early strengthening, and advanced strengthening.

Reinold MM, Wilk KE, Reed J, et al: Interval sport programs: guidelines for baseball, tennis, and golf. *J Orthop Sports Phys Ther* 32:293–298, 2002.

This paper provides detailed timelines for returning an athlete back to baseball, tennis, and golf. More focused on return to sport rather than early rehabilitation of the shoulder. (Level IV evidence)

Theriault G, Lachance P: Golf injuries. An overview. *Sports Med* 26:43–57, 1998.

An overview of golf injuries. A basic primer on the injuries sustained by golfers. (Level IV evidence)

Vives MJ, Miller LS, Rubenstein DL, et al: Repair of rotator cuff tears in golfers. *Arthroscopy* 17:165–172, 2001.

A retrospective review of the success rate of return to recreational golf among 29 patients (average age: 60) after rotator cuff repair. All but two patients were able to return to recreational golf at their previous level. (Level IV evidence)

Wilk KE, Arrigo C: Current concepts in the rehabilitation of the athletic shoulder. *J Orthop Sports Phys Ther* 18:365–378, 1993.

A classic article that is an excellent precursor to modern shoulder rehabilitation. (Level IV evidence)

Multiple-Choice Questions

QUESTION 1. What percentage of the golf swing is spent with the arm elevated past 90°?

A. 5%
B. 15%
C. 30%
D. 50%

QUESTION 2. The most active muscles during the electromyographic evaluation of the golf swing are:

A. Supraspinatus and infraspintus
B. Subscapularis and teres minor
C. Biceps and triceps
D. Pectoralis major and latissimus dorsi

QUESTION 3. All of the following are important goals of the first phase of a rotator cuff repair rehabilitation program except:

A. Edema control
B. Protect repair
C. Avoid shoulder stiffness in safe range
D. Active forward elevation

QUESTION 4. An acceptable rehabilitation timeline for restoring full active range of motion in a shoulder after rotator cuff repair is:

A. 2 to 4 weeks
B. 6 to 8 weeks
C. 10 to 12 weeks
D. 24 weeks

QUESTION 5. During EMG testing of the shoulder, the rotator cuff muscle that was most active was the:

A. Subscapularis
B. Supraspinatus
C. Infraspinatus
D. Teres minor

Answer Key

QUESTION 1. Correct answer: **D** (see Introduction)

QUESTION 2. Correct answer: **D** (see EMG Analysis of Golf Swing)

QUESTION 3. Correct answer: **D** (see Phase I of Rehabilitation)

QUESTION 4. Correct answer: **C** (see Rehabilitation Timeline)

QUESTION 5. Correct answer: **A** (see EMG Analysis of Golf Swing)

ACROMIOCLAVICULAR AND STERNOCLAVICULAR JOINT INJURIES

Chapter 7

Acromioclavicular Joint Injuries and Sternoclavicular Joint Injuries

INTRODUCTION

John Apostolakos, BS, Mark P. Cote, PT, DPT, MSCTR, Knut Beitzel, MA, MD, and Augustus D. Mazzocca, MS, MD

Epidemiology

- Acromioclavicular (AC) joint injuries are considered among the most common orthopedic injuries to the shoulder in the young athletic population.[1-12]
- Incidence often reported to be either 9% or 12% of all injuries to the shoulder; however, review of citations reveals the source of these percentages to be a book published in 1958.
- In Chapter 17, Rowe and Marble report on an analysis of 1603 shoulder girdle injuries treated at Massachusetts General Hospital of which 52 (3.2%) were injuries to the AC joint.[13]
- Type I, II, and III are the most common.[7]

Age

- Most common among patients in their 20s (43.5%)[2,4,7,11]
- A majority of injuries affecting this joint occur in the first three decades of life (66%)[7]

Sex

- AC dislocation has been reported to be more common in males than females (5:1 to 10:1).[2,4,7,10-12]

Sport

- AC dislocation is the most prevalent sports injury to participants in contact sports including hockey, rugby, and American football.[2,4,7,10,11,14]
- AC injury has been reported as 38.5% of shoulder injuries in athletes.[7,15]
- The incidence has been reported as 40% and 41% of all shoulder injuries in contact athletes such as National Football League (NFL) quarterbacks and collegiate football players respectively.[2,10,11,16,17]

Position

- Kaplan et al.[17] conducted a study of 336 elite collegiate American football players to determine position specific trends in shoulder injuries and reported the following AC joint injuries by position (%=number of AC joint injuries for position/$n \times 100$; n = total shoulder injuries by position):
  - Running Backs 47% ($n = 19$)
  - Quarterbacks 56% ($n = 25$)
  - Wide Receivers 70% ($n = 33$)
  - Tight Ends 43% ($n = 7$)
  - Offensive Lineman 18% ($n = 28$)
  - Defensive Lineman 32% ($n = 37$)
  - Defensive Backs 36% ($n = 44$)
  - Linebackers 38% ($n = 29$)
  - Place Kickers 0% ($n = 4$)

Pathophysiology

Intrinsic Factors

- Subcutaneous position of the joint, without a large amount of muscle protection, theoretically increases the incidence of AC joint injury[4,8]

Extrinsic Factors

- Trainer et al.[2] report an overall decline in the incidence of AC joint injuries in American football players but a steady rate among ice hockey players.
  - A possible explanation is that protective gear in American football is specifically designed for repeated force to the shoulder.
  - Ice hockey pads have a more loose fit designed for greater mobility.

Traumatic Factors

Direct Force

- Fall or blow to the superior aspect of the shoulder with arm in the adducted position driving the acromion downward and medially (most common mechanism) (Figure 7-1).[1,2,4-9,11,12,18]
- The magnitude of force determines severity of injury.[8,11]

Indirect Force

- Caused by falling on an adducted outstretched hand or elbow, causing the humerus to translocate superiorly, driving the humeral head into the acromion[4-7,11]

Classification of Injury/Pathological Findings

- Evaluation based on bilateral Zanca radiograph comparing the injured to uninjured shoulder

Type I Injury[4-12,18]

- AC ligament sprain
- No displacement on radiographs

Type II Injury[4-12,18]

- AC ligament tear, CC ligaments intact
- Lateral end of the clavicle superior in relation to acromion but not 100% displaced

Type III Injury[4-12,18]

- AC and CC ligaments torn
- 100% displacement of the clavicle on radiographs (Figure 7-2A)

Type IV Injury[4-12]

- Complete dislocation with posterior displacement of the distal clavicle into or through trapezius muscle
- Posteriorly displaced clavicle on axillary radiographs

Type V Injury[4-12]

- Exaggerated superior dislocation of the AC joint between 100% to 300% on radiographs (Figure 7-2B)
  - CC ligament distance increased two to three times
  - Disruption of the delto-trapezial fascia

Type VI Injury[4-12]

- Complete dislocation with inferior displacement of the distal clavicle into a subacromial or subcoracoid position

Clinical Presentation

History

- History of direct blow/fall to the AC joint[2,4,11]
- Complaints of pain over the joint[2,4]

FIGURE 7-1. The most common mechanism of injury is a fall or blow to the superior aspect of the shoulder with arm in the adducted position driving the acromion downward and medially.

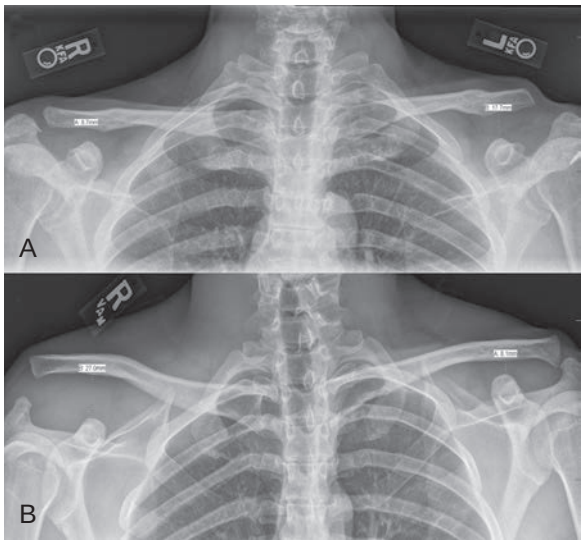

FIGURE 7-2. Bilateral Zanca view for distinguishing between grade III and grade V AC separation. **A,** Grade III AC separation with 100% displacement of the clavicle. **B,** Grade V with exaggerated superior dislocation of the AC joint between 100 and 300% on radiographs.

Physical Examination

- Point tenderness[4,8,11]
- Deformity at the AC joint and is palpable and different from contralateral (uninjured) side
- Pain at AC joint with forward elevation greater than 140° (Figure 7-3A)
- Pain at joint with cross-arm adduction[2,4,8,11]
  - May also be indicative of AC joint arthrosis
  - Cross-arm adduction test performed with arm elevated to 90° and then adducted across the chest with the elbow bent at 90° (Figure 7-3B)
  - Pain will be specifically at the AC joint
- Relief of symptoms by injection of a local anesthetic agent[4,5,8]
  - May also be indicative of AC joint arthrosis
  - Injection with or without corticosteroid can be used both diagnostically and therapeutically[5]
    - Relief of pain implicated AC joint as source of pain
    - Examination should be performed pre- and post-injection to determine change in symptoms
- Whenever possible, patient should be examined standing or sitting so the weight or the arm pulling downward stresses the AC joint and will make deformity more apparent[7,9,12]

Basic Mechanisms, Radiographic Examinations, and Clinical Examinations

- Type I (Figure 7-4)
  - Direct force to the shoulder causing sprain of AC ligaments[4,5,7,12]
  - CC and AC ligaments intact[4,5,7,12]
  - Swelling and joint tenderness[5,7,12]
  - Normal radiographic examination[4,7]
- Type II (Figure 7-4)
  - Force to shoulder causing rupture of AC ligaments[4,5,7]
  - CC ligaments intact[4,5,7]
  - Clavicular instability to direct stress examination[4,7]
  - On radiographic examination the lateral end of the clavicle may be elevated[4,5,7]
    - Stress views fail to show 100% separation of clavicle from acromion
- Type III (Figure 7-4)
  - Complete disruption of both AC and CC ligaments[4,5,7,12,18]
  - No significant disruption of the deltoid and trapezial fascia[4,5,7,12,18]
  - Upper extremity held in an adducted position[4,5,7,12,18]
    - Acromion depressed
    - Clavicle appears "high riding"
  - Clavicular instability in both the horizontal and vertical planes[4,7]
  - Abnormal stress views on radiographic examination[4,7]
    - Clavicle appears high on the upper extremity however in reality the acromion and remained of upper extremity is displaced inferior to the horizontal plane of the lateral clavicle
  - Severe pain with motions 1 to 3 weeks after injury[4]
  - Negative shrug test
- Type IV (Figure 7-4)
  - Distal clavicle displaced posteriorly into the trapezius muscle[4,7,12]
    - Easily seen on an axillary radiograph
  - Important to evaluate the sternoclavicular (SC) joint in this type of injury as there can be anterior dislocation of the SC joint and posterior dislocation of the AC joint[4,7]

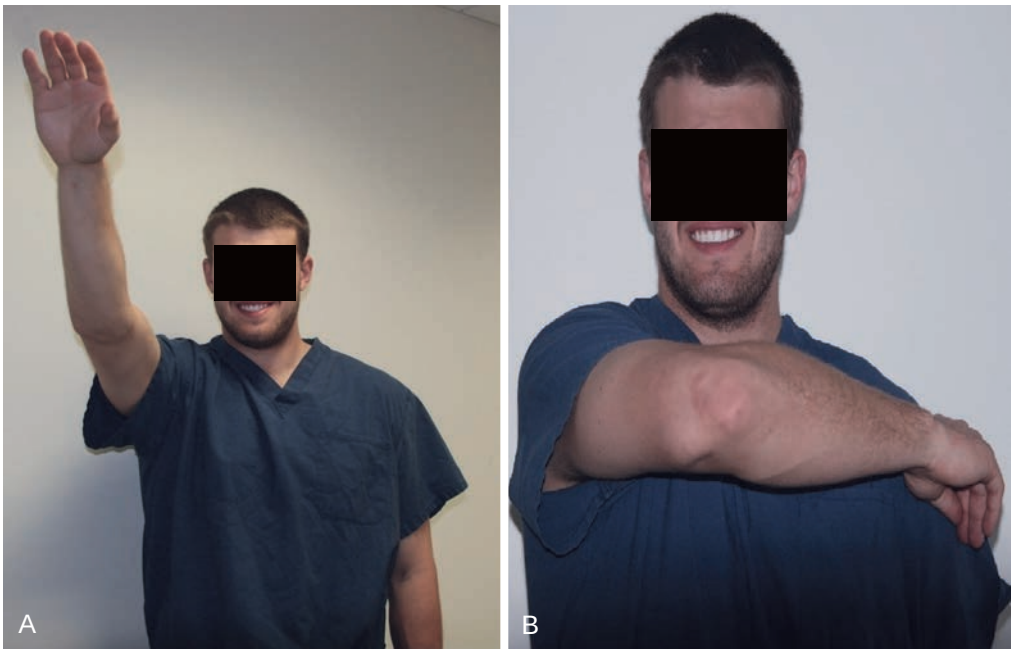

FIGURE 7-3. Physical exam. **A,** Pain at AC joint with forward elevation greater than 140° is indicative AC joint injury. **B,** Pain at joint with cross-arm adduction with arm elevated to 90° and then adducted across the chest with the elbow bent at 90° may also be indicative of AC joint arthrosis.

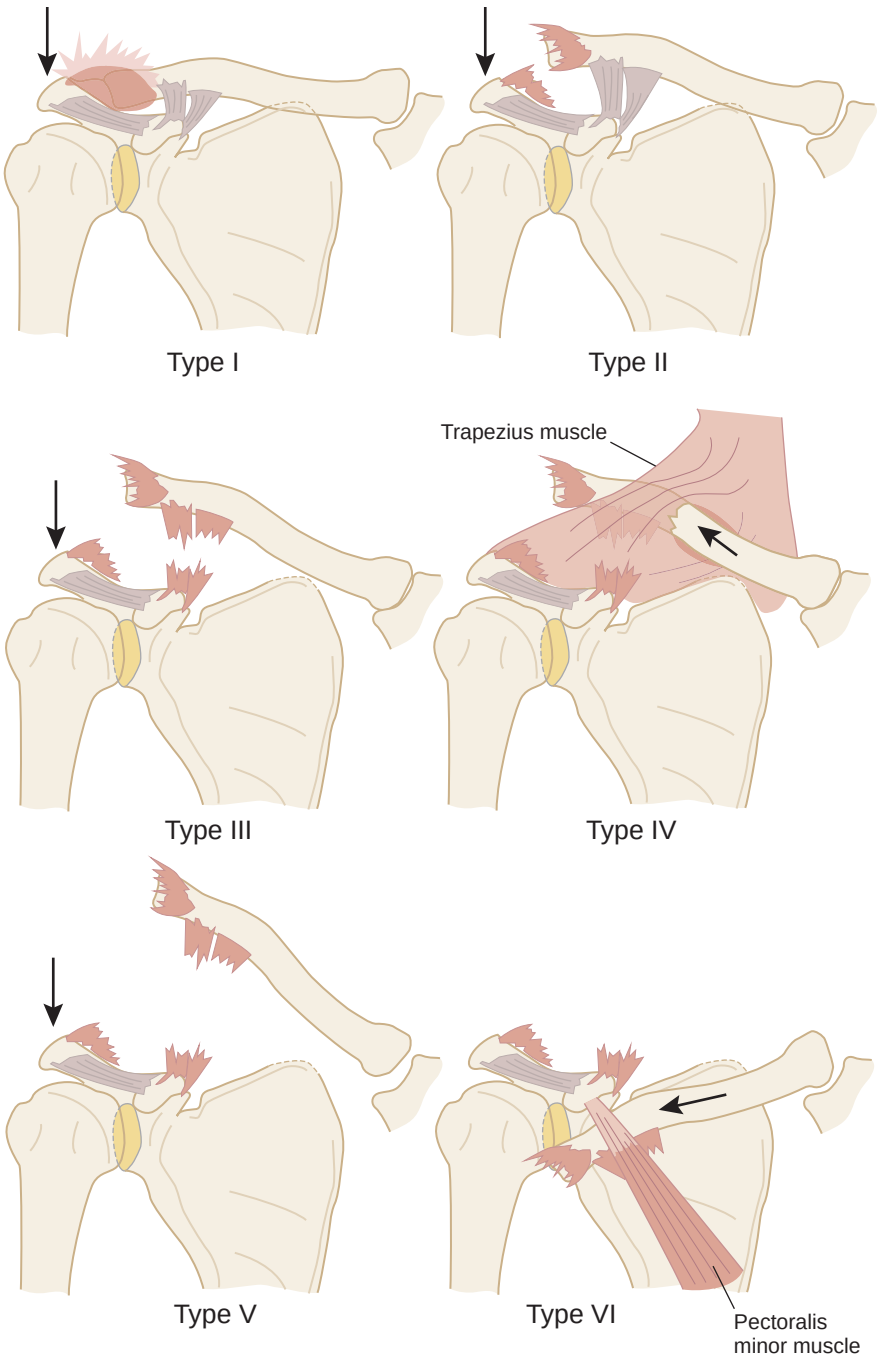

FIGURE 7-4. Diagnosis of AC joint injuries includes classification according to extent of ligament damage. Type I sprains involve a partial disruption of the AC ligament and capsule; type II sprains entail a ruptured AC ligament and capsule with incomplete injury to the CC ligament; type III separations exhibit complete tearing of the AC and CC ligaments; type IV injuries involve clavicular displacement posteriorly into or through the trapezius muscles; type V injuries are severe type III injuries with a greater CC interval; and type VI injuries entail displacement of the clavicle inferior to the coracoid process. *(From Bach BR, Van Fleet TA, Novak PJ: Acromioclavicular injuries: controversies in treatment. Physician Sports Med. 1992;20(12):87–95.)*

- Type V (Figure 7-4)
  - More severe form of type III injury with trapezial and deltoid fascia stripped off the acromion and clavicle[4,5,7]
  - On radiographic examination 100% to 300% increase in clavicle to acromion distance[4,7]
  - Severe droop secondary to downward displacement of the scapula and humerus[4,5,7]
  - Weight of the arm combined with the shape of the chest wall cause an anterior-inferior translation of the scapula around the thorax[4]
    - Referred to as the third translation of the scapula
  - Positive shrug test
- Type VI (Figure 7-4)
  - Inferior dislocation of the distal clavicle under the coracoid process[4,7]
  - Rare injury caused by severe trauma and is frequently accompanied by other injuries[4,7]
  - Mechanism of injury is believed to be severe hyperabduction and external rotation of the arm combined with retraction of the scapula[4]
  - Distal clavicle is found in either of two orientations[4,7]
    - Subacromial
    - Subcoracoid
- Clavicle becomes lodged behind the intact conjoined tendon

- The posterior superior AC ligaments which are often attached to the acromion get displaced into the AC interval

Imaging

- Radiographs of AC joint taken by a routine shoulder exam will be overpenetrated[4,5,7-9,11]
  - Radiographs of "acromioclavicular joint" must be specifically requested to avoid overlooking subtle lesions
- Bilateral Zanca view where both AC joints are visualized on a single exposure is helpful in determining asymmetry between injured and contralateral normal AC joints[2,5]
  - Zanca view is the preferred view of the AC joint[2,4-9,11,12]
  - View is obtained by tilting the x-ray beam 10° to 15° toward the cephalic direction and using only 50% of the standard shoulder anteroposterior (AP) penetration strength
- Varying configuration of AC joint on AP radiographs[2,4,5,9,11,19,20]
  - Zanca[19] reported a normal AC joint width of 1–3 mm
  - Petterson[20] reported diminishing joint space with age and considered the normal width of a 60-year-old AC joint to be 0.5 mm
- Axillary view useful for differentiating type III versus type IV injury[2,4,5,8,9,11]
  - Visualization of the scapula anterior to the clavicle indicates a type IV lesion
- Stryker notch view useful for determining a coracoid fracture in a complete AC dislocation with normal coracoclavicular interspace[6]
  - Coracoid process fracture should be suspected when radiographs reveal AC dislocations with a normal CC distance
- Stress views can be used to distinguish between type II and III injuries by testing the integrity of the CC ligaments[7-9,11,12]
  - Difference in type II and III injury is rarely significant and stress views typically aren't necessary for diagnosis[5,8]

Differential Diagnosis

O'Brien test[2,4,5,21]

- Useful for differentiating AC joint injury versus intra-articular lesions
  - Especially useful with lesions of the superior glenoid labrum
- Arm is elevated to 90°, elbow in extension, adduction of 10° to 15°, and maximum pronation of the forearm with obligate internal rotation of the arm, examiner applies downward force resisted by the patient
  - Referred pain directed to the top of the shoulder and confirmed by palpation of the joint indicate AC damage
  - Referred pain to the glenohumeral joint suggest superior labral or long head of the biceps injury

Radiographs for Differential Diagnosis

- Axillary view useful for differentiating type III versus type IV injury[2,4,5,8,9,11]
  - Visualization of the scapula anterior to the clavicle indicates a type IV lesion
- Stryker notch view useful for determining a coracoid fracture in a complete AC dislocation with normal coracoclavicular interspace[6]
  - Coracoid process fracture should be suspected when radiographs reveal AC dislocations with a normal CC distance
- Stress views can be used to distinguish between type II and III injuries by testing the integrity of the CC ligaments[7-9,11,12]
  - Difference in type II and III injury is rarely significant and stress views typically aren't necessary for diagnosis[5,8]

Shrug Test

- Used to distinguish type III from type V injuries (Figure 7-5)[5,11]
  - In a type V injury the degree of displacement is exaggerated

Manipulation of Joint

- Helpful in distinguishing type III and V injuries[5]
  - Reduction of deformity suggests an intact deltotrapezial fascia (type III)
  - Failure to reduce indicates violation of fascia with the distal clavicle buttonholed through it (type V)

FIGURE 7-5. The shrug test is performed by having the patient shrug their shoulders and observing for reduction of the clavicle. As a result of the trapezial and deltoid fascia being stripped off the acromion and clavicle, shrugging of the shoulders will not reduce the clavicle indicating a grade V injury.

Treatment

- Type I and II (incomplete injuries) are typically treated nonoperatively[1-5,7-9,11,12]
- Type IV, V, and VI (complete injuries) are typically treated operatively due to significance of morbidity[1-5,8,11,12]
- Type III injuries remain the most controversial
  - Current trends lean more towards initial nonoperative treatment[1-5,8,9,11,12,22]

Nonoperative Management

Acute Injury

- Periods of immobilization and rehabilitation[3,5,9,10,12]
  - Sling for 1 to 4 weeks with rehabilitation

Chronic Injury

- Activity modifications of rest[5]
- Antiinflammatories[5]
- Intraarticular corticosteroid injections[5]
  - Corticosteroid injections are not used by the senior author for acute injuries but are used for treatment of chronic injuries defined as pain at 3 months postinjury

Guidelines for Choosing Among Nonoperative Treatments

- Despite the numerous forms of nonoperative treatment including braces/harnesses, taping, casts, etc., no evidence proves any of these methods to be better than the use of a sling with concurrent rehabilitation

Surgical Indications

- Over 150 surgical procedures and technique variations have been described on the AC joint that can be broken down into four major categories[7]
  - Primary acromioclavicular joint fixation
  - Primary coracoclavicular ligament fixation
  - Excision of distal end of clavicle
  - Dynamic muscle transfers
- The senior author prefers an anatomical surgical treatment: Anatomical Coracoclavicular Ligament Reconstruction (ACCR)[1,4,5]
  - Tendon graft used placed in an anatomic position to reproduce conoid and trapezoid ligaments
  - Excision of 10 mm of distal clavicle

Controversial Treatments

Operative versus Nonoperative Treatment of Type III Injury

- Demands on the shoulder need to be taken into account when determining treatment[4]
  - Hand dominance
  - Occupation
  - Heavy labor
  - Position/sport requirements
  - Scapulothoracic dysfunction
  - Risk of reinjury
- General consensus for nonoperative treatment[2-4,8,11,12]
- Phillips et al.[23] conducted a literary review of 1172 type III injuries treated and identified 88% and 87% success rates for operatively and nonoperatively treated patients respectively[5]

Athletes With Type III Injury

- General consensus for nonoperative treatment of contact athletes (where risk for reinjury is high) (Figure 7-6) [4,7,11]
- Surgical treatment reserved for patients with persistent symptoms after 3 to 6 months[4,11]
- Time of injury in relation to season
  - Athletes sustaining a grade III AC injury in early preseason or offseason may lean toward reconstruction, as the window of time for recovery is large, whereas athletes with AC injury mid or late season may opt for nonoperative treatments to allow participation in sport to continue.

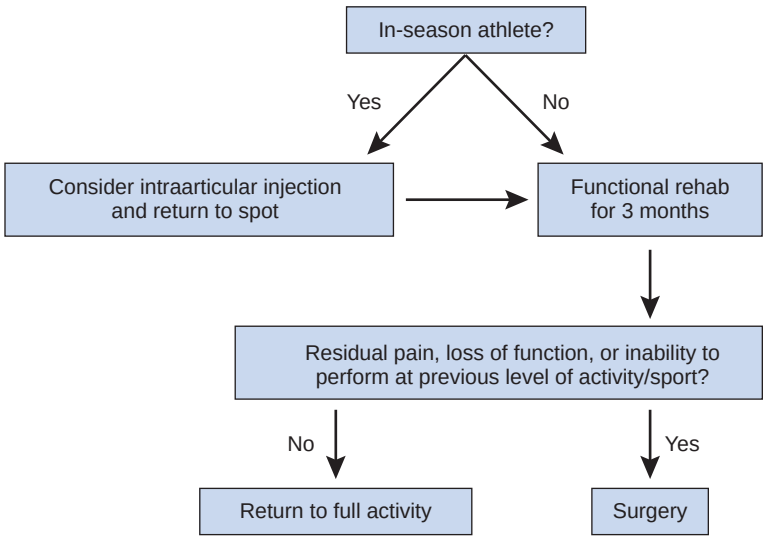

FIGURE 7-6. Algorithm that can be used when treating an athlete with an acromioclavicular joint injury.

- Position of the athlete
  - The tasks and demands of the upper extremity vary from position to position, sport to sport and as such may be affected differently by the loss of joint stability occurring with a grade III AC separation.
  - Positions that involve specific positioning of the hand throughout space (baseball pitcher, football quarterback, etc.) may be greatly affected by a loss of stability at the AC joint in comparison to other positions such as those in kicking sports or positions in which the uninjured extremity can assist in overcoming a loss of joint stability (football lineman, etc.).
- Level of play
  - In determining an athlete's appropriateness for surgical reconstruction, level of participation (recreational vs. collegiate vs. professional) should be considered.
  - Balancing the risks and time associated with surgical reconstruction with the importance of maximizing stability to allow full sport participation may be different for the recreational athlete who can change sports or positions to accommodate their shoulder versus the professional athlete whose livelihood and career is largely dependent on their ability to use their shoulder.

Evidence

Kaplan LD, Flanigan DC, Norwig J, et al: Prevalence and variance of shoulder injuries in elite collegiate football players. *Am J Sports Med* 33:1142–1146, 2005.

A study reporting on musculoskeletal injuries in elite American football players evaluated at the National Football League Combine during physical testing. Players were categorized by position to identify correlations between athletic position and occurrence of various shoulder injuries. (Level III evidence)

Kelly BT, Barnes RP, Powell JW, et al: Shoulder injuries to quarterbacks in the national football league. *Am J Sports Med* 32:328–331, 2004.

A retrospective review of all injuries to quarterbacks reported to the National Football League (NFL) between 1980 and 2001 utilizing the National Football League Injury Surveillance System (NFLISS). This review evaluated injuries based on several factors including playing time lost, injury patterns, and occurrence rates of specific injuries. (Level III evidence)

Tamaoki MJ, Belloti JC, Lenza M, et al: Surgical versus conservative interventions for treating acromioclavicular dislocation of the shoulder in adults. *Cochrane Database Syst Rev* 4: CD007429, 2010.

A systematic review aimed at assessing the relative effects of operative versus nonoperative treatment of acromioclavicular joint dislocations in adults. Included studies were randomized and quasi-randomized trials obtained in a search of the Cochrane Bone, Joint and Muscle Trauma Group Specialized Register (to February 2009), the Cochrane Central Register of Controlled Trials (The Cochrane Library 2009, Issue 1), MEDLINE (1966 to February 2009), EMBASE (1988 to February 2009), and LILACS (1982 to February 2009), trial registries and reference lists of articles. (Level II evidence)

Multiple-Choice Questions

QUESTION 1. Which of the following patients is most likely to endure an injury to the AC joint?

A. a 85-year-old inactive male
B. a 25-year-old active female
C. a 21-year-old inactive male
D. a 22-year-old active male

QUESTION 2. What is the most common mechanism of injury to the AC joint?

A. Direct force to the superior aspect of shoulder
B. Indirect force to the superior aspect of shoulder
C. Direct force caused by falling on an adducted outstretched hand
D. Indirect force caused falling on an adducted outstretched hand

QUESTION 3. Which of the following is true regarding treatment of a type III injury?

A. Surgical intervention is always needed.
B. Surgical intervention is never needed.
C. Demands on the affected shoulder should NOT be taken into account when determining treatment.
D. Treatment of type III should be individualized based on demands of the shoulder.

Answer Key

QUESTION 1. Correct answer: **D** (see Epidemiology)

QUESTION 2. Correct answer: **A** (see Pathophysiology)

QUESTION 3. Correct answer: **D** (see Treatment)

NONOPERATIVE REHABILITATION OF ACROMIOCLAVICULAR JOINT SPRAIN/SEPARATION

Karen E. Wojcik, MSPT, OCS, ATC, Mark P. Cote, PT, DPT, MSCTR, Nancy Craven, PT, DPT, OCS, Gregg Gomlinski, MSPT, OCS, CSCS, Brian T. Swanson, PT, OCS, FAAOMPT, Catherine Gauthier Trahiotis, PT, John Apostolakos, BS, and Augustus D. Mazzocca MS, MD

GUIDING PRINCIPLES OF NONOPERATIVE REHABILITATION

- Restoring stability to the AC joint through strength training of the supporting muscles of the shoulder girdle is the primary focus of rehabilitation.
- Early intervention is directed toward reducing pain and inflammation to allow strength-based exercise to begin as soon as possible.

Phase I (48 hours to weeks 2)

Goals

- Various treatments, both operative and nonoperative, have been described for patients with injury or dysfunction of the AC joint.[1-35]
  - Grades I and II separations appear to respond favorably to conservative management.
  - Considerable controversy exists over the efficacy of surgical reconstruction versus nonoperative intervention for grade III type injuries.
  - Grades IV, V, and VI often require surgical reconstruction.
- Rehabilitation both as a part of conservative management as well as the postoperative care plays an important role in the management of each of these injuries.[9]
- When discussing the approach to rehabilitation, we feel it is best to outline guidelines based on anatomy, pathoanatomy, and biological healing for the progression of activities.
  - These guidelines were designed to allow the rehab clinician to safely and appropriately progress patients through the healing and recovery process.
  - With an understanding and appreciation for the rationale for these guidelines, the rehab clinicians can utilize their entire skillset in a safe and efficient manner, thereby maximizing the quality of care provided to patients.

Protection

- Immobilization via a sling is used on as needed basis.
- The amount of time immobilized will vary depending on the grade of injury.
- Grade I separations typically require little to no sling use.
- Grade II separations involve disruption of ligamentous tissue that may result in prolonged periods of pain associated with early phases of tissue healing. During this time, a sling may be required to avoid stress on the AC joint. The sling is discontinued following cessation of pain with the arm at the side and with self-care activities. Generally speaking, this time period does not exceed 1 week.
- Grades III and V involve complete ligament rupture with little to no potential for healing. While sling use up to 4 weeks for these higher-grade AC separations has been previously reported therefore, we believe

patients should be encouraged to cease sling use as soon as their symptoms allow.
- In all cases, immobilization is discontinued following the cessation of pain at rest with the arm at the side and with self-care activities.

Management of Pain and Swelling

- Ice
- Sling

Techniques for Progressive Increase in Range of Motion

- Low load range active-assistive motion exercise is initiated within the first week of injury in an effort to decrease associated morbidity.
- Avoidance of motions that may increase stress on the AC joint is recommended.
- Behind the back internal rotation, cross body adduction, and end range forward elevation involve motion at the AC joint and therefore are approached cautiously as they have the potential to provoke pain and slow progression; however, they are not expressly limited as stability is less of a concern than in higher grade separations.

Manual Therapy Techniques

- Manual therapy techniques such as gentle grade I and II joint mobilization may be helpful modulating pain.
- Given the wide range of manual techniques and modalities, selection of these potential therapeutic interventions are at the discretion of the treating rehab clinician.

Activation of Primary Muscles Involved

- Muscle activation of scapular stabilizers with closed chain scapular exercises and kinetic chain activities to allow the patient to focus on scapular control and established movement patterns without creating excessive loads about the shoulder.[36-38]

Open and Closed Kinetic Chain Exercises

- Table slides progressing to graduated wall slides are also utilized to encourage restoration of shoulder elevation initially prescribed at a high frequency, low intensity, and short duration (Figure 7-7).
- Graduated table slide would be performed 20 to 30 times, three to four times a day (high frequency), within a comfortable or minimal discomfort range of motion (low intensity), repeatedly with no "holding" of end range for stretch (short duration).
- Supine flexion and pulley exercises are added to assist in increasing forward elevation.
- Progress reclined flexion to upright forward elevation (Figure 7-8).
- Scapular clocks for muscle activation (Figure 7-9).

Milestones for Progression to the Next Phase

- Full passive motion without pain
- Out of sling

Phase II (weeks 2 to 6)

Techniques for Progressive Increase in Range of Motion

- Active-assistive range of motion is progressed within a comfortable range of motion. In our experience, accelerating care by moving through painful and stressful ranges of motions tends to encourage continued pain and inflammation, making it difficult to progress. By allowing exercises to be progressed within the guidelines of avoiding motions or exercise producing AC joint pain, the patient can maximize their own potential for progress.

Other Therapeutic Exercises

- Conditioning (bike or elliptical)
- Nonweight bearing upper extremity core stability (bridge, crunch, etc.)

Activation of Primary Muscles Involved

- Isotonic strengthening exercises directed at restoring and maintaining adequate scapular retraction

TIMELINE 7-1: **Nonoperative Rehabilitation after AC Joint Separation**

PHASE I (first 48 hours to weeks 2)	PHASE II (weeks 2 to 6)

• Sling
  • Grade I—as needed for pain
  • Grade II—up to 2 weeks
  • Grade III—discontinue sling at 2 weeks (earlier if symptoms allow)
  • D/C sling if the patient is no longer having pain with the UE at the side during ADLs
• PT Modalities and Manual Techniques
  • As indicated to reduce pain
• Exercise
  • Closed chain AAROM (table slides, etc.)
  • Supine ER with a cane
  • Isometrics (submaximal, nonpainful)
  • Scapular clocks
	• Exercise
	  • AAROM progressing to AROM
	  • Progressive forward elevation to the wall
	  • Pulleys FE
	  • Reclined active flexion progressing to upright
	  • Gentle horizontal adduction
	  • Gentle shoulder extension
	  • Scapula strengthening exercises (emphasizing retraction to stabilize the AC joint)
	  • When there is good stability of scapula—strengthening exercises focus on the deltoid, trapezius, and rotator cuff
	  • Manual
	  • Pushup plus (protraction/retraction against the wall)
	  • Continue kinetic chain exercise
	  • Restrictions—shoulder press, bench press, pullovers, and pectoralis flys

FIGURE 7-7. Closed chain progression of active-assistive range of motion.

TIMELINE 7-1: **Nonoperative Rehabilitation after AC Joint Separation** (Continued)

PHASE III (weeks 6 to 12)	PHASE IV (weeks 12+)

• Exercise
  • 3 level rowing with tubing
  • RC muscle strengthening exercise (ER/IR) with tubing
  • Prone scapula exercises—Blackburn exercises or Ts and Ys (start with no weight and high repetitions to fatigue)
  • PNF patters with tubing
  • Pushup on wall progressing towards ground
  • Continued Kinetic chain exercise
	• Exercise
	  • Plyometric exercise (chest pass with medicine ball, etc.)
	  • Continued Kinetic chain exercise
	  • Start chest press
	  • Sport-specific training

FIGURE 7-8. Open chain progression of active-assistive range of motion.

FIGURE 7-9. Scapular clocks to facilitate muscle activity of the scapular muscles.

Open and Closed Kinetic Chain Exercises

- Pushup plus (protraction/retraction against the wall) at shoulder level or below to assist in activating the serratus anterior with less upper trapezius activity when compared to overhead activity[39]
- Multilevel rows (Thera-tubing or cable column)
- External rotation (ER) and internal rotation (IR) for RC musculature (Thera-tubing or cable column)

Neuromuscular Dynamic Stability Exercises

- Rhythmic stabilization in supine (Figure 7-10)

Functional Exercises

- Lower extremity exercise including shoulder dumps[38] (Figure 7-11), single leg trunk flexion bends, single leg balance, hip hike, squats

Sport-Specific Exercises

- Pain-free nonathletic ADLs
- Full active ROM (equal to the uninjured side with visual estimation) without pain

Phase III (weeks 6 to 12)

Techniques for Progressive Increase in Range of Motion

Manual Therapy Techniques

- Continued conditioning described in phase II
- Initiate upper extremity weight-bearing core stability exercise, e.g., plank, side plank (grades I and II may tolerate before or at 6 weeks)

Activation of Primary Muscles Involved

- Isotonic exercises are progressed at this phase with continued emphasis on maintaining scapula retraction.

FIGURE 7-10. Rhythmic stabilization. The rehab clinician applies manual resistance in alternating directions to challenge the patient's ability to stabilize the shoulder.

Scapular dyskinesis has been shown to be present in among patients with grade III AC separation reinforcing the importance of exercise encouraging scapular retraction.[40] Exercise to address scapular dyskinesis often focus on retraction to encourage normal positioning and movement patterns of the scapula. Conscious correction of scapular position has been shown increase activation levels of the trapezius in overhead athletes. When prescribing exercises for the shoulder, maintenance and correction of scapular position is encouraged to improve muscle activation and function.[41]

- With improved strength, exercise tubing or cable resistance exercises are utilized to progress the strengthening program.
- Strengthening targeted at the rotator cuff muscles (emphasis on ERs), biceps brachii, pectoralis major, and minor and scapular rotators.
- PNF utilizing rubber tubing is introduced at this time.

Techniques to Increase Muscle Strength, Power, and Endurance

- Multilevel rows
- Prone scapula exercises—Is, Ts and Ys (start with no weight and high repetitions to fatigue)[42]
- PNF patterns with tubing (D2 pattern—proprioceptive neuromuscular facilitation)
- IR/ER (tubing/cable)
- Scaption
- Upper Extremity PREs (for biceps, triceps, etc.)

Neuromuscular Dynamic Stability Exercises

- Rhythmic stabilization in supine
- Manual proprioceptive neuromuscular facilitation (PNF) patterns
- One-hand pushup on wall with light ball (Figure 7-12)

Plyometrics

- 90-90 supine ball toss (Figure 7-13A)
- Overhead supine ball toss (Figure 7-13B)
- Medicine ball chest pass

Functional Exercises

- Lower extremity exercises including shoulder dumps[38], trunk bends, single leg balance, hip hike, squats

FIGURE 7-11. Shoulder dump exercise as described by McMullen J and Uhl TL[48] to facilitate shoulder external rotation and scapular retraction. To perform the exercise for the right shoulder, the athlete stands with the left foot forward and left hip flexed and the trunk flexed and rotated to the left with the right arm positioned at the level of the knee (**A**). The athlete is then instructed to shift weight back to the right foot while extending and rotating the trunk and to move back to an upright position (**B**). As the athlete moves through this movement, the shoulder is externally rotated and the scapula retracts, as if dumping or pouring something out.

FIGURE 7-12. Pushup on the wall with light ball.

Sport-Specific Exercises

- Sports specific movements with advancement to use of lower limb or trunk from double lower extremity to single lower extremity

Milestones for Progression to Advanced Sport-Specific Training and Conditioning

- Overhead activities including ADLs without pain.
- Able to bear weight through involved upper extremity without pain. This can be evaluated by asking the athlete to hold the starting position of a pushup. If the athlete can stay in this position for a few seconds without pain or signs of difficulty (e.g., lowering to the floor, or shifting weight away from the injured side), progression to the next stage is warranted.

Phase IV (weeks 12+)

Techniques to Increase Muscle Strength, Power, and Endurance

- Return to gym (grades I and II typically can start gym activity at or before 8 weeks)
- Bench press at 50% or less than presurgical; one repetition maximum; form changes for bench press include narrower grip; avoid full lock out to minimize stress on healing tissues
- Overhead press at 50% or less than presurgical; 1 repetition maximum; form changes for bench press include narrower grip; avoid full lock out to minimize stress on healing tissues and behind the neck pressing

Manual Therapy Techniques

- Continued conditioning described in phase II

Neuromuscular Dynamic Stability Exercises

- Continue one hand ball pushup on wall. As exercise becomes less challenging, the athlete can move away from the wall to increase the amount of load through the arm to increase difficulty.

Plyometrics

- Plyometrics should start with two-hand chest pass followed by two-hand overhead pass. When two-handed activities are no longer challenging, progress to single-hand passes.

Progression is as follows: Two-handed medicine ball chest pass, standing two-handed overhead chest pass, single-hand 90/90 ball toss to upright with rebounder.

Functional Exercises

- Continue lower extremity exercises.

Sport-Specific Exercises

- Initiate throwing program. Our throwing program is adopted and modified from review of previous published programs[43-45] (Box 7-1).
- General strength and conditioning of the UE may begin during this phase if the patient demonstrates full pain-free AROM throughout all planes, full strength throughout the affected UE, and ability to bear weight on the injured side as demonstrated by successive pushups without shifting away from the injured side or complaints of pain. Measurements of strength can be made using a handheld dynamometer, which should reflect a 5% difference or less in strength in comparison to the uninvolved side. If a dynamometer is not available, 5/5 strength with manual muscle testing throughout the UE should be present.
- Exercises that the athlete will return to doing in the gym should be added on at this point at low intensity with close observation by clinician. Gym exercises tend to vary by the sport program in which the athlete is involved. The primary exercises that require vigilance for proper form are the bench press and overhead press. Guidelines listed previously should direct clinician observation. Additional exercises such as biceps

FIGURE 7-13. A, 90-90 supine ball toss. **B,** Overhead supine ball toss.

curls, triceps pushdowns and dips can be performed according to athlete's sport-specific gym program. All movements must also remain completely pain free.
- Sport-specific exercises include football lineman-contact drills, light sled push, swimming maneuvers, wrestler-partner drills in quadruped, grappling, basketball-lay up drills with defensive partner to stimulate contact, racket sports-progressive swing /volley drills starting with ground strokes and progressing to overhead service.

Milestones for Progression to Advanced Sport-Specific Training and Conditioning

- No pain at the AC joint
- Forward elevation without scapular dyskinesis as measured by the Scapular Dyskinesis Test.[46,47] The Scapular Dyskinesis Test, which classifies scapula dyskinesis as either present or absent, is used to determine the presence of dyskinesis. This system involves viewing of the scapula during humeral elevation to observe for "winging" (abnormal prominence of the medial and/or inferior boarder of the scapula) or dysrhythmia with grading of these of findings as normal, subtle (mild, questionable, or inconsistent), and obvious (striking, clear, and consistent)
- Full shoulder strength in all planes with handheld dynamometer or manual testing of the shoulder

Criteria for Abandoning Nonoperative Treatment and Proceeding to Surgery or More Intensive Intervention

- In our experience, patients who have little response after 6 weeks are offered surgical intervention.
- Patients who benefit and have a significant reduction of symptoms are encouraged to continue with rehabilitation for up to 12 weeks.
- After 12 weeks the athlete should be pain free with all shoulder motions, able to bear weight per previously listed criteria, and able to demonstrate upper extremity movements related to their sport in a controlled environment, i.e., in the clinic or gym. In our experience, patients who have little response after 6 weeks are offered surgical intervention.

BOX 7-1 Interval Throwing Program: Adult-Aged Players

- Each phase should be completed before progressing to the next level.
- Long throws represent target distance for eventual long throw workouts. We recommend 180 feet as that distance to begin with for adult rehab interval programs. Actual long throw distance is the maximum distance thrown when healthy to a specified 20-feet-wide target area.

Phase I

a) Warm up
b) 15 throws arched—45 feet
c) 15-minute rest
d) 15 throws arched—45 feet
e) Cool down

Phase II

a) Warm up
b) 20 throws arched—60 feet
c) 15-minute rest
d) 20 throws arched—60 feet
e) Cool down

Phase III

a) Warm up
b) 20 throws arched—90 feet
c) 15-minute rest
d) 20 throws on a line—45 feet
e) 15-minute rest
f) 20 throws arched—90 feet
g) Cool down

Phase IV

a) Warm up
b) 20 throws arched—120 feet
c) 15-minute rest
d) 15 throws on a line—60 feet
e) 15-minute rest
f) 20 throws arched—120 feet
g) Cool down

Phase V Long

a) Warm up
b) 20 throws arched—180 feet
c) 15-minute rest
d) 25 throws arched—180 feet
e) 15-minute rest
f) 20 throws arched—180 feet
g) Cool down

Phase VI

a) Warm up
b) 15 throws arched—120 feet
c) 15-minute rest
d) 15 throws on a line—90 feet
e) 15-minute rest
f) 15 throws on a line—90 feet
g) 15-minute rest
h) 15 throws arched—120 feet
i) Cool down

Phase VII

Return to regular work-out regimen

Courtesy of the New England Musculoskeletal Institute; UConn Health Center. Website http://nemsi.uchc.edu.

Specific Criteria for Return to Sports Participation: Tests and Measurements

- Full active range of motion without scapular dyskinesis as measured by the Scapular Dyskinesis Test
- Full shoulder with handheld dynamometer or manual testing of the shoulder strength with manual muscle testing
- Pain-free overhead activities
- Pain-free sport-specific motions and maneuvers
  - Ability to perform sport-specific activities without pain or difficulty. (This includes successful completion of the throwing program for throwers and contact without symptoms for the collision and contact athlete.)

Evidence

Bannister GC, Wallace WA, Stableforth PG, et al: The management of acute acromiclavicular dislocation. *J Bone Joint Surg Br* 71-B(5):848–850, 1989.

This prospective randomized control trial compared operative treatment (reduction and fixation with a Kirschner screw) to conservative management consisting of 2 weeks of rest followed by a rehabilitation program. Conservatively treated patients regained motion quicker, returned to work and sport earlier, and had less unsatisfactory results compared to operative treatment. (Level II evidence)

Galpin RD, Hawkins RJ, Grainger RW: A comparative analysis of operative versus nonoperative treatment of grade II acromioclavicular separations. *Clin Orthop Relat Res* 193:150–155, 1985.

Retrospective review of 37 patients who either opted for early motion and rehabilitation or treatment by Bosworth clavicu-locoracoid screw. Patients in the nonoperative group had equal if not superior results, with an earlier return to activities, sports, and work. (Level IV evidence)

Gstettner C, Tauber M, Hitzl W, et al: Rockwood type III acromioclavicular dislocation: surgical versus conservative treatment. *Clin Orthop Relat Res* 455:38–44, 2007. *J Shoulder Elbow Surg.* 17:220–225, 2008.

Retrospective review of 41 of 50 patients treated either operatively with a hook plate to stabilize the AC joint or conservatively consisting of immobilization in a sling followed by a course of rehabilitation. Mean constant score of 80.7 was observed for the conservative group compared to 90.4 in the operative group. (Level IV evidence)

Gumina S, Carbone S, Postacchini F: Scapular dyskinesis and SICK scapula syndrome in patients with chronic type III acromioclavicular dislocation. *Arthroscopy* 25(1):40–45, 2009.

Scapulothoracic motion and clinical outcome were studied in 34 patients with chronic AC dislocation. Chronic type III AC dislocation was associated with the presence of scapular dyskinesis in 70.6% of patients. The values for the Constant score and SST were lower in patients with dyskinesis. (Level IV evidence)

Spencer EE, Jr: Treatment of grade III acromioclavicular joint injuries: a systematic review. *Clin Orthop Relat Res* 455:38–44, 2007.

A systematic review of the literature to determinate efficacy of operative vs. nonoperative care for grade III AC joint separations. Review revealed limited low-evidence literature exists on the treatment of grade III injury. Nonoperative treatment was deemed more appropriate than traditional operative treatments on account of surgical intervention being associated with higher complication rates and time away from work and sport. (Level III evidence)

Multiple-Choice Questions

QUESTION 1. The primary goal of phase I after nonoperative AC joint injury is:

A. Immobilization
B. Increase strength
C. Reduce pain and inflammation
D. Reduce ROM

QUESTION 2. When initiating strength exercises in Phase II following nonoperative AC injury, it is best to start with what type of exercise?

A. Closed kinetic chain
B. Isokinetic
C. Isotonic
D. Open kinetic chain

QUESTION 3. When the AC ligaments rupture the scapula migrates in which direction?

A. Upward
B. Downward
C. Medial
D. Lateral

QUESTION 4. _____ targets strengthening for serratus anterior.

A. Horizontal Abduction
B. Rowing
C. Wall pushup with plus
D. Scapular Clock

Answer Key

QUESTION 1. Correct answer: **C** (see Phase I)

QUESTION 2. Correct answer: **A** (see Phase II)

QUESTION 3. Correct answer: **B** (see Phase II)

QUESTION 4. Correct answer: **C** (see Phase II)

POSTOPERATIVE REHABILITATION AFTER DISTAL CLAVICULAR RESECTION (MUMFORD)

Brian T. Swanson, PT, OCS, FAAOMPT, Karen E. Wojcik, MSPT, OCS, ATC, Kimberly Cubeta-Gileau, PT, MSAH, Thomas J.S. Durant, MPT, John Apostolakos, BS, Mark P. Cote, PT, DPT, MSCTR, and Augustus D. Mazzocca, MS, MD

Indications for Surgical Treatment

- Pain at the acromioclavicular (AC) joint exacerbated with cross body adduction.
- Failure of conservative management (≥3 months of physical therapy, nonsteroidal antiinflammatory drugs, steroid injection into the AC joint)
- Radiographic findings consistent with AC joint disease

Brief Summary of Surgical Treatment

Major Surgical Steps

- Open Approach[1,2]
  - A transverse or "saber" type incision is made over the AC joint with careful dissection of the superior AC ligament, deltoid and trapezial fascia from their flap to expose the distal clavicle.
  - An oscillating saw resects 5 to 10 mm of the distal clavicle from superolateral to inferomedial.[3]
  - The superior joint capsule and deltoid insertion are repaired to preserve clavicular stability and preserve continuity of the deltotrapezial attachment.
- Arthroscopic Approach—Direct[4]
  - Anterosuperior and posterosuperior portals are created with two small stab incisions in line with the AC joint.
  - A 2.7-mm arthroscope and motorized bur is used to excise 2 to 3 mm off the acromial spur and 5 to 7 mm off the distal clavicle for a total of 8 to 10 mm of excision (confirmed with c-arm and spinal needles).
  - Once the joint is sufficiently widened, a standard 4-mm arthroscope is introduced to complete the resection.
- Arthroscopic Approach—Indirect[5,6]
  - Standard arthroscopic anterior, posterior, and lateral portals are created to allow bursectomy and permit visualization of the AC joint.
  - A round or oval bur is used to resect the inferior distal clavicle cortex

Factors That May Affect Rehabilitation

- Rarely does the AC pathology that leads to a Mumford procedure occur in isolation, and has been shown to occur as occult pathology in up to 50% of apparent AC joint cases.[7]

- The concurrent pathology (impingement, labral tear, etc.) will frequently lead to concurrent surgical procedures. This is an important consideration as the nature of concurrent procedures will often dictate the pace of rehabilitation, or will lead to the consideration of other tissues that will need to heal. Recognition of the other involved tissues will allow for a more comprehensive rehabilitation program.

Before Surgery: Overview of Goals, Milestones, and Guidelines[1]

GUIDING PRINCIPLES OF POSTOPERATIVE REHABILITATION

- Biologic tissue healing time frames guide progression of rehabilitation.
- Concomitant operative procedures often involve tissue repair and therefore guide progression of therapeutic activities.
- Absent of any concomitant procedures, pain is the limiting factor for progression of therapeutic activity. Therapeutic intervention early in the postoperative period should be directed at reducing pain to optimize the potential recovery.
- Educate patient to the principles guiding to rehabilitation.

Phase I: Immediate Postoperative Period (days 0 to 14)

Clinical Pearl

- Following distal clavicular resection (DCE), immediate motion can be very painful and difficult to perform. Glenohumeral joint mobilization can be useful in this stage for both pain control and ROM.
- The use of a wedge under the scapula can be useful to isolate motion and avoid stresses through the AC joint soft tissues while inflammation subsides.
- With the scapula stabilized, restrictions on the glenohumeral joint, should they exist, can be addressed (Figure 7-14).

Goals

- D/C sling (if concomitant procedures do not conflict)
- Reduce pain
- Ensure adequate patient education to allow patient to progress motion accordingly

[1]*Prehabilitation, if appropriate, is described in the Nonoperative Rehabilitation section of this chapter.*

FIGURE 7-14. Positioning for glenohumeral mobilization with wedge to stabilize scapula. In this set up, the rehab clinician would perform general joint mobilizations for pain relief and ROM while avoiding excessive stress to the AC joint and surrounding soft tissue.

Management of Pain and Swelling

- Use of sling and ice for the first 24 to 48 hours (additional immobilization to be directed by concomitant procedures)

Techniques for Progressive Increase in Range of Motion

- If concomitant procedures do not conflict, range of motion (ROM) can be progressed according to the patient's pain response.
- Motion should start with forward elevation in the plane of scapula and external rotation at 30° of abduction with the arm supported.
- Upper extremity motion of the elbow, forearm, wrist, and hand is also encouraged.
- Begin passive and active-assisted ROM through formal rehabilitation and home exercise program 2 days postoperatively.

Open and Closed Kinetic Chain Exercises

- CKC: ROM exercises with limb-supported activities like the table or wall slide. These closed chain exercises have been shown to elicit low amounts of shoulder muscle activity.[8]
- OKC: Supine forward elevation and cane ER.

Neuromuscular Dynamic Stability Exercises

- The use of side lying manually resisted proprioceptive neuromuscular facilitation (PNF) patterns to the scapula can be useful to initiate strength and control activities without stressing inflamed tissues by allowing for immediate modification of the amount and direction of force applied to the shoulder. This early initiation of resisted exercises may help offset post-operative atrophy and inhibition in the athlete (Figure 7-15).

FIGURE 7-15. Positioning for PNF patterns in side lying. The use of manually resisted PNF patterns to the scapula can be useful to initiate strength and control activities without stressing inflamed tissues. This positioning allows for immediate modification of the amount and direction of force applied to the shoulder.

Phase II (weeks 2 to 6)

Clinical Pearls

- In isolated cases of distal clavicle excision (no concomitant procedures), progression of rehabilitative activities is based upon the patient's tolerance to these activities.
- If pain is persistent, ROM exercises can be adjusted to focus on high frequency (motion exercises three to four times a day), at low intensity (within a pain-free or to-pain ROM) for short durations (20 to 30 repetitions or 2 to 3 minutes worth). This approach allows existing motion to be maintained and carefully increased while facilitating a reduction in pain and inflammation. It is in these cases that initiating strength training too quickly will lead to continued pain and stiffness.
- As the patient's tolerance to rehabilitation (ability to improve mobility without increases in pain) increases, motion exercises can be adjusted to produce more permanent gains, and strengthening can then be initiated.

Goals

- Full active range of motion equal to uninvolved shoulder
- Initiate scapular strengthening
- Return to non-athletic ADLs

Protection

- Continued immobilization via a sling only if indicated by nature of concomitant procedures, e.g., rotator cuff repair, labral repair, etc.

Management of Pain and Swelling

- Continued immobilization via a sling only if indicated by nature of concomitant procedures, e.g., rotator cuff repair, labral repair, etc.

Techniques for Progressive Increase in ROM

- Progressive ROM exercise emphasizing closed chain (limb supported) and moving to open chain exercises as patient's tolerance and response to treatment allows.
- In the absence of concomitant procedures, ROM is progressed at the patient's tolerance to rehabilitation (ability to improve mobility without increases in pain).
- Cross-body adduction should be avoided, as it can be provocative at this stage.

Other Therapeutic Exercises

- Conditioning (bike or elliptical)
- Nonweight bearing upper extremity core stability (bridge, crunch, etc.)
- Exercises with uninvolved arm (i.e. "cross-talk"/ contralateral overflow)

Open and Closed Kinetic Chain Exercises

- Closed chain exercises performed on a flat surface can be gradually progressed to inclined surfaces and finally a vertical surface (Figure 7-7).
- Supine flexion and pulley exercises can be added to assist in increasing forward elevation.
- Reclined flexion progressed to upright forward elevation (Figure 7-8).
- Scapular clocks for muscle activation[9] (Figure 7-9).

Neuromuscular Dynamic Stability Exercises

- Continued use of side lying manually resisted PNF patterns to the scapula

TIMELINE 7-2: **Postoperative Rehabilitation after Distal Clavicular Resection (DCE) (Mumford)**

PHASE I (weeks 1 to 2)	PHASE II (weeks 3 to 6)
• Sling (48 h unless concomitant procedures conflict) • Ice • ROM-scapular plan elevation, supine cane ER • Active-assistive table slides for forward elevation • Glenohumeral mobilization with wedge • Scapular PNF exercises in side lying	• ROM—active-assistive ROM in all planes permitted • Avoid excessive horizontal adduction • Progressive active-assistive motion from closed chain to open chain • Closed chain scapular exercises • Glenohumeral rhythmic stabilization in supine • Lower extremity exercise and conditioning

- Initiate GH rhythmic stabilization in supine (Figure 7-10)

Functional Exercises

- Lower extremity exercises including shoulder dumps[11] (Figure 7-11) trunk bends, single leg balance, hip hike, squats.

Milestones for Progression to the Next Phase

- Absence of pain at rest
- Full active ROM that is pain free. Residual soreness at the beginning or following activity that subsides on its own is expected and is not considered "pain" in terms of establishing appropriateness to progress to Phase III. It is important to distinguish between lactic acid pain, which resolves following the completion of an exercise or activity, and other sources of pain. Pain that is persistent between therapeutic treatments may be a sign of continued inflammation or delayed onset muscle soreness, which can last for several days. In these cases, progression to the next stage should be delayed until persistent pain is eliminated.
- Minimal to no scapular substitution with active forward elevation, measured posteriorly, ensuring that the medial border of the scapula is symmetrical and remains protracted to the rib cage during shoulder flexion, and retracts/upwardly rotates appropriately during abduction.

Phase III (weeks 6 to 10)

Clinical Pearls

- As Phase III progresses to the initiation of sport-specific activity, it's not uncommon to have the athlete experience some pain in the surgical region.
- Careful monitoring of the intensity and provocative maneuver can lead to a more successful return.
- This is a good time to reassess scapular mechanics to ensure that scapular dyskinesis is not present. The Scapular Dyskinesis Test, which classifies scapula dyskinesis as either present or absent, is used to determine the presence of dyskinesis.[12,13] This system involves viewing of the scapula during humeral elevation to observe for "winging" (abnormal prominence of the medial and/or inferior boarder of the scapula) or dysrhythmia with grading of these findings as normal, subtle (mild, questionable, or inconsistent), and obvious (striking, clear, and consistent).

Goals

- Restore strength of the shoulder musculature
- Initiate return to sport training
- Unrestricted ADLS

Management of Pain and Swelling

- Careful monitoring of intensity and provocative movements with rehabilitation activities to allow adjustments to be made

Techniques for Progressive Increase in ROM

Manual Therapy Techniques

- Glenohumeral mobilization as needed

Soft Tissue Techniques

- Pectoralis minor stretching as needed

Stretching and Flexibility Techniques for the Musculotendinous Unit

- Stretching/flexibility techniques for the musculotendinous unit: Posterior capsule/sleeper stretching as needed.

Other Therapeutic Exercises

- Continued conditioning and exercises described in Phase II
- Initiate upper extremity weight-bearing core stability exercises (plank, side plank, etc.)

Sensorimotor Exercises

- Continue upper extremity PNF patterns
- Continue rhythmic stabilization exercises
- Initiate mirroring exercise (Figure 7-16) utilizing matched motion in multiple planes of movement in a mirror to improve proprioception and control. The goal of this exercise is the have the athlete match the motion of the involved to the uninvolved side through repetitive synchronous movements

TIMELINE 7-2: **Postoperative Rehabilitation after Distal Clavicular Resection (DCE) (Mumford)** (Continued)

PHASE III (weeks 6 to 10)	PHASE IV (weeks 10 to 14)	PHASE V (weeks 14 to 24)
• ROM should be full • Mobilizations as needed • Scapular and rotator cuff musculature PRE • PNF exercise • Upper extremity plyometrics in supine (90-90 & overhead ball toss) at 10 weeks	• Scapular and rotator cuff musculature PRE • Blackburn exercises (Ts, Ys, and Is) • TAS—biceps/triceps PREs • Glenohumeral exercises –PREs • Rotator cuff exercises –PREs • Upper extremity core stability (plank, side plank) • PNF exercises • Upright 90-90 and overhead ball toss	• Throwing program • Modified bench and overhead press (≤50% of preop reps weight) • Glenohumeral exercises—PREs • Scapular and rotator cuff musculature PRE • PNF exercises • Sport-specific training

FIGURE 7-16. Mirror exercise. Patient works on position the postsurgical shoulder in the same position as the nonsurgical shoulder.

Techniques to Increase Muscle Strength, Power, and Endurance

- Multilevel cable column or tubing rows (Figure 7-17)
- Advanced strengthening such as Blackburn exercises[14] can be integrated after the patient has demonstrated the ability to complete Phase II exercises without pain or substitution.
- Cable column or tubing external rotation (ER) and internal rotation (IR)
- Scaption with a hand-held weight

Neuromuscular Dynamic Stability Exercises

- One-hand push up on wall with light ball (Figure 7-12)

Plyometrics

- Medicine ball chest pass
- Overhead supine ball toss (Figure 7-13*A*)
- 90-90 supine ball toss (Figure 7-13*B*)
- Repeat progression in standing once supine progression completed without pain or loss of control

Functional Exercises

- Continued lower extremity described in Phase II

Sport-Specific Exercises

- Lower extremity drills (shuttle runs, back pedal, lateral step, etc.)

Milestones for Progression to the Next Phase

- Pain-free motion
- Strong and painless rotator cuff strength at 0° ABD
- No scapular substitution with forward elevation or abduction as discussed earlier

Phase IV (weeks 10 to 14)

Clinical Pearls

- In the late phases of rehabilitation, it is essential that the athlete continue to work to correct any strength or flexibility deficits that have been identified during the rehabilitation process.
- It is not uncommon for patients to discontinue the exercise regimen prematurely and suffer a return of pain and a functional set back as a result.
- Frequent communication with the athlete reinforcing the need to continue with the program is critical.

Goals

- Full restoration of shoulder strength
- Appropriate return to sport program
- Throwing program at 12 weeks

Other Therapeutic Exercises

- Continue conditioning and exercise per Phase II and III.

Techniques to Increase Muscle Strength, Power, and Endurance

- Continue strengthening exercise for scapula and rotator cuff musculature
- Return to gym 12 to 14 weeks with focus on regaining appropriate exercise form and early training/hypertrophy phase
- Low-weight bench pressing. In our experience, bench press beginning at 50% or less than presurgical one repetition maximum
- Form changes to include narrower grip, avoid full lock out to minimize stress on healing tissues

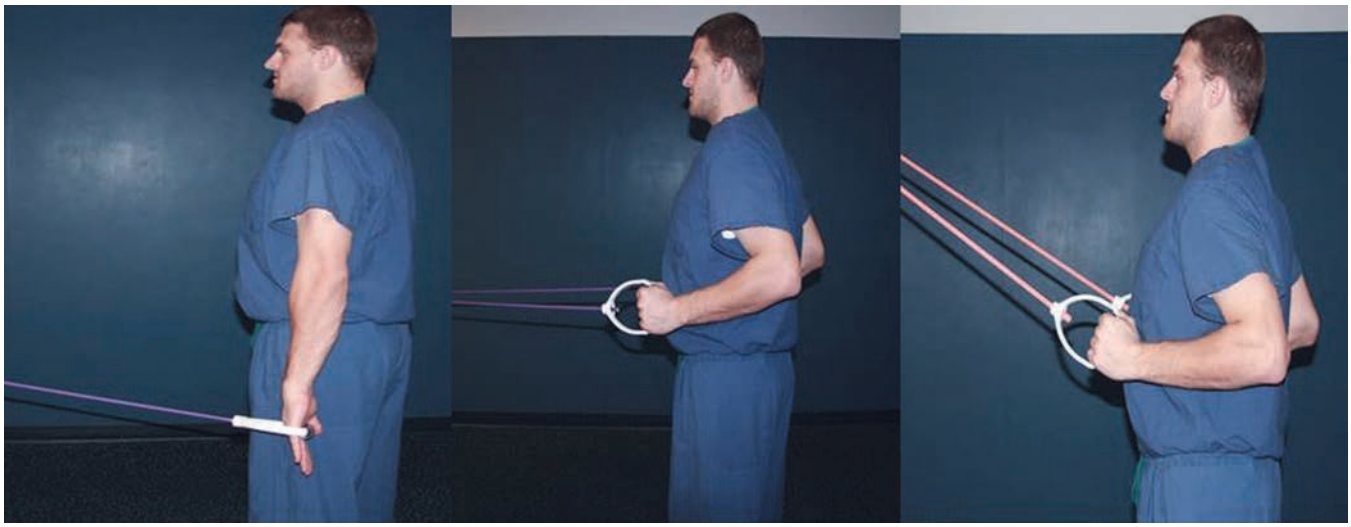

FIGURE 7-17. Multilevel rows.

- Low weight overhead press, in our experience beginning at 50% or less than presurgical one repetition maximum
- Form changes include avoiding full lock out at top and no behind neck presses
- Gradual return to previous level, progressing as tolerated

Neuromuscular Dynamic Stability Exercises

- One hand ball push up on wall progressing toward floor as athlete demonstrates appropriate form and control without pain in earlier phase exercises

Plyometrics

- Medicine ball chest pass
- Standing overhead ball toss
- Progress 90/90 ball toss to upright with rebounder

Functional Exercises

- Continue lower extremity exercises

Sport-Specific Exercises

- Progress lower extremity drills
- Initiate throwing program. Our throwing program is adopted and modified from review of previous published programs.[15-17] (See Table 7-1.)

Phase V (weeks 14 to 24)

Goals

- Successful or near completion of throwing program
- Sport-specific drills without complaints
- Discharge from formal care in preparation for return to sport

Sport-Specific Exercises

- Overhead throwing athletes may begin an interval-throwing program with short distance throws and frequent observation of proper throwing mechanics by the clinician. (Please see interval throwing program guidelines in Table 7-1.)
- General strength and conditioning of the UE may begin during this phase if the patient demonstrates full pain free AROM throughout all planes, and 5/5 strength throughout the affected UE, and no excessive soreness following rehabilitation exercises. Measurements of strength can be made using a hand-held dynamometer, which should reflect a 5% difference or less in strength in comparison to the uninvolved side. If a dynamometer is not available, 5/5 strength with manual muscle testing throughout the UE should be present.
- Exercises that the athlete will return to doing in the gym should be added on at this point at low intensity with close observation by clinician. All movements must also remain completely pain free.
- LE strength and agility exercises, combined with UE strengthening, may be incorporated at this stage for athletes in which UE function is dependent on LE stability and strength.
- Activities in this category may include box jumping with medicine ball, squat based kettle bell swings, or lateral shuttle run with intermittent medicine ball chest past between therapist and patient. These movements should be performed at low intensity for the purposes of improving endurance and technique rather than strength.
- Sport-specific drills at 24 weeks (football lineman-contact drills, light sled push, swimming maneuvers, wrestler-partner drills in quadruped, etc., basketball-lay up drills with partner to stimulate contact, racket sports-progressive swing/volley drills, etc.)

Criteria for Return to Sport

General

- Full active ROM without scapular dyskinesis as measured by the Scapular Dyskinesis Test.

- Full shoulder strength with handheld dynamometer or with manual muscle testing Successful completion of rehabilitation progression without residual soreness/pain
- Pain-free overhead activities
- Pain-free sport specific motions and maneuvers

Sport-Specific

- Thrower—successful completion of throwing program
- Contact athlete—contact without symptoms

After Return to Sport

- Focus on maintenance of parascapular strength
- Continuation of return to sport phase exercises for total body strength
- Return to team strength and conditioning program

Evidence

Charron KM, Schepsis AA, Voloshin I: Arthroscopic distal clavicle resection in athletes: a prospective comparison of the direct and indirect approach. *Am J Sports Med* 35:53–58, 2007.

Randomized controlled clinical trial comparing direct and indirect arthroscopic approaches for distal clavicle excision. Outcome scores were comparable at 2-year follow up in both groups, however athletes treated with the direct superior approach improved faster clinically and returned to sports earlier.[18] (Level II evidence)

Flatow EL, Duralde XA, Nicholson GP, et al: Arthroscopic resection of the distal clavicle with a superior approach. *J Shoulder Elbow Surg* 4(1 Pt 1):41–50, 1995.

Forty-one patients who underwent arthroscopic distal clavicle resection were followed for a minimum of 2 years postoperatively. At follow up 18 excellent, 16 good, and 7 poor results were found. High failure rate was associated with previous grade II acromioclavicular separations or acromioclavicular hypermobility.[4] (Level IV evidence)

Freedman BA, Javernick MA, O'Brien FP, et al: Arthroscopic versus open distal clavicle excision: comparative results at 6 months and 1 year from a randomized, prospective clinical trial. *J Shoulder Elbow Surg* 16:413–418, 2007.

Randomized, prospective clinical trial comparing the 6-month and 1-year outcomes between patients undergoing arthroscopic DCE to those undergoing open DCE. Both groups had comparable outcomes at 1 year. There was a trend for earlier improvement in the arthroscopic group.[7] (Level II evidence)

Kay SP, Dragoo JL, Lee R: Long-term results of arthroscopic resection of the distal clavicle with concomitant subacromial decompression. *Arthroscopy* 19:805–809, 2003.

Retrospective review of 20 patients followed for a mean of 6 years following combined arthroscopic DCE and subacromial decompression. Good to excellent scores on the Constant score and UCLA were observed in all 20 patients.[20] (Level IV evidence)

Robertson WJ, Griffith MH, Carroll K, et al: Arthroscopic versus open distal clavicle excision: a comparative assessment at intermediate-term follow-up. *Am J Sports Med* 39:2415–2420, 2011.

Comparison of 49 shoulders in 48 patients treated either with an open or arthroscopic approach. At 4-to 5-year follow-up, both groups had comparable outcome scores and were satisfied with the result of the procedure.[19] (Level III evidence)

Multiple-Choice Questions

QUESTION 1. Pain is an important component in determining the progression of therapeutic activities. Which of the following is ***most*** important when making decisions regarding the pace of rehabilitation?

A. Sport played
B. Concomitant procedures
C. Operative approach
D. Mechanism of original injury

QUESTION 2. What is the described progression of ROM exercises in the postsurgical setting?

A. Start with exercises like the pulleys that elicit moderate amounts of muscle activity. If the patient can't tolerate this switch to exercises with the limb supported.
B. Active ROM can be initiated immediately. Only patients reporting high levels of pain need to start with active assistive motion exercises
C. ROM exercises should start with the limb supported as they produce low levels of muscle activity thereby allowing the patient to move in a tolerable range. As motion improves and pain subsides, active-assistive exercise such as the pulleys and open chain activities like reclined flexion that produce progressive amounts of muscle activity.
D. All of the above.

QUESTION 3. Which of the following exercises allow the patient to focus on scapular control and established movement patterns without creating excessive loads about the shoulder?

A. Scaption with a hand-held weight
B. Scapular clock
C. Active forward elevation
D. Cable column external rotation

Answer Key

QUESTION 1. Correct answer: **B** (see Factors that May Affect Rehabilitation)

QUESTION 2. Correct answer: **C** (see Phases I and II Under Increase Range of Motion)

QUESTION 3. Correct answer: **B** (see Phase II, Muscular Activation)

NONOPERATIVE REHABILITATION OF STERNOCLAVICULAR JOINT SPRAINS

Richard L. Romeyn, MD, and Becky Heinert, MS, PT, SCS

Introduction

Anatomy

- The structure of the sternoclavicular (SC) joint is unique. It is a saddle-type articulation of partially incongruent surfaces, but it essentially functions as a ball-and-socket joint. Virtually any motion of the upper extremity produces some degree of stress upon the SC joint. Because the medial clavicle's articular surface is much larger than that on the sternum (less than half of the medial clavicle actually articulates with it), a lack of bony stability means that SC joint stability is largely dependent upon the integrity of its investing soft tissue constraints to control rotation and resist displacement.
- The posterior capsule (posterior sternoclavicular ligament) and the costoclavicular ligaments are the strongest and most important.[1,2] Typically, 30° to 35° of upward elevation, 35° of combined anterior/posterior displacement, and 45° to 50° of rotation about the long axis of the clavicle are allowed.[3,4]
- The muscles that act upon the SC joint do so indirectly, and as with the AC joint, stresses upon it are significantly influenced by scapulothoracic (kinematics).
- Adjacent to the SC joint is the epiphysis (growth center) of the medial clavicle. That epiphysis is the last one to close as skeletal maturity is reached, and it generally remains patent until midway through the third decade of life.[5]

Symptoms

- SC joint pathology produces localized pain over the joint surfaces and adjacent capsule. Distant pathologies do not generally refer pain to the area of the SC joint, and SC joint pathologies generally do not produce pain referred to other locations.
- Because the SC joint is superficial, even in muscular or obese patients, swelling is usually visually evident, and discomfort and instability can be readily palpated.
- The SC joint can be difficult to assess with standard radiographic views. Cephalic tilt views may allow more sensitive images to be obtained, but the current standard of care, if significant pathology or injury is suspected, is an advanced imaging study such as a CT or MRI scan.[6,7]

Etiology of Symptoms

Acute sprain:

- The minimal and incongruous contact between the articular surfaces of the medial clavicle and sternum would suggest that the SC joint may be easily predisposed to instability. However, it actually is uncommonly injured. In one large series, SC joint trauma represented just 3% of all injuries to the shoulder girdle.[8]
- Ligamentous injury can occur due to a direct force applied to the anteromedial aspect of the clavicle—producing posterior subluxation or dislocation of the joint, or from an indirect force applied to the arm or

shoulder—which can result in either anterior or posterior instability.

- In approximately 75% of cases, the instability is anterior, and is produced when an abduction/external rotation force is applied to the ipsilateral shoulder.[3,9] As with all joints, ligamentous injury can be classified as mild (pain without instability), moderate (subluxation), or severe (complete disruption of all SC ligaments).[10]
- Although discomfort generally increases in proportion to the degree of injury, trauma producing anterior instability may be only minimally painful with the arm at rest.
- However, a position of provocation, such as the cocking motion in throwing, which levers the medial clavicle anteriorly, will generally reproduce and exacerbate the symptoms.
- Posterior dislocations typically produce far greater pain than injuries producing anterior instability, and because the displaced medial clavicle can compress the mediastinum, that injury may be associated with venous congestion of neck or upper extremity, cough or hoarseness, shortness of breath, and difficulty swallowing.[9,11]
- The deformity produced by a posterior dislocation may be obscured by swelling, but the edge of the sternum is palpable, and should provide confirmation during clinical examination. This injury may have life threatening consequences, generally requires prompt reduction in an operating room setting, and so must not be overlooked.
- Many "dislocations" of the SC joint are not ligamentous injuries at all, but represent traumatic separation of the adjacent epiphysis (growth center).[6,10,12] The epiphysis of the medial clavicle does not even appear on radiographs until the late teenage years, and is vulnerable into the mid-20s. Most of these injuries readily heal, will remodel with time, and require only initial supportive care.
- Initial treatment for acute ligamentous injuries of the SC joint consists of that typical of all joint sprains: ice and immobilization. The length and degree of protection required are dependent upon the degree of injury.
- Anterior dislocations tend to be unstable after reduction no matter what initial treatment is provided. Posterior dislocations are generally stable after reduction. Although the prominence of the medial clavicle often remains present after an anterior subluxation or dislocation has occurred, scaring about the joint capsule generally prevents symptomatic instability, and the majority of patients with chronic SC joint laxity may be expected to have, at most, minimal functional limitations.
- Although techniques for surgical reconstruction of anterior ligamentous laxity have been described, outcomes are not uniformly successful, and there is significant risk to operating on the SC joint due to its proximity to multiple large vessels.[8,7,13]

Spontaneous instability:

- This condition is most common in the late teen to early adulthood years in those individuals who have significant generalized ligamentous laxity (Figure 7-18). There is a moderate female preponderance.[14]
- The condition is characterized by painful popping localized to the SC joint with elevation of the arm, and (by definition) there is no history of trauma producing ligamentous compromise.
- Participation in overhead sports such as baseball, basketball, and volleyball, and swimming are often associated with this condition. Scapulothoracic dyskinesia and core stability deficits are often present.
- This is a self-limited condition, generally responding successfully to an appropriate rehabilitation algorithm; it should NOT be treated surgically.[14] In fact, operative intervention is associated with an increase in symptoms.

FIGURE 7-18. An athlete with spontaneous anterior instability of the right SC joint.

Arthritis:

- Systemic rheumatoid arthritis may affect the SC joint, and that articulation may upon occasion even represent the initial clinical manifestation.
- Localized osteoarthritis of the SC joint, and avascular necrosis of the medial clavicle may also occur; typical patients are middle aged or elderly, often with an employment history of repetitive overhead work.
- Although localization of arthritic symptoms to the SC joint is generally obvious clinically, confirmation requires appropriate radiographs. SC joint arthritis usually responds to treatment of the systemic condition when secondary to rheumatoid disease and its variants.
- Resection of the proximal clavicle for disabling osteoarthritis that is non-responsive to all other treatment has been reported as successful if the CS ligaments and capsule are intact.[4] Otherwise, intervention must also include ligamentous reconstruction. Multiple techniques have been described.[3,8,12,13]

Infection:

- In individuals at risk of recurrent bacteremia, such as those with HIV infection; and with drug addiction, alcoholism, and other chronic debilitating diseases, the SC joint may be a site of localized sepsis.[15]
- In addition to pain localized to the SC joint area, erythema, warmth, fluctuant exquisite tenderness to palpation, and other signs of joint infection and abscess are evident. Intravenous antibiotics and/or incision and drainage may be necessary.

GUIDING PRINCIPLES OF REHABILITATION

- Protect the SC joint to help minimize the likelihood of chronic subluxation.
- Correct any underlying scapulothoracic dyskinesia to allow normalized shoulder girdle biomechanics during arm elevation.
- Prevent chronic SC joint subluxation through strengthening of the shoulder and scapular stabilizers and improved flexibility of the sternocleidomastoid, upper trapezius, pectoralis major, and pectoralis minor muscles.

Phase I (weeks 0 to 4)

Goals

- The SC joint pathology can be divided into those caused by trauma and those of insidious onset.
- The acute sprain can be classified into grade I (mild), grade II (moderate) and grade III (severe). The duration of immobilization and progression through the rehabilitation program will be dependent on the degree of instability in the SC joint.
- A grade I SC joint sprain is symptom-limited with a fairly rapid return to activity based on resolution of symptoms within 7 to 10 days.
- The treatment of grade II and III SC joint sprain is identical except the period of immobilization. For grade III SC joint sprains, the timeline for the rehabilitation protocol provided will be delayed by approximately 2 weeks to help minimize the likelihood of chronic SC joint subluxation.
- For the rehabilitation of a non-traumatic SC joint injury it is recommended that provocative activities be avoided for 2 to 3 weeks and that local modalities such as ultrasound, interferential current and iontophoresis be utilized for inflammatory and pain control. Upon resolution of acute symptoms, the athlete can begin the rehabilitation protocol beginning with Phase II.

Protection

Grade I: 5 to 10 days in a sling
Grade II: 2 to 3 weeks using a sling for anterior instability and "figure of 8" brace for posterior instability
Grade III: 3 to 4 weeks using a sling for anterior instability and "figure of 8" brace for posterior instability

Management of Pain and Swelling

- Ice, Ultrasound, Interferential Current Electrical Stimulation

Techniques for Progressive Increase in Range of Motion

- PROM flexion and scaption:
  - 0° to 90° (week 1 to 2) to avoid excessive clavicular retraction, elevation, and posterior rotation on the thorax
  - 0° to 180° (week 2 to 3)
- AAROM 0° to 90° flexion and scaption (week 2 to 3)
- Pendulum exercises
- Active elbow and wrist ROM

Stretching and Flexibility Techniques for the Musculotendinous Unit

- TBS, Core, TLS as tolerated and recommended

Techniques to Increase Muscle Strength, Power, and Endurance

Week 2 to 3: Submaximal isometric flexion, abduction, IR, ER in neutral; progress to maximal isometric if pain-free
Week 2 to 3: Active scapular retraction and depression, scapular protraction, biceps curls, triceps extensions

Milestones for Progression to the Next Phase

- D/C sling or brace
- Visual analog scale (VAS) 0/10 at rest
- PROM 0° to 180° for flexion/scaption
- Pain-free maximal isometrics for shoulder flexion, abduction, IR, ER in neutral
- Correct sitting posture demonstrated

Phase II (weeks 4 to 8)

Protection

- Taping prn for anterior instability (Figure 7-19)

FIGURE 7-19. Utilization of kinesiotape for chronic anterior SC joint instability.

Techniques for Progressive Increase in Range of Motion

Manual Therapy Techniques

- For the anteriorly displaced AC joint, posterior SC joint mobilizations prn
- Thoracic anterior-posterior glides with overpressure prn to improve lower trapezius activation. Progression of range of motion is based on the absence of SC joint pain and instability
  - AAROM 0° to180° (week 3 to 4)
  - AROM 0° to 90° (week 3 to 4); 0° to 180° (week 4 to 6)

Stretching and Flexibility Techniques for the Musculotendinous Unit

- Address cervicothoracic muscle imbalances through continued stretching of the SCM, upper trapezius and pectoralis muscles prn, and strengthening of middle and lower trapezius, rhomboids and deep cervical flexor muscle groups.

Other Therapeutic Exercises

- TBS, Core, TLS as tolerated and recommended

Sensorimotor Exercises

- Rhythmic stabilization, beginning in neutral with a progression to increasing degrees of arm elevation, decreasing upper extremity support, and greater intensity of perturbation placed distally on the extremity.
- PNF patterning in a pain-free ROM
- Body blade progression from neutral to 90°

Open and Closed Kinetic Chain Exercises

- Biodex VSRP for IR/ER from 60° to 180°/sec in neutral.
- Week 6 to 8: Initiate closed chain progression based on patient tolerance. A standard progression includes transitioning from a bilateral to unilateral activity with increasing weight bearing on the extremity.

FIGURE 7-20. Prone ball punches.

- One example may include press-ups, wall pushup with a plus, table pushup, 4-point weight shifts, prone on elbows, prone ball punches (Figure 7-20), standing ball punches with perturbations, modified pushups, partial ball walk-outs, full-walk-outs and full pushups.

Techniques to Increase Muscle Strength, Power, and Endurance

- Continue total arm strengthening, including bicep curls, triceps extensions

TIMELINE 7-3: **Nonoperative Rehabilitation of the Sternoclavicular Joint Sprain**

PHASE I (week 0 to 1)	PHASE II (weeks 2 to 4)
• Sling or "figure of 8" brace • PT modalities • PROM–flexion and scaption 0°–90° • Active ROM-elbow, wrist • Codman's exercises • TBS/TAS/TLS activities as recommended and tolerated	• D/C sling or "figure of 8" brace • PT modalities as needed • PROM–flexion and scaption 0°–180° • AAROM flexion and scaption 0°–90° (week 2–3) • AAROM flexion and scaption 0°–180° (week 3–4) • Submaximal to maximal isometrics for GH joint muscles • Biceps, triceps, and scapular exercises • SCM, UT, Pectoralis stretches • TBS/TAS/TLS activities as recommended and tolerated

- Progress strengthening of scapular stabilizers, posterior cuff, and glenohumeral muscles
  - Standing flexion, scaption 0° to 90°; increase ROM as strength and dynamic control improve
  - Prone rows
  - Prone GH extension
  - Supine protraction
  - Horizontal abduction with external rotation
  - Sidelying ER
  - TheraBand IR/ER

Plyometrics

- Week 6 to 8: Initiate a plyometric progression based on patient tolerance. A typical plyoback progression may begin with a two-handed chest level toss, progress to an overhead throw, and then to a single arm 90/90 step-throw.
- In addition, the base of support may be altered through the utilization of devices such as the BOSU ball or foam to increase the difficulty and engage more of the core muscles.

Milestones for Progression to the Next Phase

- VAS 0/10 with activities of daily living.
- Full AROM
- Manual muscle test 5/5 glenohumeral, scapular, and rotator cuff strength
- Isokinetic strength testing within 10% of the uninvolved shoulder for IR/ER in neutral at 60°/second, 180°/second and 300°/second
- Normal scapular assessment and/or normal scapular dyskinesis test

Phase III (weeks 8 to 12)

Protection

- Taping prn for anterior instability

Management of Pain and Swelling

- Ice, Ultrasound, Interferential Current Electrical Stimulation prn

Techniques for Progressive Increase in Range of Motion

Stretching and Flexibility Techniques for the Musculotendinous Unit

- As needed: Address cervicothoracic muscle imbalances through continued stretching of the SCM, upper trapezius and pectoralis muscles and strengthening of middle and lower trapezius, rhomboids and deep cervical flexor muscle groups.

Other Therapeutic Exercises

- TBS, Core, TLS as tolerated and recommended

Sensorimotor Exercises

- Incorporate exercises from 90° to the overhead position to improve dynamic control through the full arc of motion.
- Examples include wall dribbles (Figure 7-21), body blade in the overhead position or using PNF patterns, or 90/90 internal and external rotation using resistive tubing.

Open and Closed Kinetic Chain Exercises

- Progress to an isokinetic Velocity Spectrum Rehabilitation Protocol 180°/sec to 300°/sec in the 90/90 position.
- Continue to progress the CKC pushup activity by incorporating an unstable surface, an elevated position (box pushups), or unilateral support (Figures 7-22 and 7-23).

TIMELINE 7-3: **Nonoperative Rehabilitation of the Sternoclavicular Joint Sprain** (Continued)

PHASE III (weeks 4 to 8)	PHASE IV (weeks 8 to 12)
• Brace/taping prn • PT modalities as needed • AROM–full • Mobilizations (SC join, GH, thoracic spine) as needed • SCM, UT, pectoralis stretches prn • TBS/TAS/TLS activities as recommended and tolerated • Scapular exercises—PREs • TAS–biceps/triceps PREs • Glenohumeral exercises—PREs • Rotator cuff exercises–PREs • PNF exercises • Week 6–Plyometric progression (two-hand chest pass progressing to one-arm 90/90 step-throw) • Week 6–CKC progression (supported weight shift progressing to full pushup; bilateral progressing to unilateral)	• Brace/taping prn • PT modalities as needed • PROM–full • Mobilizations as needed • SCM, UT, Pectoralis stretching prn • TBS/TAS/TLS activities as recommended and tolerated • Scapular exercises–PREs • TAS–Biceps/Triceps PREs • Glenohumeral exercises–PREs • Rotator cuff exercises–PREs • Overhead strengthening exercises • PNF exercises • OKC rhythmic stabilization exercises • CKC exercises • Initiate sport-specific exercises • Return to sport program

FIGURE 7-21. Overhead wall dribbles.

FIGURE 7-22. Pushup with ball rolls.

FIGURE 7-23. Pushup with unilateral touches.

FIGURE 7-24. Prone Y exercise.

FIGURE 7-25. Prone T exercise.

Techniques to Increase Muscle Strength, Power, and Endurance

- Continue to increase resistance to the rotator cuff, scapular stabilizers and glenohumeral muscles. Utilize high repetition, low resistance for endurance training for the postural muscles such as the lower and middle trapezius muscle groups. Consider using a stability to engage more of the core muscles including:
  - Prone "Y"s (Figure 7-24)
  - Prone "T"s (Figure 7-25)
  - Prone goalpost (Figure 7-26)

Neuromuscular Dynamic Stability Exercises

- Integrate functional movement patterns, such as multi-directional lunges or squats with overhead press (Figures 7-27 and 7-28) that incorporated the entire upper and lower kinetic chain and require adequate core stability for proper completion.

FIGURE 7-26. Prone goalpost exercise.

FIGURE 7-27. Lunge with overhead press.

Sport-Specific Exercises

- A graduated return to throwing program prn (Table 7-1)

Milestones for Progression to Advanced Sport-Specific Training and Conditioning

- Successful completion of Phase III exercises, including closed kinetic chain, plyometric, functional movement pattern progressions, and return to throwing program with VAS 0-1/10 pain reported.

FIGURE 7-28. Squat with overhead press.

Criteria for Abandoning Nonoperative Treatment and Proceeding to Surgery or More Intensive Intervention

- Continued pain or instability interfering with upper extremity function

Performance Enhancement and Beyond Rehabilitation: Training/ Trainer and Optimization of Athletic Performance

- For an athlete returning to sport, a gradual transition is necessary to avoid excessive stress across the SC joint.
- The athlete with the goal of returning to a contact sport or one that requires overhead power may benefit from a biomechanical assessment by a physical therapist or athletic trainer, with the assistance of their positional coach to provide recommendations for technique modifications.

Specific Criteria for Return to Sports Participation: Tests and Measurements

- VAS 0-1/10 during sport-specific exercises
- Closed Kinetic Chain Upper Extremity Test scores within 10% of the uninvolved shoulder
- Isokinetic strength testing within 10% of the uninvolved shoulder for desired motions. IR/ER in 90/90

Table 7-1 High School and College Baseball Pitchers Interval Throwing

PHASE I Return to Throwing Throws at 50% effort	PHASE II Return to Pitching Throws at Effort Level Given	PHASE III Intensified Pitching
Step 1 Warm-up toss to 60 feet 15 throws at 30 feet 15 throws at 30 feet 15 throws at 30 feet 20 long tosses to 60 feet	**Step 8** 15 throws at 60 feet, 6 in (75%) 20 throws at 60 feet, 6 in (75%) 20 throws at 60 feet, 6 in (75%) 15 throws at 60 feet, 6 in (75%)	**Step 13** 25 fastballs (75%) 20 fastballs (100%) 10 fastballs (75%) 15 fastballs (100%) 25 fastballs (75%)
Step 2 Warm-up toss to 75 feet 15 throws at 45 feet 15 throws at 45 feet 15 throws at 45 feet 20 long tosses to 75 feet	**Step 9** 20 throws at 60 feet, 6 in (75%) 20 throws at 60 feet, 6 in (75%) 20 throws at 60 feet, 6 in (75%) 20 throws at 60 feet, 6 in (75%)	**Step 14 (Active Rest)** 20 throws at 80 feet 20 throws at 80 feet 20 throws at 80 feet 20 throws at 80 feet
Step 3 Warm-up toss to 90 feet 15 throws at 75 feet 15 throws at 75 feet 15 throws at 75 feet 20 long tosses to 90 feet	**Step 10** 20 fastballs (50%) 20 fastballs (50%) 20 fastballs (50%) 20 fastballs (50%) 25 throws at 60 feet, 6 in (75%)	**Step 15** 20 fastballs (75%) 20 fastballs (100%) 5 off speed pitches 15 fastballs (100%) 5 off speed pitches 20 fastballs (100%) 5 off speed pitches Field bunts and comebacks (Relievers and closing pitchers can go to step 21 on the next throwing day after completing this step)
Step 4 Warm-up toss to 105 feet 15 throws at 75 feet 15 throws at 75 feet 15 throws at 75 feet 20 long tosses to 105 feet	**Step 11** 20 fastballs (50%) 20 fastballs (75%) 20 fastballs (50%) 15 fastballs (75%) 25 throws at 60 feet, 6 in (75%)	**Step 16** 20 fastballs (100%) 15 fastballs (100%) 5 off speed pitches 5 pickoff throws to 1st 20 fastballs (100%) 5 off speed pitches 20 fastballs (100%) 5 off speed pitches

Multiple-Choice Questions

QUESTION 1. The etiology of symptoms involving the sternoclavicular joint includes all of the following except:

A. Recurrent bacteremia (HIV infection, drug addiction, alcoholism)
B. Trauma to the anterior lateral clavicle
C. Referral pain from the cervical spine
D. Systemic rheumatoid arthritis

QUESTION 2. Which of the following is NOT a typical finding of a potential sternoclavicular joint pathology:

A. Painful popping in the SC joint region with arm elevation
B. Generalized multi-joint laxity
C. Shortness of breath
D. Abnormality obvious on standard plain x-ray views

QUESTION 3. A key component of Phase II of rehabilitation includes:

A. Immobilization of the joint to maximize healing and prevent chronic shoulder subluxation
B. Overhead strengthening
C. Return to sport program
D. Closed chain exercise progression

QUESTION 4. The timeline for return to sports is most closely related to:

A. Severity of the sprain
B. Location of pain
C. Direction of the sprain (anterior versus posterior)
D. Age of the athlete

Answer Key

QUESTION 1. Correct answer: **C** (see Introduction—Etiology of symptoms)

QUESTION 2. Correct answer: **D** (see Introduction)

QUESTION 3. Correct answer: **D** (see Phase II)

QUESTION 4. Correct answer: **A** (see Phase I)

POSTOPERATIVE REHABILITATION AFTER JOINT RECONSTRUCTION OF ACROMIOCLAVICULAR SEPARATIONS

Nathan A. Mall, MD, Amy Resler, PT, DPT, CSCS, Wendell M.R. Heard, MD, and Nikhil N. Verma, MD

Indications for Surgical Treatment

- Some acute Type III dislocations, mostly in elite athletes
- Type II and III dislocations that have continued pain or symptoms following conservative treatment
- Acute or chronic Type IV, V, VI dislocations
- Instability and pain following distal clavicle excision

Brief Summary of Surgical Treatment

Major Surgical Steps

- Hook plate (+/– ligament reconstruction)
  - Plate is hooked on undersurface of acromion and placed on superior surface of clavicle, secured with bicortical screws, thereby reducing the acromioclavicular (AC) joint
  - May be combined with ligament reconstruction
  - Plate is removed at 8 weeks postoperatively
- Coracoclavicular fixation (+/– ligament reconstruction)
  - Synthetic suture loops or screw fixation from clavicle around or into coracoid process (Figure 7-29)
  - May be combined with ligament reconstruction
  - Staged removal of coracoacromial screw
- Coracoacromial ligament transfer (Weaver-Dunn or equivalent)
  - Coracoacromial (CA) ligament is detached from inferior surface of acromion
    - May or may not be removed with chip of bone; some authors believe this improves healing
  - Transferred to clavicle to recreate coracoclavicular ligaments
  - Can be augmented with suture loop
  - Distal clavicle is excised to prevent AC arthritis as late pain generator
  - Can be performed arthroscopically
- Semitendinosus autograft or allograft (authors' preferred method)
  - If autograft used, harvest graft from proximal medial tibia at pes anserine insertion using tendon stripper.
  - Doubled semitendinosus graft can be secured into coracoid with a bone tunnel or can be looped around the coracoid base. Coracoid tunnel may predispose to coracoid fracture.
  - Clavicle drill holes in the location of the trapezoid and conoid ligaments (Figure 7-30) are made and the graft secured with interference screws.
  - +/– Distal clavicle resection—recent study demonstrated that maintaining AC joint (i.e., preserving the distal clavicle) leads to reduced contact forces and increased AC stability.
  - Remaining graft can be secured into distal acromion to recreate AC ligaments (Figures 7-31 and 7-32).
  - Figures 7-33 *A* and *B* demonstrate typical preoperative and postoperative radiographs showing anatomic reduction of the downward displacement of the acromion with respect to the clavicle using an anatomic reconstruction technique with autograft.

Factors That May Affect Rehabilitation

Anesthetic

- Preferred technique is general anesthesia with interscalene block for postoperative pain control.
- Interscalene block with sedation may be possible although entire operative field may not be covered.

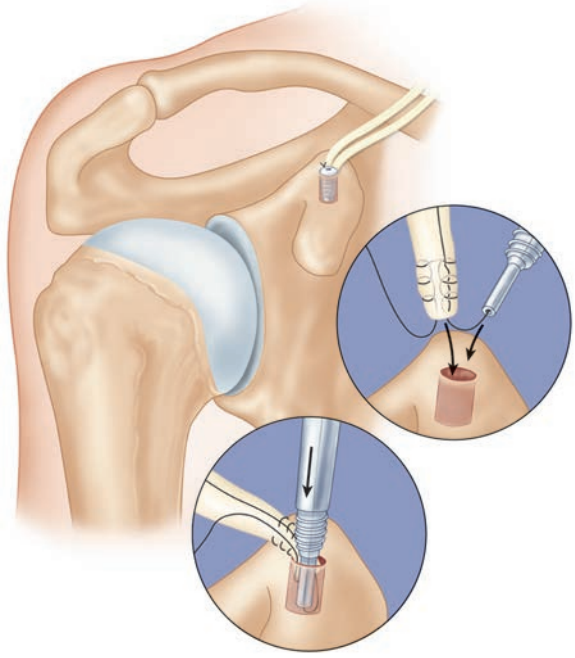

FIGURE 7-29. Coracoid bone repair—the sutures from the graft are tied together over the screw to provide dual functionality of the construct interference screw and suture anchor. *(From Provencher MT, LeClere LE, Mazzocca AD, et al: Acromioclavicular joint reconstruction. In Reider B, Terry MA, Provencher MT, editors: Operative techniques: sports medicine surgery, 2010, Elsevier.)*

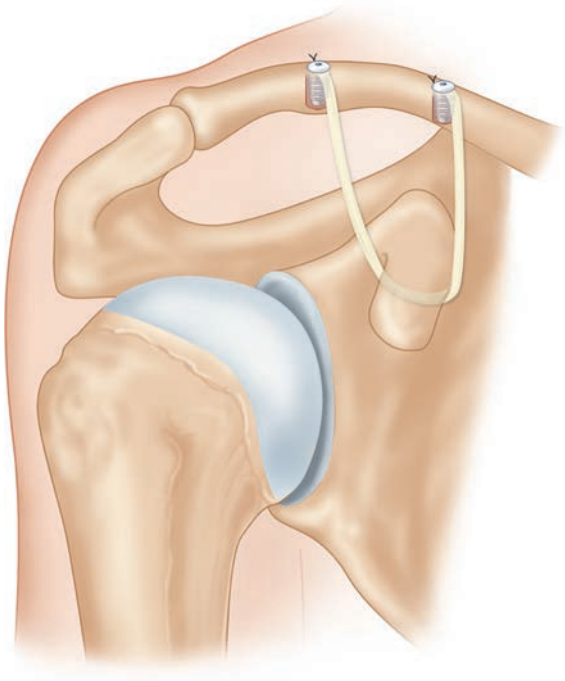

FIGURE 7-30. An alternative method of reconstruction involves passing a loop of the graft under the coracoid from lateral to medial. This is an excellent way to reconstruct the CC ligaments. *(From Provencher MT, LeClere LE, Mazzocca AD, et al: Acromioclavicular joint reconstruction. In Reider B, Terry MA, Provencher MT, editors: Operative techniques: sports medicine surgery, 2010, Elsevier.)*

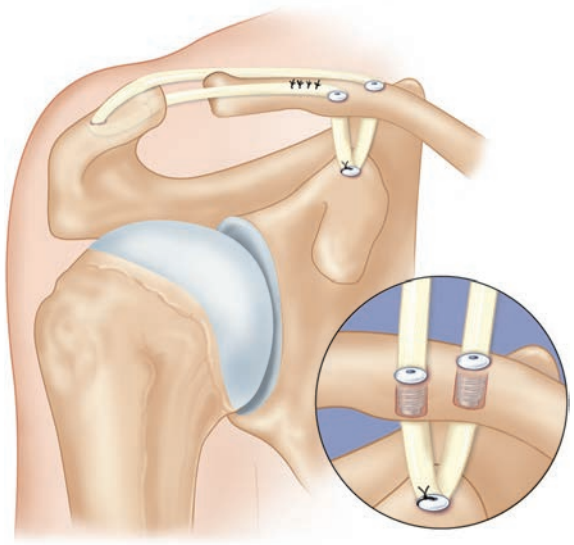

FIGURE 7-31. The tendon, driver, and screw are placed into the acromion bone tunnel and the screw is advanced. *(From Provencher MT, LeClere LE, Mazzocca AD, et al: Acromioclavicular joint reconstruction. In Reider B, Terry MA, Provencher MT, editors: Operative techniques: sports medicine surgery, 2010, Elsevier.)*

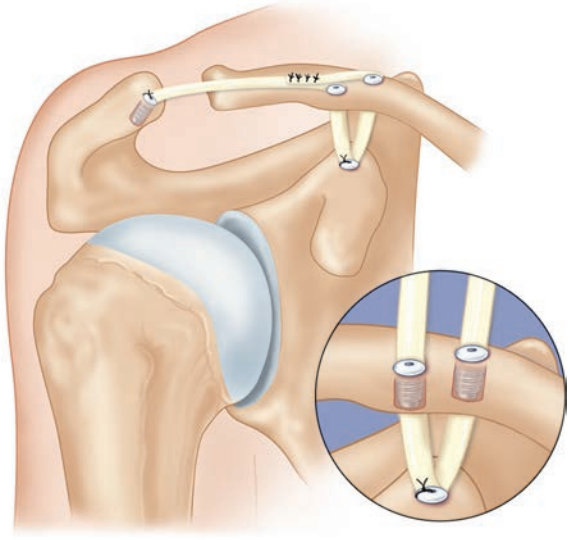

FIGURE 7-32. If both limbs of the graft can reach the acromion, then create two bone tunnels for interference screw insertion and security. *(From Provencher MT, LeClere LE, Mazzocca AD, et al: Acromioclavicular joint reconstruction. In Reider B, Terry MA, Provencher MT, editors: Operative techniques: sports medicine surgery, 2010, Elsevier.)*

Surgical

- CA ligament transfer only provides about 25% of the strength of an intact CC complex if not augmented with suture loop.
- Rockwood coracoclavicular screw has highest tensile strength and stiffness with lowest elasticity, which may predispose to screw cutout or breakage of the screw.
- Mazzocca et al.[1] found that an anatomic reconstruction using doubled semitendinosis through a coracoid

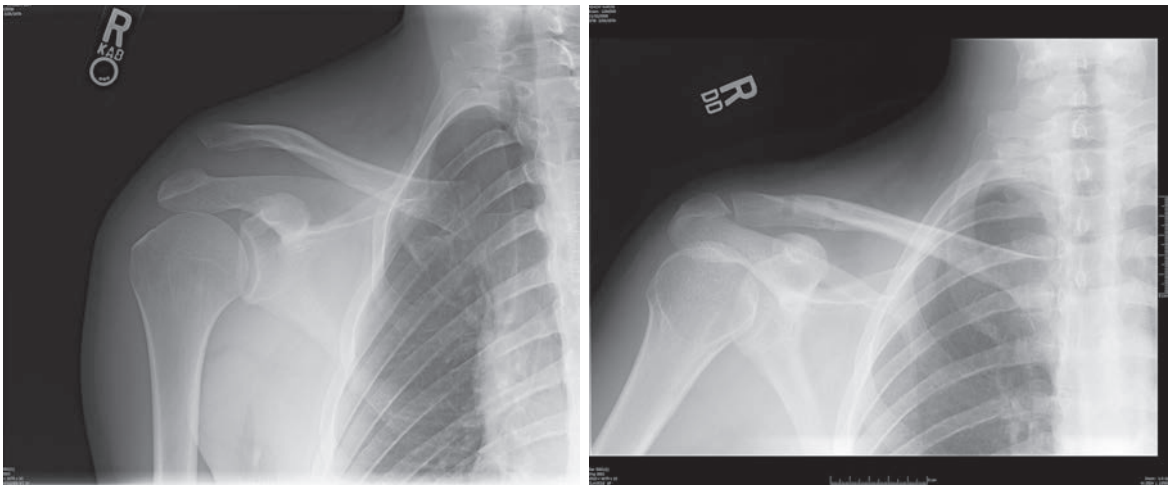

FIGURE 7-33. A, Preoperative radiographs demonstrating type III acromioclavicular dislocation. **B,** Postoperative radiographs following anatomic AC reconstruction.

bone tunnel provided similar resistance to anterior, posterior, and superior forces as the intact CC and AC ligament complex.

Other Surgical Techniques and Options

- The technique chosen for surgical fixation may depend on acuity of injury. Acute injuries may provide some opportunity for healing of the native CC ligament complex. In this case, fixation alone with screw of suture based construct may be considered.
- In chronic situations, healing of the CC ligaments is not expected. Augmentation with allograft or autograft tendon should be considered.
- Choice of surgical technique has minimal impact on postoperative rehabilitation. As all procedures are extraarticular, the risk of stiffness following surgery is limited, and the repair should be protected with support and limited range of motion. Graft or native ligament healing can be expected at 12 weeks at which time strengthening is initiated.
- Early return to play can result in graft stretching and loss of reduction, or in contact sports can lead to clavicle fracture (Figure 7-34).
  - Two drill holes of 5 to 6 mm in diameter are created in a bone that is typically 15 to 20 mm in diameter.

FIGURE 7-34. Clavicle fracture through a bone tunnel after anatomic AC reconstruction.

Before Surgery: Overview of Goals, Milestones, and Guidelines[2]

- Rehabilitation following AC joint reconstruction using tendon autograft or allograft is limited by the time to achieve tendon to bone healing, relying on fixation methods or supplementary suture loop until this time.
- A study by Rodeo et al.[2] found that tendon to bone healing occurs approximately 12 weeks following reconstruction in a dog model, however, allograft reconstruction may require even longer time to incorporate.
- Also, understanding the extremity motions that stress the AC joint is key to preventing stretching or failure of the graft. Forward elevation and abduction have been shown to produce rotational forces at the AC joint.
- Scapular protraction and retraction also produce significant forces at the AC joint and should be avoided until graft remodeling has occurred.
- In addition, the weight of the arm is suspended by the clavicle-scapular complex and early support of the arm is indicated to minimize stress on the graft.

[2]*Prehabilitation, if appropriate, is described in the Nonoperative Rehabilitation section of this chapter.*

GUIDING PRINCIPLES OF POSTOPERATIVE REHABILITATION

- Several studies have shown that translation at the AC joint may be corrected with reconstruction of the CC and AC ligaments, but still fail with less force than the intact ligaments.
- There is a significant difference in the force required to cause the reconstruction to fail depending on technique, and thus rehabilitation protocols may differ based on technique of reconstruction.
- The weight of the arm can produce a significant and constant force on the AC joint and thus sling immobilization is key to prevent downward displacement of the scapula and upper extremity with respect to the clavicle.
- Tendon to bone healing occurs at approximately 3 months, with allograft potentially taking slightly longer.
- AC reconstruction is an extraarticular procedure which decreases the risk of postoperative stiffness, therefore, therapy regimens can be less aggressive with delay of early motion compared with intra-articular shoulder procedures.

Phase I: Immediate Postoperative Period (days 0 to 14)

Clinical Pearls

- The weight of the upper extremity is often a source of pain and potential disruption of the surgically reconstructed AC joint if not sufficiently supported, in particular, during sleep or rest.
- To maintain a position of comfort with minimal stress to the repair, bolstering the extremity with pillows (as well as wearing the sling during rest and sleep) prevents the arm from falling into extension or adduction relative to the torso.
- Ensure that the sling is properly fitted and adjusted to eliminate any unnecessary traction across the AC joint, which will improve sling compliance as well.
- When patients perform elbow range of motion activities, we recommend doing so in the supine position with the elbow supported by a pillow to minimize the force of gravity on the repair.

Goals

- Minimize postoperative pain and swelling.
- Ensure patient understanding of the movements that stress the AC joint to avoid stretching the graft; emphasize the importance of sling compliance.
- Surgeon communication with therapist regarding type of repair, graft used, and any planned hardware removal.
- Protect distal clavicle and re-approximated ligaments/healing structures.

Protection

- Some authors recommend using a platform brace with no shoulder motion for 6 to 8 weeks after surgery.
  - The arm is immobilized in external rotation as this has been shown by some authors to reduce postbracing stiffness.
  - The platform is used to immobilize the AC joint, which is the only link between the thorax and the upper extremity.
- Others recommend a simple sling with wedge to provide some external rotation of the glenohumeral joint.
  - Sling immobilization is recommended by most for at least 2 weeks, others recommend 6 to 8 weeks, whereas some prefer sling immobilization for up to 3 months.
- The authors recommend sling with abduction pillow immobilization for 6 weeks. This provides immobilization of the shoulder with support of the arm.

Management of Pain and Swelling

- Multimodal pain management has been shown to decrease the amount of narcotics needed as well as the side effects of these medications.
- With the arm immobilized, pain medication typically is only required for 3 to 5 days after surgery.
- A combination of narcotic pain medication, short course of ketorolac, and ice are the mainstays of treatment.
  - A short course of ketorolac likely does not affect tendon to bone healing significantly.
  - Cold therapy is an effective pain control method as well as that it decreases swelling.
  - Some pain specialists recommend a scheduled dose of acetaminophen 1000 mg every 6 hours combined with a non-acetaminophen containing narcotic medication used as needed, stating this can reduce the overall amount of narcotic required.
- The physician must be very specific when discussing the patient's symptoms as many patients will verbally communicate muscle spasms as pain. Valium (diazepam) or flexeril can be added for patients experiencing spasm.
- Swelling can be a major source of discomfort for the patient and efforts to reduce swelling should be instituted. This includes a short course of ketorolac (2 to 3 days) if the patient has normal renal function, an ice pack or circulating ice machine (Figure 7-35), and sleeping slightly upright to elevate the shoulder.

Techniques for Progressive Increase in Range of Motion

Manual Therapy Techniques

- May begin active and passive range of motion of the wrist and hand immediately. Active and passive elbow

FIGURE 7-35. Cryotherapy with operative upper extremity supported.

flexion and extension is allowed without weight in the early postoperative period, and should be encouraged several times per day to prevent elbow stiffness.
- The authors recommend against shoulder ROM in the first 6 weeks following surgery. At this point shoulder ROM may be instituted with avoidance of motions that stress the AC joint, including: forward elevation and abduction (especially greater than 90°), cross-body adduction, and scapular protraction and retraction.

Soft Tissue Therapy Techniques

- Soft tissue techniques to cervical musculature (i.e., scalenes), torso, parascapular and shoulder girdle musculature

Stretching and Flexibility Techniques for the Musculotendinous Unit

- No stretching to the pectoralis minor or upper trapezius during this phase due to their attachments at the coracoid and clavicle respectively.

Other Therapeutic Exercises

- For the elite athlete, lower body strengthening can continue safely in the early postoperative period.
- Core strengthening can be performed with the arm in the sling.
- Stationary bicycle can be used for cardiovascular conditioning to prevent displacing forces on the AC joint caused by arm motion with running.

Activation of Primary Muscles Involved in Injury Area or Surgical Structures

- Deltoid and trapezius muscle activation is typically minimized until 6 weeks following reconstruction to minimize the pull on the components of the AC joint.
- Depending on the technique used for reconstruction, the coracoid process can be weakened by screws, bone tunnels or drill holes. Thus, the authors recommend against resisted elbow flexion with even minimal weight in the early postoperative period to prevent fracture of the coracoid process. This can safely be introduced approximately 8 weeks following surgery with light weights, and strengthening can begin at 12 weeks.

Sensorimotor Exercises

- Again, for the elite athlete these can begin several days following surgery in a supervised setting with the arm in a sling. This could include basic core and kinetic work that is supervised, with the arm in a sling. For most patients this would be restricted until at least 6 to 8 weeks to avoid falling or stumbling that may produce sudden movements with the operative extremity.

Open and Closed Kinetic Chain Exercises

- No AROM of the glenohumeral joint
- Supported or short lever Codmans (Figure 7-36) exercises during this phase, three times a day
- Ball squeeze for hand
- Wrist and gripping exercises

TIMELINE 7-4: **Postoperative Rehabilitation after AC Joint Reconstruction for AC Separations**

PHASE I (weeks 0 to 6)	PHASE II (weeks 6 to 10)
• Sling or platform brace • PT modalities • ROM elbow, wrist, hand • Week 2 begin TBS/TAS/TLS activities as recommended and tolerated	• DC sling • PT modalities as needed • PROM for GHJ to 90° advance to full after 8 weeks • Mobilizations as needed • Limit cross body adduction, scapular protraction/retraction, and end-range FE/ABD • TBS/TAS/TLS activities as recommended and tolerated

FIGURE 7-36. Supported Codman's.

Techniques to Increase Muscle Strength, Power, and Endurance

- Strengthening should be avoided until full passive and active motion have returned, which is likely at 10 to 12 weeks following AC reconstruction.

Neuromuscular Dynamic Stability Exercises

- Elite athletes may begin this in the next phase.

Plyometrics

- Lower extremity plyometrics can begin at 8 weeks following surgery.

Functional Exercises

- These can be incorporated at the same time as strengthening exercises begin, at about 10 to 12 weeks.

Sport-Specific Exercises

- These can be incorporated into the rehabilitation program once full passive and active motion of the glenohumeral joint has been achieved. Typically after 12 weeks.

Milestones for Progression to the Next Phase

- Minimal to no pain
- 100% sling/immobilizer compliance
- No signs or symptoms of compromise or failure of the repair

Phase II: Early Post-Operative Healing (weeks 2 to 6)

Clinical Pearls

- Again, the patient should be informed that the graft takes time to incorporate. The therapist and surgeon must remind the patient of the precautions and the anatomical and biomechanical reasons for these precautions to avoid non-compliance.
- As pain improves, the patient will naturally attempt more activities and allowed activity should be reiterated.

Goals

- Prevent loss of motion of hand, wrist, and elbow.
- Protect the reconstruction.
- Prevent loosening or migration of fixation.
- Eliminate residual postoperative pain and swelling.

Protection

- Some authors recommend using a platform brace with no shoulder motion for 6 to 8 weeks after surgery.

TIMELINE 7-4: Postoperative Rehabilitation after AC Joint Reconstruction for AC Separations (Continued)

PHASE III (weeks 10 to 14)	PHASE IV (weeks 14 to 24)	PHASE V (weeks 24 to 52)
• PT modalities as needed • PROM-full • Mobilizations as needed • Begin AAROM/AROM when full PROM • Week 12 begin ABIR, ABER stretch • TBS/TAS/TLS activities as recommended and tolerated • Scapular exercises—PREs • TAS—Biceps/Triceps – PREs • Glenohumeral exercises—PREs • Rotator cuff exercises—PREs • PNF exercises • OKC Rhythmic stabilization exercises • CKC exercises	• PROM—maintain full motion • Mobilizations as needed • TBS/TAS/TLS activities as recommended and tolerated • Scapular exercises—PREs • TAS—biceps/triceps PREs • Glenohumeral exercises—PREs • Rotator cuff exercises—PREs • PNF exercises • OKC rhythmic stabilization exercises • CKC exercises • CKC manual perturbation exercises • Sport-specific exercises begin • Overhead throwing athletes can begin an easy interval throwing program	• SEE non-operative AC joint injury chapter • Maintenance Program • PROM-maintain full motion • Mobilizations as needed • TBS/TAS/TLS activities as recommended and tolerated • Scapular exercises—PREs • TAS—biceps/triceps—PREs • Glenohumeral exercises—PREs • Rotator cuff exercises—PREs • IR/ER exercises at 90° • Thrower's Ten progress intensity • PNF exercises • OKC rhythmic stabilization exercises • CKC exercises • CKC manual perturbation exercises • Sport-specific exercises progressed • Overhead throwing athletes progress through an interval throwing program

  - The arm is immobilized in external rotation as this has been shown by some authors to reduce postbracing stiffness.
  - The platform is used to immobilize the AC joint, which is the only link between the thorax and the upper extremity.
- Others recommend a simple sling with wedge to provide some external rotation of the glenohumeral joint.
  - Sling immobilization is recommended by most for at least 2 weeks, others recommend 6 to 8 weeks, whereas some prefer sling immobilization for up to 3 months.
- The authors recommend sling with abduction pillow immobilization for 6 weeks. This provides immobilization of the shoulder with support of the arm.

Management of Pain and Swelling

- The patient should require very little in terms of pain medication at this time; acetaminophen may be all that is needed.
- Cold therapy is not only an effective method at reducing swelling but it also improves pain control.

Techniques for Progressive Increase in Range of Motion

Soft Tissue Techniques

- Continue soft tissue mobilization to muscles discussed in Phase 1. Begin scar mobilization when incisions are sufficiently closed.

Stretching and Flexibility Techniques for the Musculotendinous Unit

- No stretching to the pectoralis minor or upper trapezius during this phase due to their attachments at the coracoid and clavicle respectively.

Other Therapeutic Exercises

- Stationary bike at weeks 3 to 4 while wearing sling.
- Isometrics exercises for the transverse abdominals, gluteals, and uninvolved muscle groups

Activation of Primary Muscles Involved in Injury Area or Surgical Structures

- No glenohumeral AROM during this phase.
- Isometrics within the sling may be initiated.

Sensorimotor Exercises

- Elite athletes may begin LE unilateral balance (Figure 7-37) and proprioceptive exercises.
- Single limb LE balance with head movements, including neck flexion and extension, lateral tilt to the right and left, cervical rotation and combine motions such as looking over shoulder and sport-specific head/neck movement patterns. This can improve vestibular and neck proprioceptive input and improve balance.

FIGURE 7-37. Lower extremity unilateral balance.

Open and Closed Kinetic Chain Exercises

- May begin trunk or thoracic rotation while wearing sling.

Functional Exercises

- Functional 1/3 squats (wearing sling) for elite athletes
- Steps ups/step downs
- Stationary lunges for elite athletes

Milestones for Progression to the Next Phase

- No postoperative swelling or pain
- Elbow, wrist and hand ROM equal to the contralateral extremity
- No signs or symptoms of compromise or failure of the repair

Phase III: Mobilization (weeks 6 to 10)

Clinical Pearls

- Pain during this phase is often generated from mild glenohumeral stiffness or from the subacromial space. This may occur upon initiating PROM of the glenohumeral joint.
- Clinically, we have had success eliminating pain during this phase with soft tissue mobilization techniques to the supraspinatus tendon while the GH joint is in the loose pack position.
- In addition, gentle Grades 1 to 2 joint mobilization to the GH joint (generally, posterior glides due to ROM limitations) may be applied to improve arthrokinematics that may be contributing to subtle rotator cuff impingement due to stiffness and faulty mechanics.

Goals

- Pain-free glenohumeral (GH) joint PROM and progression to AROM within postoperative restrictions to prevent stiffness.
- Limit motions that increase stress on the AC joint-Internal rotation behind the back, cross-body adduction, abduction, scapular protraction and retraction, and end-range forward elevation.
- If coracoclavicular screw was used, this is typically removed at 8 weeks at which point patients may progress to full active and passive motion.
- Prevent fixation failure before 8 weeks by limiting motion to below shoulder level and lifting to less than 5 pounds.

Protection

- Discontinue sling after week 6; may continue use until week 8 for comfort until motion returns.

Management of Pain and Swelling

- Continue or initiate pain modalities as needed.
- Apply moist heat to the AC joint for stiffness.
- Continue cryotherapy following physical therapy.
- Ice the rotator cuff/ subacromial space if indicated.

Techniques for Progressive Increase in Range of Motion

Manual Therapy Techniques

- No active GH joint ROM. PROM only for the GHJ to 90° of flexion in the scapular plane. Continue PROM to the wrist and elbow. Grades 1 to 2 joint mobilization to the GH joint (no AC joint mobilization) to facilitate PROM. Primarily, mobilization of the GH joint in the anterior to posterior direction is applied during this phase.

Soft Tissue Techniques

- Continue scar mobilization and soft tissue mobilization as described in previous phases.

Stretching and Flexibility Techniques for the Musculotendinous Unit

- Begin very gentle stretching of levator and pectoralis at weeks 8 to 10.

Other Therapeutic Exercises

- LE gym weights and machines; light resistance
- Elliptical using LEs only; no UEs
- Stationary bike with increased resistance

Activation of Primary Muscles Involved in Injury Area or Surgical Structures

- May begin AAROM and AROM when PROM returns to within approximately 75% of full ROM
- Dowel or pulley for AAROM flexion, scaption, ER/IR beginning in supine, progressing to upright position as the patient advances (Figure 7-38)

FIGURE 7-38. Active assisted range of motion in supine with dowel.

FIGURE 7-39. Lower extremity proprioceptive exercise on BOSU ball.

Sensorimotor Exercises

- Elite athletes may begin LE unilateral balance and proprioceptive exercises (Figure 7-39).
- Single limb LE balance with head movements, including cervical rotation, flexion/extension and combine movements.

Open and Closed Kinetic Chain Exercises

- Closed chain range of motion exercises are used such as table or wall slides, and have been shown to limit the activation of shoulder musculature.
- Supine flexion or pulleys can be used to improve forward elevation, keeping the upper extremity below shoulder level (less than 90° of flexion).
- Closed chain scapular exercises and kinetic chain exercises begin at 8 weeks, allowing the patient to improve scapular kinetics. These can include shoulder shrugs, shoulder rolls, rows, stability ball wall circles and push-ups. Scapular clocks, scapular depression, and

closed chain protraction can also improve scapular kinetics.

Techniques to Increase Muscle Strength, Power, and Endurance

- Seated small arc scapular depression at weeks 8 to10.
- Seated scapular retraction at weeks 8 to 10.
- Biceps and triceps strength with no weight > 5 lbs at weeks 8 to 10.

Neuromuscular Dynamic Stability Exercises

- Scapula PNF in sidelying; repeated isometric progressing to slow reversals (Figure 7-40)
- Elbow PNF
- Begin with rhythmic stabilization in supine with GH joint flexed to 90°
- Body blade at side weeks 8 to 10

Plyometrics

- LE low impact plyometrics at week 8 for elite athletes

Sport-Specific Exercises

- LE sport-specific agility drills for elite athletes

Milestones for Progression to the Next Phase

- GH joint: 90° of PROM flexion in the scapular plane
- No postsurgical pain or swelling
- Repair intact

Phase IV: Strengthening (weeks 10 to 14)

Clinical Pearls

- As the patient begins AROM, clinically we have observed the patient exhibiting signs and symptoms consistent with impingement. Continue soft tissue mobilization to the supraspinatus or posterior RC if tender and painful during this phase.
- Restore scapulohumeral rhythm with manual cueing to further improve faulty arthrokinematics.

FIGURE 7-40. Scapula PNF in sidelying.

Goals

- Restore scapulohumeral rhythm
- Optimize strength of UE and parascapular musculature
- Full pain-free AROM by week 14

Protection

- May apply postural tape, kinesiotape to cue or facilitate parascapular muscles.

Techniques for Progressive Increase in Range of Motion

Manual Therapy Techniques

- Continue joint mobilization, manually facilitate scapulohumeral rhythm. This is performed by guiding the scapula through rotation, abduction, and depression during active glenohumeral flexion and abduction. The therapist's hand placement can vary, but standing behind the patient with one hand just superior to the spine of the scapula and the other at the inferior medial scapular border is a comfortable and effective positioning. Continue PROM and AAROM to full ROM by week 12.
- Low-load long-duration capsular stretch if lacking end-range combined ABIR or ABER.

Soft Tissue Techniques

- Continue scar mobilization and soft tissue mobilization as described in previous phases.

Stretching and Flexibility Techniques for the Musculotendinous Unit

- Hold relax stretching of pectoralis major, minor, latissumus dorsi, levator scapula as needed.

Other Therapeutic Exercises

- Upper body ergometer (Figure 7-41)
- LE gym weighs and machines; increase resistance

Activation of Primary Muscles Involved in Injury Area or Surgical Structures

- Full can to 90° only for nonthrowers with light weights
- Shoulder raises (flexion, abduction) to 90° with light weights
- Biceps curls; begin with supported preacher curl

Sensorimotor Exercises

- Hand on baps board in partial UE weightbearing
- Increase UE weightbearing on unstable surface (i.e., ½ kneeling UE balance on BOSU ball)
- Progress UE resistance band exercises with decrease base of support (unilateral balance or on unstable surface)

Open and Closed Kinetic Chain Exercises

- Scapular clocks (Figure 7-42)
- Wall protraction at weeks 9 to 10 with Bilateral UEs, progressing to Unilateral UE

FIGURE 7-41. Upper body ergometer.

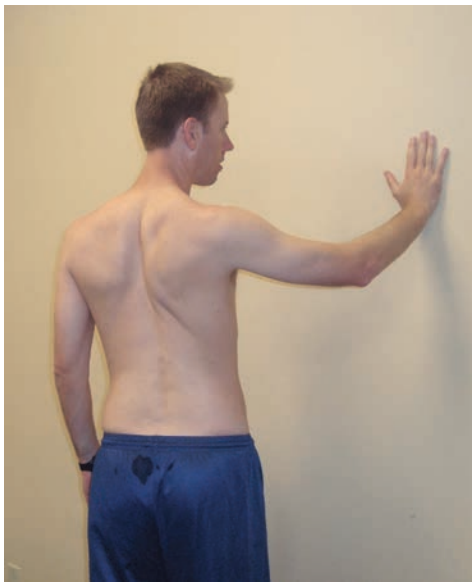

FIGURE 7-42. Scapular clocks.

- AAROM using towel for IR
- AAROM using with wand or dowel for flexion, abduction, ER.

Techniques to Increase Muscle Strength, Power, and Endurance

- Sidelying ER with no resistance
- Prone "I" scapular 3-step exercise at weeks 10 to 12. (The patient is positioned prone with arms at the sides. There are three distinct movements emphasized: (1) scapular depression, followed by (2) scapular retraction and finally (3) glenohumeral extension.)
- Isometric ER, IR, flexion, extension and abduction at week 10
- Progress to light resistance band for rotator cuff strength, in neutral at week 12
- Progress to scapular depression and rows with light resistance band at week 12

Neuromuscular Dynamic Stability Exercises

- GH joint PNF in supine position; rhythmic stabilization progressing to slow reversals
- Progress to seated GH joint PNF
- Body blade at varying flexion, abduction and scaption angles (Figure 7-43)

Plyometrics

- Progress LE plyometrics (i.e., hopping, jumping, box jumps)

Functional Exercises

- Lawnmowers. Utilizing a bench, with one leg kneeling, one standing, a dumbbell weight is used in a simulated lawnmower starting (i.e., pulling the rope to start a lawnmower engine) while the core is stabilized
- Russian dead lifts (RDLs) a "stiff-legged" deadlift, often performed unilaterally with dumbbell
- Begin jogging at week 12

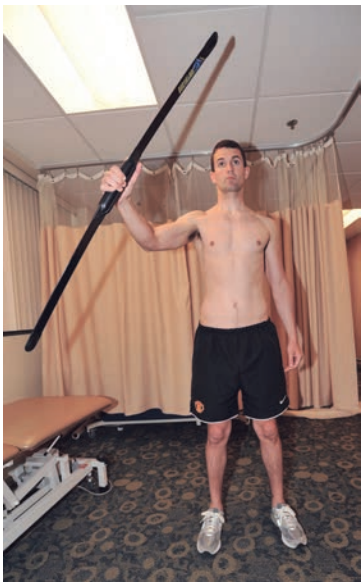

FIGURE 7-43. Body blade dynamic stability.

Sport-Specific Exercises

- LE sport-specific agility drills for elite athletes

Milestones for Progression to the Next Phase

- Full PROM, AROM GH joint compared with the nonoperative side or if this has a prior or concurrent injury, then compared to normative values
- Strength of UE at least 4+/5 using manual muscle testing (MMT)
- No pain or swelling noted by observation or palpation
- Repair intact

Phase V: Functional Recovery and Initial Return to Sport (weeks 14 to 24)

Clinical Pearls

- Surgical technique should be taken into consideration. If graft reconstruction was performed, graft incorporation and remodeling will continue for 6 months or more, and delayed integration may occur with allograft tissue.
- Patient and therapist should understand the biologic phases of graft incorporation and remodeling and the implications to return to sport.
- If continued pain at the subacromial space (SAS) or rotator cuff during this phase, assess pectoralis minor length and formally assess lower and middle trapezius during this phase using manual muscle testing.
- If flexibility or strength is impaired, emphasize correction of these deficits during this phase. ACJ mobilization may be considered during the latter part of this phase as well.

Goals

- Continue strengthening, focusing on scapular stabilizing muscles and core strengthening
- Initiate sports specific exercises
- Maximize muscular strength, flexibility and endurance

Techniques for Progressive Increase in Range of Motion

Manual Therapy Techniques

- Continue Grades 3 to 4 GH joint mobilization, with scapulothoracic joint mobilization as needed.

Soft Tissue Techniques

- Continue scar mobilization and soft tissue mobilization as described in previous phases.

Stretching and Flexibility Techniques for the Musculotendinous Unit

- Continue stretching of pectoralis major, minor, latissimus dorsi, levator scapula as needed.

Other Therapeutic Exercises

- Sit ups
- Add bent over low row with light weight
- Progress to low and mid row machine (low resistance)
- Begin plank progression (start with half planks or pillars)

Activation of Primary Muscles Involved in Injury Area or Surgical Structures

- Full can with increased weights
- Shoulder raises (flexion, abduction) with increased weight
- Biceps curls, unsupported with dumbbell or bar
- Triceps press or extensions with dumbbell in neutral (not overhead)
- Kettlebell low row mid phase
- Chest press; begin seated with machine
- Seated short arc machine flys and progress to cable flys later in this phase

Sensorimotor Exercises

- Hand-eye coordination drills for racquet or overhead athletes.

Open and Closed Kinetic Chain Exercises

- Increase resistance to rotator cuff, middle, lower trapezius and serratus anterior strength
- Protraction progression: unilateral at wall, bilateral at table, bilateral half kneeling unstable surface

Techniques to Increase Muscle Strength, Power, and Endurance

- Add PNF patterns with resistance bands.
- Perform Prone T and Y exercises (Figures 7-44 and 7-45).
- Begin isokinetics of shoulder girdle/upper extremity musculature (i.e., rotator cuff, biceps, triceps).
- Do wall push up progression (i.e., leaning on wall to leaning on bench to ½ or kneeling pushups to full pushups).
- Late phase: add "endurance" sets to all PREs.

FIGURE 7-44. Prone scapular strength "T" exercise.

FIGURE 7-45. Prone scapular strength "Y" exercise.

- Transition from hypertrophic (lower weight, higher volume and repetition maximum) to strength load (heavier load and lower repetition maximum with failure at 8 to 12 repetitions).

Neuromuscular Dynamic Stability Exercises

- Progress UE weight on unstable surface (i.e., unilateral wall ball perturbations)
- Body blade in end range positions and varying planes

Plyometrics

- Begin UE plyometrics (i.e., dribble on floor, progress to wall dribble)
- PlyoBall/medicine ball rebound and pass (Figure 7-46)

Functional Exercises

- Begin swimming at week 16.

Sport-Specific Exercises

- Overhead athletes begin throwing program (Figure 7-47): Thrower's Ten and interval throwing program
- Thrower's Ten[3]

FIGURE 7-46. Upper extremity plyometric weighted ball toss.

FIGURE 7-47. Resistance band overhead throwing exercise.

- UE agility exercises later in this phase (i.e., dribbling drills on floor and overhead onto wall, timed volleyball setting frills against wall)

Milestones for Progression to the Next Phase

- Strength 5/5 including RC, middle and lower trapezius and serratus anterior on manual muscle testing
- No pain or limitation with throwing program (for overhead athletes)

Phase VI: Advanced Functional Recovery and Return to Sport (weeks 24 to 52)

Goals

- Return to sport when full ROM and strength at 90% of contralateral extremity.
- Perform maintenance scapular stabilizing exercises and core strengthening
- Prevent future injury/AC joint preservation by constructing a maintenance program that parallels treatment of non-surgical AC joint disruption.
- Refer to the nonsurgical treatment section of this chapter.

Criteria for Return to Sport

General

- No pain with sport-specific movements
- Full active and passive shoulder ROM without pain as compared to the opposite extremity
- Strength greater than or equal to 90% of the contralateral extremity using manual muscle testing or Cybex

Sport-Specific

- Overhead (Racquet) athlete: Achieve GHJ ROM symmetrical as well as ROM of C/S and T/S within normal limits as measured with a goniometer.
- Overhead (throwing) athlete: Will require gradual return to throwing with structured throwing program. Close attention to restoring abduction, external rotation and eliminating glenohumeral internal rotation deficit is recommended. Scapular strength including serratus anterior, lower and middle trapezius, as well as hip rotator strength symmetrical on manual muscle testing.
- Contact sports: Pain-free loaded adduction symmetrical. Minimum 6 months before return to contact activities recommended for graft reconstruction.

Continuing Fitness or Rehabilitation Exercises

- Cardiovascular program, and cross training to avoid repetitive strain

- Interval training to include varying speeds and plyometrics
- Comprehensive balanced strength/weight training program for extremities and core
- Sport-specific agility drill program
- Progressive strengthening should be continued after return to sport (Maximum strength recovery occurs at approximately one year postoperatively.)

Exercises and Other Techniques for Prevention of Recurrent Injury

- No specific exercise may prevent risk of recurrence
- Risk is associated with activity level and type of activities being performed
- Taping to stabilize the AC joint, proper fitting footwear, uniform, shoulder padding and bracing
- Proper pregame warm-up program
- Maintenance stretching program
- No good evidence demonstrating the ability of these exercises and techniques to help prevent recurrence

Evidence

Cote M, Wojcik K, Gomlinski G, et al: Rehabilitation or acromioclavicular joint separations: operative and nonoperative considerations. *Clin Sports Med* 29:213–228, 2010.

This manuscript reviews the relevant literature on nonoperative and postoperative rehabilitation for AC joint injuries and recommends a treatment protocol. The rehabilitation protocol following AC joint reconstruction described is similar to that described in this chapter with prolonged immobilization based on the healing of the soft tissue graft to bone.

Culp L, Romani W: Physical therapist examination, evaluation, and intervention following the surgical reconstruction of a grade III acromioclavicular joint separation. *Phys Ther* 86:857–869, 2006.

This was a case report of a 34-year-old male who underwent an AC reconstruction. The patient was able to return to preinjury levels of function at 5 months from surgery. (Level V evidence)

Mazzocca AD, Santangelo SA, Johnson ST, et al: A biomechanical evaluation of an anatomical coracoclavicular ligament reconstruction. *Am J Sports Med* 34:236–246, 2006.

This study compared 42 cadaveric AC reconstructions randomly assigned to three groups: arthroscopic reconstruction, anatomic coracoclavicular reconstruction, and a modified Weaver-Dunn procedure. The Weaver-Dunn procedure was significantly more lax than the other two procedures, and the anatomic reconstruction had significantly less anterior and posterior translation.

Rios CG, Arciero CA, Mazzocca AD: Anatomy of the clavicle and coracoid process for the reconstruction of the coracoclavicular ligaments. *Am J Sports Med* 35:811–817, 2007.

This cadaveric study evaluated the osteology of the clavicle and coracoid as well as the anatomic location of the insertions of the coracoclavicular ligaments. The aim of this study was to develop an anatomical coracoclavicular reconstruction technique.

Rodeo SA, Arnoczky SP, Torzilli PA, et al: Tendon-healing in a bone tunnel. A biomechanical and histological study in the dog. *J Bone Joint Surg Am* 75:1795–1803, 1993.

This study evaluated the time for tendon to bone healing in a dog model. This group demonstrated that, after 12 weeks, tendons began failing due to intersubstance tearing rather than at the tendon bone interface, indicating the tendon had healed within the bone tunnel.

Multiple Choice Questions

QUESTION 1. What is the appropriate duration of postoperative immobilization following ACJR?

A. 3 weeks
B. 3 months
C. 4 weeks
D. 6 weeks

QUESTION 2. During the initial 6 weeks of postoperative rehabilitation, the ROM allowed is:

A. AROM to 90° flexion after 2 weeks of no GHJ ROM
B. PROM GHJ flexion to 90° in the scapular plane only after 2 weeks of no GHJ ROM
C. No PROM of GHJ until week 6
D. PROM flexion to 120° at week 4 and elbow AROM beginning postop day 1

QUESTION 3. Which of the following is a known complication following anatomic AC joint reconstruction?

A. axillary nerve palsy
B. short head of the biceps tendon rupture
C. clavicle fracture
D. proximal humerus fracture

QUESTION 4. What is the rate limiting step in terms of preventing failure following AC reconstruction and how long does this take?

A. soft tissue to bone healing, 6 weeks
B. soft tissue to bone healing, 3 months
C. biocomposite screw absorption, 6 months
D. graft remodeling, 4 weeks

QUESTION 5. What of the listed complications is not a theoretical or known complication of using a coracoid screw for temporary or permanent fixation?

A. potential musculocutaneous nerve injury
B. coracoid fracture
C. screw pull-out
D. acromial fracture

Answer Key

QUESTION 1. Correct answer: **D** (see Phase I, Protection)

QUESTION 2. Correct answer: **B** (see Phase I, Manual Therapy Techniques)

QUESTION 3. Correct answer: **C** (See Other Surgical Techniques and Options)

QUESTION 4. Correct answer: **B** (See Overview of Goals, Milestones and Guidelines)

QUESTION 5. Correct answer: **D** (See acromial fracture (D)

BEYOND BASIC REHABILITATION: RETURN TO ICE HOCKEY AFTER ACROMIOCLAVICULAR INJURY

Amy Resler, PT, DPT, CSCS, Wendell M.R. Heard, MD, Nathan A. Mall, MD, and Nikhil N. Verma, MD

Introduction

ASPECTS OF HOCKEY THAT REQUIRE SPECIAL ATTENTION IN REHABILITATION*

- In the case of acromioclavicular joint injuries in ice hockey, several intrinsic characteristics of the sport itself must be taken into account while rehabilitating an athlete to return to play.
- The contact sport routinely involves direct blows, checking opposing players, and frequent falls.
- In addition, the low friction surface of ice provides an unstable platform for players while shooting, propelling, and checking.
- The high anaerobic requirements of hockey must also be considered when determining whether a player is sufficiently fit to return.

*The same criteria and procedures are employed to return a patient back to weightlifting.

- It has been shown that in men's collegiate hockey in the United States, collisions with an opponent can cause as many as 32.8% of injuries, whereas collisions with the boards account for 18.6% of all injuries.[1]
- Overall the injury rate in hockey is 4.9 per 1000 athletic exposures, with an athletic exposure being defined as a single player participating in a single game or practice.[1] In this study, acromioclavicular joint injuries were the third most common injury behind concussion and medial collateral ligament sprains.[1]
- Another study of 77 hockey players by Norfray[2] demonstrated that 45% had asymptomatic x-ray abnormalities, which included osteolysis of the acromioclavicular joint and callus from united and nonunited distal clavical fractures.
- Despite these injuries, Pettersson and Lorentzon showed that only one in four players with acromioclavicular joint separation were shown to miss more than 1 week of practice or games.[3]
- Gladstone et al.[4] have provided the current rehabilitation program for athletes suffering an AC joint injury. Phase I consists of ice and short-term immobilization with sling use of up to 2 weeks. Pain and inflammation reduction with subsequent range of motion exercises are the goals. Active assisted motion is advanced in the pain-free patient.
- Phase II begins when 75% of motion is regained, AC joint palpation produces minimal pain, and there is 4/5 manual muscle testing for the deltoid and upper trapezius. Phase II concentrates on advancing to full pain-free motion and increasing isotonic strength. Strengthening of the deltoid, trapezius, and rotator cuff is emphasized. Once full, painless range of motion is achieved with no tenderness to palpation of the AC joint and muscle strength 75% of the contralateral side, Phase III is begun.
- Phase III strengthens the shoulder and increases power and endurance using plyometric drills and isotonic exercises. When isokinetic strength is equal to the other side.
- Phase IV is started and concentrates on sport-specific drills.

Phase I: Advanced Strength and Conditioning Programs

Periodization

- Rehabilitation of the immediate postoperative patient must be separated from the postinjury patient.
- In patients undergoing nonoperative treatment, Phase I can begin once the patient has adequate pain control. The total rehabilitation time in such a case is 6 to 8 weeks.
- The postoperative patient, however, should be strictly immobilized for the first 6 weeks after injury. During this time, range of motion of the wrist, hand, and fingers can be performed. To protect the repair from having to support the entire weight of the arm, elbow range of motion exercise should only be performed in the supine position with a pillow under the elbow for support.

- After this initial 6-week period of immobilization, the Phase I regimen can be started.
- Phase I begins following the initial postoperative or postinjury period during the athlete's off-season.
- This mesocycle occurs for approximately 6 to 8 weeks in the postoperative patient.
- The nonoperative patient will be in Phase I until 75% of motion is regained, AC joint palpation produces minimal pain, and there is 4/5 manual muscle testing of the deltoid and upper trapezius.

Program Design/Performance Training Program

Sport-Specific Concepts of Integrated Training

- Flexibility/joint mobility for joint stability
- Sensorimotor and balance training
- Training for optimum muscle balance
- Neuromuscular dynamic stability exercises
- Functional training

Training Principles Used in the Design of the Program

- Principle of progression
- Principle of overload

Application of Acute Training Variables

- Phase I is the hypertrophy or endurance phase. The focus is on balancing muscle groups, in particular the shoulder girdle, in order to stabilize the acromioclavicular (AC) joint. This phase is particularly important for reconditioning following an injury or surgery, as well as for prevention of injury, re-injury, or surgical failure.
- It has been proposed that capillarization occurs during this time, which is necessary for strength optimization in the later training phases.
- Phase I training regimens involve high repetitions of low loads performed to isolate opposing muscle groups. These are carried out at low intensity with the focus on body mechanics and avoiding compensatory strategies.
  - Repetitions: 12 to 25
  - Sets: 2 to 4
  - Rest interval: 1 minute
  - Intensity: low
  - Repetition tempo: slow, progressing to moderate as approaching next phase
  - Training frequency: 2 to 4 days per week
  - Training duration: 30 to 60 minutes
  - Training volume: sum of all repetitions performed during one session
  - Specific exercises used in the training
    - Shoulder girdle
- Three-way shoulder raise
- Chest press
- Seated rows
- One-arm dumbbell row and latissimus dorsi row
- Latissimus dorsi pulls
- Bent-over row
- Chest fly
- Rotator cuff program with pulleys
  - Elbow
- Triceps press
- Biceps curl
  - Forearms
- Wrist curls
- Pronation

TIMELINE 7-5: **Returning to Hockey After AC Joint Injury: Nonoperative Treatment**

PHASE I (weeks 1 to 6)	PHASE II (weeks 4 to 8)	PHASE III (weeks 6 to 12)
• Time of injury until 75% of motion is regained. AC joint is minimally tender to palpation, and there is 4/5 manual muscle strength of deltoid and upper trapezius. • Repetitions: 12 to 25 • Sets: 2 to 4 • Rest Interval: 1 min • Intensity: low • Rep tempo: slow to moderate • Duration: 3 to 60 min • Frequency: 2 to 4 days/week • Shoulder: shoulder raises, chest press/fly, rows, lat pull, rotator cuff • Elbow: triceps press, biceps curl • Forearm: wrist curl, pronation, supination • Legs/hip: leg press, squats, glute press, hamstring curl, glute/calf raise • Vestibular/balance: posturography, unstable surgace progression • Functional: fitter, side-to-side slide board, thoracic spine ROM • CV: rowing machine, jogging, stationary cycling, skating • Flex/stretch: shoulder girdle, adductors, quads	• Begins with 75% of motion is regained, AC joint is minimally tender to palpation, and there is 4/5 manual muscle strength of deltoid and upper trapezius. Phase II will continue until full painless range of motion is achieved, there is no tenderness to palpation of the AC joint, and strength is 75% of the contralateral side. • Repetitions: 8 to 12 • Sets: 3 to 5 • Rest interval: 1 min • Intensity: moderate • Rep tempo: slow to moderate • Duration: 3 to 60 min • Frequency: 3 to 4 days/week • Shoulder: bench press, incline, decline, dumbbells • LE: multi-planar lunge, step-ups, kettlebell lawnmowers, cable pulleys, diagonals, crossovers • Vestibular/balance: perturbation on unstable surface • Functional: push-ups, planks, unstable surface planks, abdominals • CV: increase intensity, rowing, running, cycling, elliptical, skating	• Begins when full painless range of motion is achieved, there is no tenderness to palpation of the AC joint, and strength is 75% of the contralateral side. Phase III will continue until isokinetic strength is equal to the other side. • Repetitions: 3 to 6 (max) • Sets: 3 to 5 • Rest interval: 3 to 5 min • Intensity: moderate-high • Rep tempo: moderate-high • Duration: 30 to 90 min • Frequency: 1 to 3 days/week • Add power load to strength exercises • Olympic lifts: snatch, power clean • Plyometrics: PlyoBall sit-ups, drop-catch push-ups, medicine ball plyopass, LE bounding • Sprints, drills, agility, running with resistance • Obstacles, cutting, punching bag, "check" drills • Falls and "checks: strategies • Low level skating/shooting drills • Focus on recover, stretching, flexibility • Adequate nutrition, hydration • Injury prevention: shoulder pads, taping

- Supination
  - Legs/hip Girdle
- Unilateral leg press
- Squats using Smith machine
- Four-way hip machine
- Glute press
- Hamstring curls
- Calf raises
- Glute-hamstring raise
  - Vestibular and balance training
- Posturography
  - Lui and colleagues[5] found that use of a sling for immobilization following shoulder injury affects balance and decompensates the vestibular system. They used computerized dynamic posturography (CDP). CDP makes an objective assessment of balance and postural stability by providing a dynamic test condition.
  - In addition, Alpini and colleagues[6] propose that the vestibular systems of ice hockey players are particularly stressed due to the brisk movements of the game. The proprioceptive input to the vestibular system from the ice as a stable surface is not reliable. This is another challenge to the motor control and balance of the ice hockey athlete.
  - This equipment, commonly known as the Equitest is used for evaluation and training or rehabilitation purposes in rehabilitation, physical therapy and athletic training centers. The authors feel that the addition of posturography training would be an excellent adjunct in the rehabilitation program for return to hockey following sling use.
- Unstable surface balance—B LE to U LE progression
  - Functional exercises
- Fitter
- Side-to-side slide board
- Thoracic spine range of motion exercises
  - Cardiovascular training
- Rowing machine
- Jogging
- Stationary cycling
- Upper body ergometer
- Skating

Application of Chronic Training Variables

- Cardiovascular conditioning is performed during this phase, though at low intensity, and for moderate to long duration.
- Flexibility and stretching—in particular across the shoulder girdle (to focus on the pectoralis major, pectoralis minor, and levator scapulae), adductors, and quadriceps—are integrated into the training program.

Phase II: Performance Enhancement Training Techniques

Periodization

- Phase II is initiated at about 12 weeks after surgery for the postoperative patient.
- The nonoperatively treated patient will begin Phase II when 75% of motion is regained, AC joint palpation produces minimal pain, and there is 4/5 manual muscle testing for the deltoid and upper trapezius.
- Phase II will continue until full, painless range of motion is achieved, with no AC joint tenderness and muscle strength at 75% of the contralateral side.

Program Design/Performance Training Program

Sport-Specific Concepts of Integrated Training

- Core training
- Cardiorespiratory training
- Multi-planar training activities
- Training for optimum muscle functional strength
- Training for optimum muscle functional power
- Training for speed, agility, quickness (SAQ)
- Sport-specific training

Training Principles Used in the Design of the Program

- Principle of progression
- Principle of overload
- Principle of variation
- Principles of specificity—specific adaptation to imposed demands (SAID)

Application of Acute Training Variables

- Phase II is the strength phase. The goal here is to maximize strength at varying speeds and joint angles, with a decreased base of support, taking measures not to use compensatory muscles or re-injure the AC joint. Compared to the previous phase, Phase II calls for an increase in load, with an accordant decrease in the number of repetitions.
- Repetitions: 8 to 12
- Sets: 3 to 5
- Rest interval: 1 minute
- Intensity: moderate
- Repetition tempo: low to moderate
- Training frequency: 3 to 4 days per week (alternating days, no consecutive days of same muscle group)
- Training duration: 30 to 60 minutes
- Training volume: the amount lifted or number of repetitions per the training session
- Specific exercises used in the training
  - Continue Phase I shoulder girdle, elbow, wrist, and lower extremity exercises, incorporating modified acute training variables (increased load and intensity; decreased number of repetitions)
  - Advance chest press to bench press, incline, and decline; progress from using bar to using dumbbells
  - Add multi-planar lunging, step-ups, kettle bell lawnmowers, cable pulleys, diagonals, and crossovers
  - Vestibular and Balance training: include perturbation on unstable surfaces
  - Functional exercises: pushups, planks, unstable surface planks, abdominals
  - Cardiovascular training: increase intensity of rowing, cycling, running, elliptical, and skating
  - Body blade

Phase III: Sport-Specific Training

Periodization

- Phase III takes place during weeks 20 to 26 of the rehabilitation program in the postoperative patient.
- The nonoperatively treated patient will progress to Phase III when full, painless range of motion is achieved with no AC joint tenderness and muscle strength 75% of the contralateral side.
- Phase III will continue until isokinetic strength is equal to the other side.

Program Design/Performance Training Program

Sport-Specific Concepts of Integrated Training

- Cardiorespiratory training
- Multi-planar training activities
- Training for optimum muscle functional power
- Neuromuscular dynamic stability exercises
- Training for speed, agility, quickness (SAQ)
- Plyometric training
- Sport-specific training

Olympic Lifts Used in the Training Program

- Snatch
- Power clean

Training Principles Used in the Design of the Program[7]

- Principle of progression
- Principle of overload
- Principle of variation
- Principle of individualization
- Principles of specificity—Specific Adaptation to Imposed Demands (SAID)

Application of Acute Training Variables

This mesocycle is the power phase. The load is high, a 3 to 6 repetition maximum and the repetitions are decreased. Olympic lifts will be incorporated in this phase.

- Repetitions: 3 to 6
- Sets: 3 to 5
- Rest interval: 3 to 5 minutes
- Intensity: moderate to high
- Repetition tempo: moderate to high
- Training frequency: 1 to 3 times per week
- Training duration: 30 to 90 minutes
- Training volume: number of repetitions or amount lifted per duration of session
- Specific exercises used in the training
  - Add power load to strengthening exercises
  - Add Olympic lifts (snatch, power clean)
  - Add plyometrics: PlyoBall sit ups, drop-catch pushups, medicine ball plyopass, LE bounding
  - Sprints, drills, agility, running with resistance cords or weighted sled
  - Integrate plyometrics and agility to interval training drills
  - Obstacles, cutting, punching bag, "check" drills
  - Falls and "checks" strategies (i.e., rolling, protect shoulder and AC joint)
  - Low-level skating drills
  - Low-level shooting drills
    - Wrist shot
    - Slap shot
    - Work on upper body/trunk rotation
    - Upper trunk rotation in quadruped
    - Alternate medicine ball pass rotating to partner behind

Application of Chronic Training Variables

- Given that exertion in hockey is 2/3 anaerobic and 1/3 aerobic, interval and cardiovascular training must match this ratio. It is important to maximize functional training and sport-specific training during Phase III to include scrimmages.
- Power training or plyometrics should not be performed on the same day as scrimmage, or on the days before or after; the training schedule will thus need to be appropriately manipulated.
- Recovery is especially important during Phase III, as is an awareness of adequate nutrition and hydration.

TIMELINE 7-6: **Returning to Hockey after AC Joint Injury: Operative Treatment**

PHASE I (weeks 1 to 6)	PHASE II (weeks 6 to 12)
• Strict sling immobilization; no shoulder range of motion • Finger, hand, wrist range of motion • Elbow range of motion in the supine position with the elbow supported	• Repetitions: 12 to 25 • Sets: 2 to 4 • Rest interval: 1 min • Intensity: low • Rep tempo: slow to moderate • Duration: 30 to 60 minutes • Frequency: 2 to 4 days/week • Shoulder: shoulder raises, chest press/fly, rows, lat pull, rotator cuff • Elbow: triceps press, biceps curl • Forearm: wrist curl, pronation, supination • Legs/Hip: leg press, squats, glute press, hamstring curl, glute/calf raise • Vestibular/Balance: posturography, unstable surface progression • Functional: fitter, side-to-side slide board, thoracic spine ROM • CV: rowing machine, jogging, stationary cycling, skating • Flex/stretch: shoulder girdle, adductors, quads

- There is an emphasis on stretching and flexibility during this phase, as increased muscle soreness is expected secondary to plyometrics. In addition to shoulder girdle stretching, the adductors and quadriceps should be stretched, as adductor and patellar tendinopathies are common hockey injuries.
- Prevention from re-injury is equally important, and as such, proper equipment, including special shoulder pads, should be worn during practice and scrimmage to protect the AC joint. For hockey players a doughnut or spider pad can be used to protect the area and reduce the pain of a repeated impact.[8]
- Taping techniques can be applied to stabilize the joint as well. It is important to remember that with an anatomic surgical reconstruction of the AC joint, drill holes are made in the clavicle. Athletes should be made aware that there is a risk of fracture through these drill holes even after they have completed the rehabilitation protocol and returned to hockey.

Phase IV: Return to Sport or Performance Readiness Testing

Recommended Ongoing Exercises

- Recommend ongoing training programs as described in Phase II and III

Sports Performance Testing

General Information

- General history
- Subjective questionnaires
- Medical history—including history of tobacco use
- Sports injury history—assess prior injuries or new injuries that may have been sustained during off-season, preseason training, or scrimmage
- Surgical history—assess prior surgeries or recent unrelated surgeries that may have been performed during the off-season

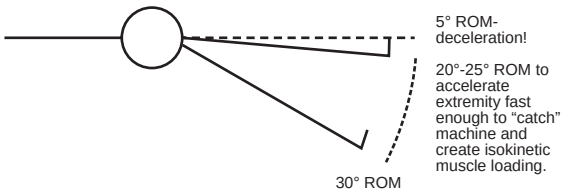

FIGURE 7-48. Acceleration and deceleration range of motion (ROM) with short-arc isokinetic exercise. *(Reprinted with permission from A Compendium of Isokinetics in Clinical Usage and Rehabilitation Techniques. 4th edition. Copyright 1992, S&S Publishers.)*

- Chronic conditions/medication—assess for respiratory condition, cardiac condition, head injuries, concussions, vestibular disease, systemic diseases

Specific Criteria for Progression to the Next Stage to Determine Readiness for Hockey

- Objective tests
  - VO_2 max/submax test when the athlete has history of "ice hockey" lung or recent respiratory illness
  - Side to side symmetry in ROM, strength, and mechanics of involved and uninvolved UE
- Objective questionnaires.
  - DASH.

Specific Criteria for Release to Unsupervised Complete Participation in Hockey

- Although the Kerlan-Jobe Orthopedic Clinic (KJOC) Shoulder and Elbow Questionaire[9] is a sensitive subjective measurement for detection of upper extremity dysfunction, it is generally applied to the overhead athlete. In addition, it is not a functional screen for return to sport. There is a lack of validated functional tests to assess readiness for return to sport following shoulder injury.
- Ellenbecker and Davies[10] propose functional tests and an isokinetic testing algorithm as a measure for readiness and successful return to sport. Davies Closed Kinetic Chain Upper Extremity Stability Test (Figure 7-48) has been found to be a highly reliable clinical tool.

TIMELINE 7-6: **Returning to Hockey after AC Joint Injury: Operative Treatment** (Continued)

PHASE III (weeks 12 to 20)	PHASE IV (weeks 20 to 26)
• Repetitions: 8 to 12 • Sets: 3 to 5 • Rest interval: 1 min • Intensity: moderate • Rep tempo: slow to moderate • Duration: 30 to 60 min • Frequency: 3 to 4 days/week • Shoulder: bench press, incline, decline, dumbells • LE: multi-planar lunge, step-ups, kettlebell, lawnmowers, cable pulleys, diagonals, crossovers • Vestibular/balance: perturbation on unstable surface • Functional: push-ups, planks, unstable surface planks, abdominals • CF: increase intensity, rowing, running, cycling, elliptical, skating	• Repetitions: 3 to 6 (max) • Sets: 3 to 5 • Rest interval: 3 to 5 min • Intensity: moderate-high • Rep tempo: moderate-high • Duration: 30 to 90 min • Frequency: 1 to 3 days/week • Add power load to strength exercises • Olympic lifts: snatch, power clean • Plyometrics: PlyoBall sit-ups, drop-catch push-ups, medicine ball, plyopass, LE bounding • Sprints, drills, agility, running with resistance • Obstacles, cutting, punching bag, "check" drills • Falls and "check" strategies • Low level skating/shooting drills • Focus on recovery, stretching, flexibility • Adequate nutrition, hydration • Injury prevention: shoulder pads, taping

Evidence

Alpini D, Hahn A, Riva D: Static and dynamic postural control adaptations induced by playing ice hockey. *Sport Sci Health* 2:85–92, 2008.

In this study among elite and amateur hockey players and healthy controls, the authors performed sensory organization, head stabilization stance and step testing. They concluded that ice hockey practice induces modifications in static and dynamic postural control. (Level II evidence)

Bradley JP, Elkousy H: Decision making: operative versus nonoperative treatment of acromioclavicular joint injuries. *Clin Sports Med* 22:277–290, 2003.

This review discusses the types of AC joint injuries as described in the classification system of Allman and Tossy (revised by Rockwood). The authors acknowledge the controversy over management of Type III AC joint injuries and agree with the consensus regarding initial conservative treatment of these injuries.

Flik K, Lyman S, Marx RG: American collegiate men's ice hockey: An analysis of injuries. *Am J Sports Med* 33:183–187, 2005.

In this prospective cohort study among Division I men's collegiate hockey, the authors found the following statistics regarding injuries: Collision with an opponent (32.8%) or the boards (18.6%) caused more than half of all injuries. Concussion (18.6%) was the most common injury, followed by MCL sprains, acromioclavicular joint injuries, and ankle sprains. (Level II evidence)

Lui DF, Mermon A, Kwan S, et al: Computerized dynamic posturography analysis of balance in individuals with a shoulder stabilization sling. *Eur J Trauma Emerg Surg* Published online. 28, June 2013.

The authors conclude that sling immobilization affects balance. Computerized dynamic posturography (CDP) was applied as a valid measure to objectify the balance decompensation. They suggest that sling use is important for healing shoulder injuries, however, when early range of motion without a sling can be promoted, it may potentially limit falls related to balance disturbance from the use of a sling. (Level II evidence)

Multiple-Choice Questions

QUESTION 1. What is the typical rehabilitation time for AC joint injuries that are treated nonoperatively?

A. 2 to 4 weeks
B. 6 to 8 weeks
C. 12 to 14 weeks
D. 16 to 18 weeks

QUESTION 2. After surgical reconstruction of the AC joint, for how long should the extremity be immobilized?

A. 2 weeks
B. 4 weeks
C. 6 weeks
D. 8 weeks

QUESTION 3. Which phase of the rehabilitation protocol is the first to use plyometric training and Olympic lifts?

A. Phase I
B. Phase II
C. Phase III
D. Phase IV

QUESTION 4. At what point does the nonoperatively treated patient progress from Phase III to Phase IV?

A. When palpation of the AC joint is not painful
B. When VO_2 testing is normal
C. When range of motion is equal to the opposite side
D. When isokinetic strength is equal to the opposite side

QUESTION 5. Patients who undergo anatomic reconstruction of the AC joint are at a theoretical increased risk for which of the following?

A. Sternoclavicular joint dislocation
B. Rotator cuff tear
C. Clavicle fracture
D. Biceps tendon rupture

Answer Key

QUESTION 1. Correct answer: **B** (see Phase I: Advanced Strength and Conditioning Programs)

QUESTION 2. Correct answer: **C** (see Phase I: Periodization)

QUESTION 3. Correct answer: **C** (see Phase III: Application of Acute Training Variables)

QUESTION 4. Correct answer: **D** (see Phase III: Periodization)

QUESTION 5. Correct answer: **C** (see Phase III: Application of Chronic Training Variables)

NONOPERATIVE REHABILITATION OF CLAVICLE FRACTURES

Theresa A. Chiaia, PT, DPT, Miho J. Tanaka, MD, and Christopher S. Ahmed, MD

GUIDING PRINICPLES OF NONOPERATIVE REHABILITATION

- Understand the healing rates of clavicular fractures
- Avoid positions and movements that place the most stress on fracture stability and healing
- Avoid painful ROM and/or strengthening exercises
- Avoid placing stress on the clavicle until radiographic union
- Achieve painless full range of motion and nearly symmetrical strength before return to play

Introduction

- Clavicle fractures (Figure 7-49) had historically been treated with figure-of-eight bracing, hoping that it would aid in maintaining the alignment and length of the clavicle.
- However, studies have shown that treatment of clavicle fractures in a simple sling have had comparable results with fewer complications. Therefore, nonoperative management of clavicle fractures is generally performed with a simple sling (Figure 7-50).

Phase I (weeks 0 to 6)

Goals

- Protect the healing fracture
  - Sling immobilization
- Promote patient compliance through patient education with:
  - Activity modification (axial load, distractive/traction forces, active arm elevation, and ROM above shoulder height)
  - Use of sling

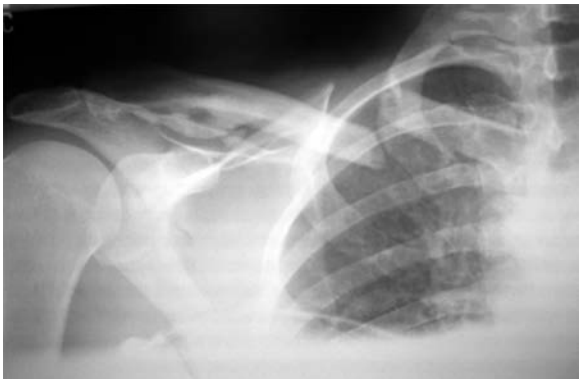

FIGURE 7-49. Clavicle fractures without significant shortening or displacement can be treated nonoperatively.

FIGURE 7-50. The injured extremity is immobilized in a sling.

- Minimize rotator cuff inhibition
- Ensure proper balance and gait while wearing a sling
- Maintain conditioning (exercise bike, ambulation)
- Check for glenohumeral stiffness and consider early gentle ROM exercises (limited to <90° abduction and forward flexion) if necessary
- Maintain scapular mobility

Protection

- Sling immobilization at all times.
- Resting positions: lying supine with pillow support; lying on the contralateral side with pillow support; lying on the ipsilateral side, as well as, without pillow support on the opposite side, is contraindicated

Management of Pain and Swelling

- Oral pain medications
- Resting positions: UE positioned on a pillow with the arm supported in the scapular plane.
- Education in activity modification and importance of sling immobilization
- Therapeutic modalities:
  - Cryotherapy
  - Transcutaneous electrical nerve stimulation (TENS)

Techniques for Progressive Increase in Range of Motion

Manual Therapy Techniques

- Initiate manual therapy techniques for IR and ER in the plane of the scapula

Soft Tissue Techniques

- Myofascial release for pectorals, trapezius
- Stretching/flexibility techniques for the musculotendinous unit:
- AROM wrist extension/flexion; pronation/supination; elbow flexion/extension with arm at side; gripping exercises

Stretching and Flexibility Techniques for the Musculotendinous Unit

TBS

- Can be incorporated early while wearing the sling
- Exercises that challenge the individual's balance are discouraged
- Stationary cycling and elliptical trainer

Core stability

- Lower abdominals; hip musculature (seated machines)

TLS

- The patient can perform exercises that do not stress the repair site, or present the risk of falling, such as ball squats, seated LE machines for hamstrings, quads, and hip musculature
- Contraindication:
  - Leg press with shoulder pads
  - Carrying weights which create distractive forces.

Activation of Primary Muscles Involved

- Muscle activation of the primary muscles (pectorals, anterior deltoid, upper trapezius, SCM) is not indicated during this healing phase
- Postural retraining (Figure 7-51)
- Submaximal rotator cuff isometrics in the plane of the scapula (PoS).

Techniques to Increase Muscle Strength, Power, and Endurance

- Postural exercises such as scapular retraction to neutral and lower trapezius isometrics may be initiated
  Neuromuscular Dynamic Stability Exercises

FIGURE 7-51. Postural training is initiated to avoid forward shoulder posture.

- Pain-free, submaximal IR/ER rhythmic stabilization exercises in the plane of the scapula may be initiated in this phase if adequate ROM is present (30° ER)

Milestones for Progression to the Next Phase

- No pain at rest
- Pain and swelling controlled
- Radiographic evidence of union

Phase II (weeks 6 to 10)

Goals

- Discontinue sling
- Limit ROM to 90° abduction and forward flexion
- Begin progressive ROM when signs of radiographic healing

TIMELINE 7-7: **Rehabilitation After Clavicle Fracture**

PHASE I (weeks 1 to 6)	PHASE II (weeks 6 to 10)
• Sling immobilization • Patient education: sling, activity modification • PT modalities, prn • AROM of elbow, wrist, hand • AAROM of shoulder for plane of scapula IR/ER • Myofascial release for pectorals • Postural retraining • Codman's exercises • Isometric rotator cuff strengthening as tolerated • TBS/TAS/TLS activities as recommended and tolerated	• Discontinue sling • PT modalities, prn; moist heat, cryotherapy • Patient education: activity modification, carrying heavy weights • ROM—Start scapular plane elevation, PROM, AAROM • Manual therapy, evaluation-based: joint mobilization • Soft-tissue techniques, evaluation-based: pectorals, subscapularis, latissimus, trapezii. • Pendulums • Isometric strengthening of deltoid, trapezius • Rotator cuff strengthening: PREs • Periscapular strengthening exercises • Hydrotherapy • Upper body ergometry, limited arc • CKC physioball stabilization • Rhythmic stabilization • PROM limited to <90° of abduction • TBS/TAS/TLS activities as recommended and tolerated

- Avoid pain with ADLs, exercise
- Avoid distractive forces
- Minimize rotator cuff inhibition
- Compliance with home exercise program
- Normalized scapulohumeral rhythm to 90° scapular plane elevation to shoulder height

Protection

- Discontinue sling.
- Limit active abduction/flexion to 90°.
- Pillow support for sleeping will be used to avoid deleterious positions such as side lying on ipsilateral side and unsupported lying on the contralateral side.

Management of Pain and Swelling

- Oral pain medications, prn; however, pain should be controlled without meds through safe progression of therapeutic exercise and introduction of activities into daily life
- Cryotherapy
- Patient education in:
  - UE positioning
  - Activity modification

Techniques for Progressive Increase in Range of Motion

Manual Therapy Techniques

- ROM exercises: passive-to-active assistive-ROM of shoulder flexion/abduction, ER at 90° abduction, IR, scapular mobility in sidelying.
- Evaluation based glenohumeral, sternoclavicular, and acromioclavicular joint mobilization

Soft Tissue Techniques

- Scapular mobilization to maintain mobility
- Therapeutic massage for the pectorals, subscapularis, posterior cuff, latissimus, trapezii

FIGURE 7-52. After signs of healing, flexion ROM exercises in the plane of the scapula can be performed to maintain glenohumeral motion.

Stretching and Flexibility Techniques for the Musculotendinous Unit

- Passive-AAROM exercises for shoulder flexion are performed in sitting or standing with the arm positioned in the plane of the scapula (Figure 7-52). ROM exercises for shoulder IR and ER may be performed in supine in the plane of the scapula.
- Increase ER at 90° abduction with cane/stick.
- Pulleys can be initiated with adequate humeral head control and ROM of approximately 130°.
- Can begin doorway or corner stretch for pectorals (major and minor).
- Supine "T towel" positioning, with a towel roll positioned along the spine, and a second along the base of the head, is recommended to promote thoracic extension, and to allow the anterior positioned humeral head to sit back.
- Pendulum exercises

TIMELINE 7-7: **Rehabilitation after Clavicle Fracture** (Continued)

PHASE III (weeks 10 to 14)	PHASE IV (weeks 15 to 20)
• PT modalities, prn • Pulleys • Upper body ergometry • ROM: evaluation-based • Manual therapy: evaluation-based • Doorway stretch • Achieve full ROM • Rotator cuff PREs • Periscapular strengthening PREs: advance to prone exercises • TBS/TAS/TLS activities as recommended and tolerated	• PT modalities, prn: cryotherapy • RO: evaluation-based • Rotator cuff PREs: 90/90 position • Advanced periscapular strengthening • PNF diagonal patterns • Sport-specific exercises • RTP may differ by sport, hand dominance • TBS/TAS/TLS activities as recommended and tolerated

Other Therapeutic Exercises

TBS

- Stationary cycling, elliptical, and in latter phase, begin pain-free utilization of upper body with c-v equipment.

Core

- Lower abdominals, bridging, gluteals

TAS

- Avoid carrying heavy weights and traction forces with training program.
- Perform pain-free exercise within the available ROM such as biceps curls, triceps curls, scapular retraction, scapular protraction, extension.
- Latter phase: Upper body ergometry; use of arms in c-v equipment (elliptical, bicycle) pain-free.

TLS

- Emphasize sports specific training exercises including:
- Squats, RDLs, knee extension, knee flexion.
- Machines for hip abd/add, gluteals.

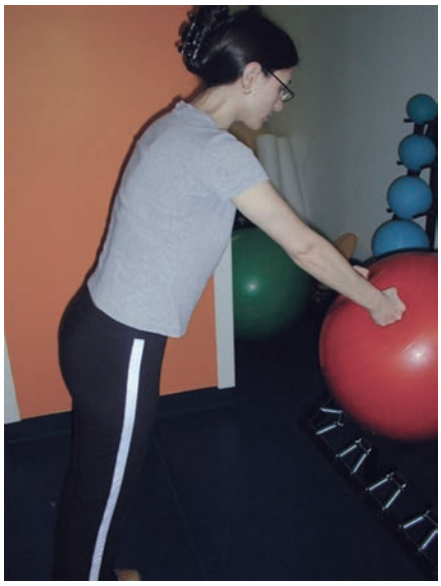

FIGURE 7-53. CKC physioball scapular stabilization exercises below horizontal are initiated with double arm support.

Activation of Primary Muscles Involved

- Scapular stabilization exercises beginning in supported sidelying position and progressing to manual strengthening, then to resisted exercises such as shrugs, forward flexion in the plane of the scapula, and in latter phase, begin supine bench press with light weights (arms below shoulder height).

Sensorimotor Exercises

- Hydrotherapy
- Rhythmic stabilization
- Physioball scapular stabilization, CKC.

Open and Closed Kinetic Chain Exercises

- CKC exercises such as physioball scapular stabilization exercises below horizontal are initiated with double arm support (Figure 7-53)

Techniques to Increase Muscle Strength, Power, and Endurance

- Progressive strengthening of the scapular musculature such as rhomboids, serratus anterior, lower trapezius to begin to address force couple involved in shoulder flexion/abduction.
- Rotator cuff strengthening is progressed from submaximal isometrics to isotonics (ER in side lying position to elastic bands).
- Forward elevation in the plane of the scapula—full can—is initiated with evidence of good scapulohumeral rhythm
- Hydrotherapy exercises are utilized for its buoyancy and hydrostatic properties
- In latter phase, begin pain-free, upper body ergometry may be initiated at this time.

Neuromuscular Dynamic Stability Exercises

- Continue with rhythmic stabilization exercises, progressing to more challenging positions, such as greater angles of ER, without towel roll support, and at shoulder height) (Figure 7-54)
- Perturbation in latter phase with adequate strength base with arm close to side

FIGURE 7-54. Rhythmic stabilization exercises below horizontal are imitated with double arm support.

Functional Exercises

- Begin scapula plane elevation—full can position—to shoulder height when good, pain-free scapulohumeral rhythm is evident (no shrug).
- Hydrotherapy may be used initially to provide environment for active-assistive exercise.

Milestones for Progression to the Next Phase

- Normal ER ROM in the plane of the scapula
- Shoulder flexion/abduction PROM to >90°

- Normal scapulo-humeral rhythm with PoS shoulder flexion to shoulder height
- 0/10 pain with exercise progression, and ADLs
- Compliance with home exercise program

Phase III (weeks 10 to 14)

Goals

- Achieve full range of motion
- Begin progressive overhead activities
- Progressive shoulder strengthening

Management of Pain and Swelling

- Pain should be controlled without medication

Techniques for Progressive Increase in Range of Motion

Manual Therapy Techniques

- Evaluation based SC, AC, GH joint mobilization, as necessary
- ROM exercises for flexion, abduction, ER at 90° abduction, IR
- Scapular mobility in side lying position

Soft Tissue Techniques

- Therapeutic massage for the pectorals, subscapularis, trapezii, posterior cuff, latissiumus

Stretching and Flexibility Techniques for the Musculotendinous Unit

- Increase ER at 90° with cane/stick.
- Pulleys can be initiated with adequate humeral head control and ROM of approximately 130°
- Doorway or corner stretch for pectorals (major and minor)
- Evaluation-based posterior cuff, posterior capsule, as necessary
- Evaluation-based ROM exercises, as necessary

Other Therapeutic Exercises

TBS

- Stationary cycling, elliptical, utilization of upper body with c-v equipment, pain-free

Core

- Lower abdominals, bridging, gluteals

TAS

- Avoid carrying heavy weights and traction forces with training program.
- Perform pain-free exercise within the available ROM such as biceps curls, triceps curls, scapular retraction, scapular protraction, extension (dumbbell row).
- Upper body ergometry; use of arms in c-v equipment (row, elliptical, bicycle) progresses pain-free.

TLS

- Emphasize sports-specific training exercises including:
  - Squats, RDLs, knee extension, knee flexion, side lying hip abduction
  - Machines for hip abd/add, gluteals

Activation of Primary Muscles Involved

- Scapular stabilization exercise progression
- Forward flexion in plane of scapula—full can position (Figure 7-55)
- Supine chest press with light weights, arms below shoulder height

Sensorimotor Exercises

- Hydrotherapy
- Rhythmic stabilization
- Physioball stabilization
- PNF diagonal patterns, D2 flexion/extension in supine

Open and Closed Kinetic Chain Exercises

- CKC exercises such as physioball scapular stabilization exercises can progress to single arm as tolerated
- Pushup progression, arms below shoulder height
- Quadruped position

Techniques to Increase Muscle Strength, Power, and Endurance

- Progressive, advanced periscapular strengthening such as prone exercises for lower trapezius, middle trapezius, latissimus to continue to address force couple involved in shoulder flexion/abduction.
- PREs for the rotator cuff, progressing from side lying to elastic band exercises.
- Forward flexion in the plane of the scapula
- Upper body ergometry, cycle, Airdyne

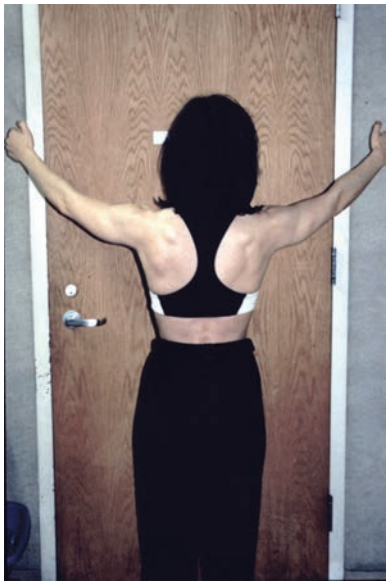

FIGURE 7-55. Forward flexion in plan of scapula—full can position.

Neuromuscular Dynamic Stability Exercises

- Continue with rhythmic stabilization exercises
- Perturbation in later phase with adequate strength base with arm close to side

Functional Exercises

- Shoulder flexion in the PoS
- Pushing activities such as wall push-ups

Milestones for Progression to the Next Phase

- Normal scapulo-humeral rhythm above shoulder
- ROM WNLs
- 0/10 pain with exercise progression and ADLs

Phase IV (weeks 15 to 20)

Management of Pain and Swelling

- Safe exercise progression
- Monitor for swelling

Techniques for Progressive Increase in Range of Motion

- Maintain ROM or if not FROM, please refer to Phase III

Other Therapeutic Exercises

- Without restriction

Activation of Primary Muscles Involved

- Chest press
- Shrugs
- Push-ups

Sensorimotor Exercises

- PNF diagonal pattern progressions to D1 flexion/extension
- Upright posture with elastic bands

Open and Closed Kinetic Chain Exercises

- Progress to single arm ball stabilization
- Pushup progression

Techniques to Increase Muscle Strength, Power, and Endurance

- Advanced periscapular strengthening
- Rotator cuff strengthening in 90/90 position

Neuromuscular Dynamic Stability Exercises

- Body blade
- Ball stabilization exercises (single arm)
- PNF diagonal patterns

Plyometrics

- Activity-specific plyos
- Ball tosses: chest pass, overhead pass
  Functional Exercises
- PNF diagonal pattern progressions

Sport-Specific Exercises

- Throwing program

Milestones for Progression to Advanced Sport-Specific Training and Conditioning

- Radiographic signs of fracture union
- Full, painless range of motion of affected shoulder
- Near symmetric strength in shoulders

Criteria for Abandoning Nonoperative Treatment and Proceeding to Surgery or More Intensive Intervention

- Increased fracture shortening or displacement
- Signs of malunion
- Signs of nonunion

Tips and Guidelines for Transitioning to Performance Enhancement

- Transition to performance will begin in the latter phases (phase III and IV) with regard to training the upper extremity.
- When the patient has achieved the phase II milestones, transition to performance can be made.
- Core exercises and lower body transition to performance can be ongoing from the early phases. This will help keep the athlete engaged.
- As always, communication between the physical therapist and performance specialist must be ongoing.

Performance Enhancement and Beyond Rehabilitation: Training/Trainer and Optimization of Athletic Performance

- Maintaining a solid foundation of strength is important for safe progression of functional exercises.
- Care is taken to monitor ROM and flexibility throughout to ensure proper shoulder mechanics.
- Lower extremity and trunk strength and mobility will take stress off the shoulder.
- Adequate core strength will transfer power from the lower extremities to the upper extremities.

- Adequate rest is incorporated into upper extremity training program so as not to flare the joint.
- Close attention is paid to the volume of exercise. The performance specialist must recognize signs and symptoms of inflammation such as pain, loss of motion, and a decrease in strength, and readily communicate with the physical therapist. The athlete will not be pushed through pain and inflammation to avoid setbacks.

Specific Criteria for Return to Sports Participation: Tests and Measurements

- Radiographic signs of fracture union
- Full, painless range of motion of affected shoulder
- Near symmetric strength in shoulders

Evidence

Canadian Orthopaedic Trauma Society: Nonoperative treatment compared with plate fixation of displaced mid-shaft clavicular fractures. A multicenter, randomized clinical trial. *J Bone Joint Surg Am* 89:1–10, 2007.

The authors performed a prospective study on outcomes and complication rates following nonoperative vs. plate fixation of displaced mid-shaft clavicle fractures. A total of 132 patients were randomized to treatment and outcomes were assessed using the Constant score, DASH score, and radiographs. The mean time to radiographic union was 16.4 weeks in the group with plate fixation, versus 28.4 weeks in the nonoperative group. Nine symptomatic malunions and seven nonunions were noted in the nonoperative group, versus two nonunions and no malunions in those with plate fixation. The operative group showed higher satisfaction rates than the nonoperative group at 1 year. (Level XX evidence)

Judd DB, Pallis MP, Smith E, et al: Acute operative stabilization versus nonoperative management of clavicle fractures. *Am J Orthop (Belle Mead NJ)* 38:341–345, 2009.

This was a prospective, randomized study of 57 subjects with midshaft clavicle fractures which were either treated nonoperatively (28 subjects) or with intramedullary fixation (29 subjects) with a modified Hagie pin. The authors reported that one subject in each group sustained a refracture within 1 year of the original injury. (Level XX evidence)

McKee MD, Pedersen EM, Jones C, et al: Deficits following nonoperative treatment of displaced mid-shaft clavicular fractures. *J Bone Joint Surg Am* 88:35–40, 2006.

The authors identified 30 patients (22 male, 8 female) who were treated nonoperatively for a displaced mid-shaft clavicle fracture. Their functional outcomes were measured using the Constant Score and the DASH (Disabilities of the Arm, Shoulder and Hand) Score, and objective muscle testing was performed using the Baltimore Therapeutic Equipment Work Simulator. The authors found that these patients had residual deficits in shoulder strength and endurance, with strength testing of the injured shoulder at 81% for maximum flexion compared to the uninjured side, 81% and 85% for maximum external and internal rotation, respectively, and 82% and 78% for endurance of external rotation and internal rotation, respectively. The mean Constant Score was 71, and the mean DASH score was 24.6. Range of motion appeared to be well preserved and averaged 170° +/– 20°, with abduction averaging 165°+/– 25°. (Comparative study, Level XX evidence)

Morgan RJ, Bankston LS, Jr, Hoenig MP, et al: Evolving management of middle-third clavicle fractures in the National Football League. *Am J Sports Med* 38:2092–2096, 2010.

Of 13 100% displaced mid-shaft clavicle fractures in the National Football League, 6 underwent open reduction internal fixation with plating and 7 were treated nonoperatively. Of those treated operatively, players returned to play within the same season, whereas 4 of the 7 treated nonoperatively sustained refracture of their clavicle within 1 year and missed an average of 1.5 seasons. (Level XX evidence)

Robinson CM, Court-Brown CM, McQueen MM, et al: Estimating the risk of nonunion following nonoperative treatment of a clavicular fracture. *J Bone Joint Surg Am* 86-A(7):1359–1365, 2004.

The authors performed a prospective, observational cohort study of 868 patients with a clavicle fracture over 51 months. Median age was 29.5 years. At 24 weeks, 6.2% showed signs of nonunion, with 8.3%, 4.5% and 11.5% in the medial, mid-shaft and lateral clavicle fractures, respectively. Risk of nonunion was increased by increased age, female gender, fracture displacement and presence of comminution. (Level XX evidence)

Multiple-Choice Questions

QUESTION 1. In the first 2 weeks after injury, physical therapy may include all of the following EXCEPT:

A. Pendulum exercises
B. Isometric strengthening of RTC
C. Isometric strengthening of deltoid
D. Passive ROM to 120 degrees of abduction

QUESTION 2. In the first 6 weeks after injury, exercises of the rotator cuff and deltoid should involve:

A. Unlimited passive ROM
B. Resisted strengthening
C. Isometric strengthening
D. Strict immobilization

QUESTION 3. Unlimited range of motion exercises should typically begin after signs of clinical or radiographic union, typically after:

A. 2 weeks
B. 4 weeks
C. 6 weeks
D. 12 weeks

Answer Key

QUESTION 1. Correct answer: **D** (see Phase I: Weeks 0 to 6)

QUESTION 2. Correct answer: **C** (see Phase I: Weeks 0 to 6)

QUESTION 3. Correct answer: **C** (see Phase III: Weeks 10 to 14)

POSTOPERATIVE REHABILITATION AFTER REPAIR OF CLAVICLE FRACTURE

Miho J. Tanaka, MD, Theresa A. Chiaia, PT, DPT, and Christopher S. Ahmed, MD

Indications for Surgical Treatment

- Significant fracture displacement, shortening or comminution (Figure 7-49)
- Tenting of skin, impending skin necrosis
- Neurovascular compromise
- Open fracture
- Polytrauma and need for early mobilization
- Inability to tolerate immobilization
- Nonunion, symptomatic malunion or failed nonoperative treatment

Brief Summary of Surgical Treatment

Major Surgical Steps

Major steps in technique for plate fixation

- Beachchair positioning with fluoroscopic unit used to obtain AP and 45° cephalad views
- Exposure of fracture, and avoiding supraclavicular nerve
- Preparation of fracture site
- Reduction of fracture, with restoration of length and rotation
- Fixation with lag screw if appropriate fracture pattern
- Selection of appropriate size and position of plate
- Plate fixation with minimum three screws (six cortices) on each side of fracture
- Closure with soft tissue coverage of plate
- Postoperative sling

Major steps in technique for intramedullary fixation

- Beachchair positioning with fluoroscopic unit used to obtain AP and 45° cephalad views
- Exposure of fracture, and avoiding supraclavicular nerve
- Preparation of fracture site
- Insertion of intramedullary device, with radiographic confirmation of restoration of length and rotation
- Closure with care to minimize soft tissue trauma
- Postoperative sling

Other Surgical Techniques and Options

- Major differences in other surgical techniques:
  - Midshaft clavicle fractures can be fixed with plate fixation (Figure 7-56) or intramedullary fixation (Figure 7-57), as described above, depending on the surgeon's preference.
  - Several types of plate fixation may be used, including precontoured locking plates, noncontoured plates, dynamic compression plates, and limited contact dynamic compression plates. These plates can be placed superiorly (Figure 7-56), anterior-inferiorly (Figure 7-58), or with 90° dual plate fixation (Figure 7-59).
  - No significant differences in postoperative rehabilitation exist between these methods of fixation.
  - Lateral clavicle fractures are challenging and difficult to stabilize. Use of the precontoured plates or hook plate has been described in the treatment of lateral clavicle fractures (Figure 7-60).

FIGURE 7-56. Superior plating is a common technique in the plate fixation of midshaft clavicle fractures.

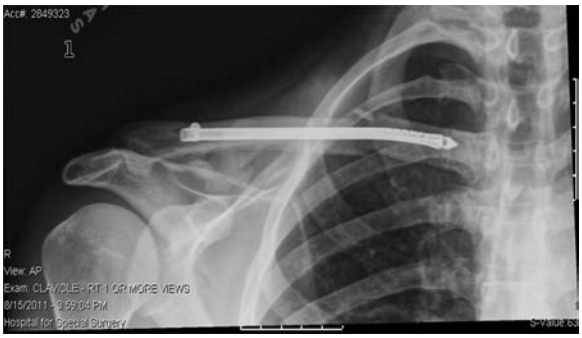

FIGURE 7-57. Intramedullary fixation is gaining popularity in the fixation of midshaft clavicle fractures due to its low profile nature.

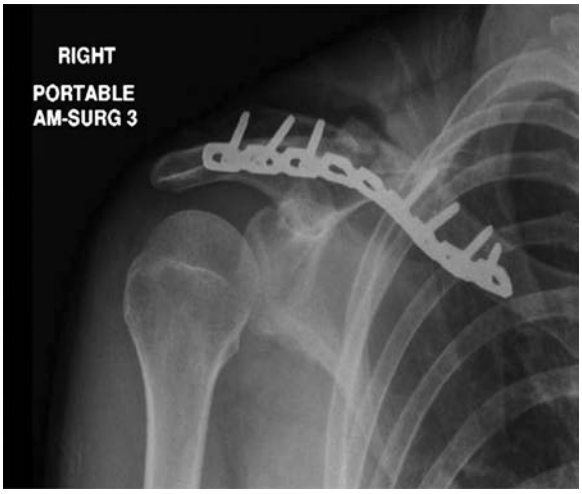

FIGURE 7-58. Anteroinferior plating is an alternative method of plate positioning in open reduction and fixation of clavicle fractures.

- However, it is important to note that the lateral portion of the hook plate lies in the subacromial space and may cause impingement with abduction and external rotation of the shoulder.
- Early removal of the hook plate is recommended to prevent complications such as impingement and acromial fractures.

Before Surgery: Overview of Goals, Milestones, and Guidelines[3]

GUIDING PRINCIPLES OF POSTOPERATIVE REHABILITATION

- Understand the healing rates of clavicular fractures.
- Avoid positions and movements that place excessive stress on fracture fixation and healing until radiographic confirmation of healing is observed.
- Avoid painful ROM.
- Achieve painless full range of motion and nearly symmetrical strength before return to play.
- Achievement of phase-specific goals will determine advancement.

Phase I: Immediate Postoperative Period (days 0 to 14)

Clinical Pearls

- Compliance with the use of the sling will assist with activity modification as well as avoidance of movements and forces that will interfere with healing. Patient education regarding the injury and healing constraints will help foster compliance.

[3]*Prehabilitation, if appropriate, is described in the Nonoperative Rehabilitation section of this chapter.*

FIGURE 7-59. Dual plate fixation is another method described for the use of clavicle fractures *(Image courtesy of Sabrina Strickland MD).*

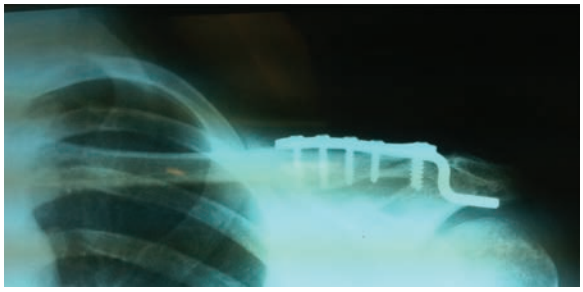

FIGURE 7-60. The hook plate can be used to fix distal clavicle fractures, however, the implant may cause impingement in shoulder abduction or acromion fractures if not removed.

Goals

- Protect surgical repair
- Control postoperative pain and swelling
- Educate the patient (regarding posture, resting positions)
- Ensure proper balance and gait while wearing a sling
- Obtain patient compliance with:
  - Activity modification (axial load, distractive/traction forces, active arm elevation, and ROM above shoulder height)
  - Immobilization
- Independence in a home exercise program to include distal ROM and grip strength
- Minimize rotator cuff inhibition

Protection

- Sling immobilization at all times
- Resting position: Supine lying with pillow support. Lying on the ipsilateral side is contraindicated

Management of Pain and Swelling

- Oral pain medications
- Positioning of the UE on a pillow with the arm supported in the scapular plane to allow the patient to rest comfortably without stressing the repair
- Patient education:
  - Activity modification will provide the patient with an understanding of how to manage pain
  - Sling immobilization
- Therapeutic modalities
  - Cryotherapy
  - Transcutaneous Electrical Nerve Stimulation (TENS)
- Activity modification
- Cryotherapy.

Techniques for Progressive Increase in Range of Motion

Manual Therapy Techniques

- ROM: Physiologic movements—IR and ER in the plane of the scapula (PoS)

Soft Tissue Techniques

- Therapeutic massage for myofascial release for pectorals, trapezii

Stretching and Flexibility Techniques for the Musculotendinous Unit

- AROM wrist extension/flexion; pronation/supination; elbow flexion/extension with arm at side; gripping exercises

Other Therapeutic Exercises

TBS

- Can be incorporated early while wearing the sling
- Exercises that challenge the individual's balance are also discouraged
- Light stationary cycling, however, perspiration is discouraged to protect the healing wound

Core stability

- Lower abdominals; hip musculature (seated machines)

TLS

- The patient can perform exercises that do not stress the repair site, or present the risk of falling, such as ball squats, seated LE machines for hamstrings, quads, and hip musculature.
- Contraindication:
  - Leg press with shoulder pads is not encouraged
  - Carrying weights which create distractive forces.

Activation of Primary Muscles Involved in Injury Area or Surgical Structures

- Muscle activation of the primary muscles (pectorals, anterior deltoid, trapezius, SCM) is not indicated during this immediate postoperative phase.
- Postural retraining
- Exercises for the distal extremity may be performed such as gripping, wrist extension/flexion, forearm pronation/supination, elbow flexion/extension.

Techniques to Increase Muscle Strength, Power, and Endurance

- Postural exercises such as scapular retraction to neutral and lower trapezius isometrics may be initiated

Neuromuscular Dynamic Stability Exercises

- Pain-free, submaximal IR/ER rhythmic stabilization exercises in the plane of the scapula (PoS) may be initiated in this phase with adequate available ROM (30° ER).

Milestones for Progression to the Next Phase

- Pain and swelling is controlled.
- Abolish rest pain.
- Obtain compliance with activity modification.
- Minimize rotator cuff inhibition.

TIMELINE 7-8: **Postoperative Rehabilitation After Repair of Clavicle Fracture**

PHASE I (weeks 1 to 2)	PHASE II (weeks 3 to 6)	PHASE III (weeks 6 to 10)
• Sling immobilization • PT modalities, prn: cryotherapy, TENS • AROM of distal joints: elbow, forearm, wrist, hand • AAROM of shoulder for plane of scapula IR/ER • Myofascial release for pectorals • Patient education: activity modification, sling • Postural retraining (avoid forward shoulder posture) • TBS/TAS/TLS activities as recommended & tolerated: avoid perspiring to protect the healing wound	• Sling immobilization • PT modalities, prn: moist heat, cryotherapy, TENS • ROM: PROM for scapular plane shoulder elevation, AAROM to 90° in sitting position • Manual therapy evaluation-based: joint mobilization for shoulder flexion/abduction; IR/ER. Manual therapy, evaluation-based: for shoulder flexion PoS; ER/IR • Soft tissue techniques—evaluation-based—for pectorals, subscapularis • Submaximal isometric strengthening: deltoid, lower trapezius • RC strengthening: progress from scapular plane submaximal isometrics to ER in side lying • Scapular mobility • Pendulums • Periscapular PREs in latter phase, progressing from supported side lying to manual resistance • Rhythmic stabilization for IR/ER in PoS • TBS/TAS/TLS activities as recommended & tolerated	• PT modalities, prn (moist heat, cryotherapy) • AAROM exercises without restriction and to tolerance: pulleys; can ER at 90° abduction, cane forward flexion • Manual therapy: joint mobilizations, evaluation-based • Soft tissue techniques—evaluation-based • Upper extremity ergometry • Flexibility exercises: evaluation-based for pectorals, posterior rotator cuff, latissimus • Periscapular PREs • CKC exercises progressing from double to single support • Hydrotherapy • Rotator cuff PREs progressing from side lying to elastic band resistance • Pushup progression: wall pushup • Neuromuscular training: Bodyblade at neutral; rhythmic stabilization, increasingly challenging positions • TBS/TAS/TLS activities as recommended & tolerated

Phase II (weeks 2 to 6)

Clinical Pearls

- ROM exercises should be pain-free. If the individual experiences pain with supine flexion in the plane of the scapula (PoS), one may consider ROM exercises in the sitting position to allow the scapula to move. The patient's body weight in the supine position will limit movement at the scapula, thereby increasing the movement at the clavicle.
- Passive-AAROM exercises for flexion/abduction may be performed in the sitting or standing position to allow for scapular movement.
- Continued use of the sling will assist with activity modification, and avoid movements and forces that will interfere with healing.

Goals

- Protect surgical repair.
- Emphasize postural awareness (avoid forward shoulder posture).
- Obtain patient compliance with:
  - Activity modification (axial load, distractive/traction forces, active arm elevation, and ROM above shoulder height)
  - Immobilization
- Minimize rotator cuff inhibition.
- Avoid pain with exercises, ADLs.
- ROM to ≤90° flexion/abduction.
- Avoid horizontal adduction beyond neutral.
- Normal ER ROM in the plane of the scapula.
- Provide independent home exercise program.

Protection

- Sling immobilization
- Limit active abduction/flexion to ≤90°
- Pillow support for sleeping will be used for proper positioning and to avoid deleterious positions such as side-lying on ipsilateral side and unsupported contralateral side lying

Management of Pain and Swelling

- Oral pain medications
- Cryotherapy
- Patient education (UE positioning, and activity modification)
- Cryotherapy
- Activity modification

Techniques for Progressive Increase in Range of Motion

Manual Therapy Techniques

- ROM: Physiologic movements—passive-to active assistive—ROM of shoulder flexion/abduction; IR and ER in the plane of the scapula (PoS)
- Joint mobilization in the posterior direction, inferior direction
- Scapular mobilization

Soft Tissue Techniques

- Therapeutic massage for myofascial release for pectorals, subscapularis, trapezii

TIMELINE 7-8: **Postoperative Rehabilitation After Repair of Clavicle Fracture** (Continued)

PHASE IV (weeks 10 to 14)	PHASE V (weeks 14 to 24)	PHASE VI (weeks 24 to 52)
• PT modalities, prn • ROM: evaluation-based • Manual therapy: evaluation-based • Flexibility: evaluation-based • UE ergometry • Advanced periscapular strengthening: prone-lying middle traps, lower traps, • RC strengthening progression to 90/90 position • Plyometrics • PNF diagonals progression • Throwing program • Swimming • Progressive neuromuscular training • TBS/TAS/TLS activities as recommended & tolerated	• RTP may differ by sport • TBS/TAS/TLS activities as recommended & tolerated	• Possible hardware removal if indicated • Postoperatively: Limit overhead strengthening and heavy lifting for a minimum of 6 weeks

Stretching and Flexibility Techniques for the Musculotendinous Unit

- AROM wrist extension/flexion; pronation/supination; elbow flexion/extension with arm at side; gripping exercises
- P-AAROM exercises for shoulder flexion are performed in sitting or standing with the arm positioned in the plane of the scapula (Figure 7-50); ROM exercises for PoS shoulder IR and ER may be performed in supine
- Supine "T towel" positioning, with a towel roll positioned along the spine, and a second along the base of the head, is recommended to promote thoracic extension, and to allow the anterior positioned humeral head to sit back.
- Pendulum exercises

Other Therapeutic Exercises

TBS

- Once the wound is healed, patient can perform exercises such as stationary cycling and elliptical trainer for cardiovascular fitness. The sling is worn during these activities.

Core stability

- Lower abdominals; hip musculature (seated machines)

TLS

- The patient can perform exercises that do not stress the repair site, or present the risk of falling, such as ball squats, seated LE machines for hamstrings, quads, and hip musculature.

Activation of Primary Muscles Involved in Injury Area or Surgical Structures

- Rotator cuff isometrics
- In latter part of this phase
- Self AAROM exercises in sitting will begin to activate the anterior deltoid.
- Scapular elevation can be initiated in a supported side lying position.

Sensorimotor Exercises

- Hydrotherapy

Techniques to Increase Muscle Strength, Power, and Endurance

- Scapular strengthening is initiated in this phase to include scapular retraction, lower trapezius to neutral.
- RC strengthening is progressed from submaximal isometrics to isotonics (ER in side lying).

Neuromuscular Dynamic Stability Exercises

- Rhythmic stabilization exercises performed for PoS IR/ER

Functional Exercises

- Hydrotherapy may be used initially to provide environment for active-assistive exercise.

Sport-Specific Exercises

- N/A with the exception of progressive ROM exercises
- Incorporating exercises for core, TBS, TAS, TLS is encouraged, keeping in mind the limitations/precautions associated with the involved shoulder

Milestones for Progression to the Next Phase

- Normal ER ROM in the plane of the scapula
- PROM shoulder flexion/abduction to 90°
- Pain and swelling is controlled
- Compliance with activity modification
- Compliance with home exercise program

Phase III (weeks 6 to 10)

Clinical Pearls

- As restrictions are lifted after fracture union, activity levels should be increased gradually in order to optimize muscular fitness and avoid aggravating the joint.
- Patients should be monitored for signs and symptoms of progressing too quickly.
- Scapular strengthening is initiated and progressed so that an adequate strength base is developed for more advanced exercises.
- Again, care is taken to follow a functional progression.
- For physical therapists, communication with the physician regarding the healing progress is imperative for appropriate progression.
- If healing is delayed, the progression of therapy should be postponed accordingly.

Goals

- Discontinue sling
- Pain free with ADLs and exercise
- Compliance with activity modification and precautions
- When signs of radiographic union, begin progressive ROM and strengthening
- Normalized scapulohumeral rhythm to 90° scapular plane shoulder elevation
- Avoid distractive forces

Protection

- The sling is discontinued.

Management of Pain and Swelling

- Pain to be controlled without medication
- A safe progression of therapeutic exercise and introduction of activities into daily life will control pain
- Patient education

- Activity modification
- Cryotherapy
- Activity modification
- Progressive ADLs, and therapeutic exercise

Techniques for Progressive Increase in Range of Motion

Manual Therapy Techniques

- Evaluation-based joint mobilization include: sternoclavicular, acromioclavicular, and glenohumeral (posteriorly and inferiorly directed) joints, as needed
- ROM exercises for physiologic movements: flexion, abduction, ER at 90° abduction, IR
- Scapular mobility in side lying

Soft Tissue Techniques

- Pectorals, subscapularis, posterior cuff, trapezii

Stretching and Flexibility Techniques for the Musculotendinous Unit

- ROM exercises with cane for ER at 90° abduction, forward flexion.
- Pulleys can be initiated with adequate humeral head control and ROM of approximately 130° flexion.
- Initiate doorway or corner stretch for pectorals (major and minor).

Other Therapeutic Exercises

- Stationary cycling, elliptical, utilization of upper body with c-v equipment, pain-free

Core

- Lower abdominals, bridging, gluteals

TAS

- Avoid carrying heavy weights and traction forces with training program.
- Perform pain-free exercise within the available ROM such as biceps curls, triceps curls, scapular retraction, scapular protraction, extension (dumbbell row).
- Upper body ergometry, use of arms in c-v equipment (row, elliptical, bicycle) progresses pain-free.

TLS

- Emphasize sports specific training exercises including:
  - Squats, RDLs, knee extension, knee flexion, side lying hip abduction.
  - Machines for hip abduction/adduction, gluteals.

Activation of Primary Muscles Involved in Injury Area or Surgical Structures

- Scapular stabilization exercises beginning with manual strengthening, progressing to resisted exercises such as shrugs, forward flexion in the plane of the scapula, supine bench press with light weights (arms below shoulder height)

Sensorimotor Exercises

- Hydrotherapy
- Rhythmic stabilization
- Physioball scapular stabilization, CKC.

Open and Closed Kinetic Chain Exercises

- CKC exercises such as physioball scapular stabilization exercises below horizontal are initiated with double arm support and progress to single arm support.

Techniques to Increase Muscle Strength, Power, and Endurance

- Progressive strengthening of the scapular musculature such as rhomboids, serratus anterior, lower trapezius to begin to address force couple involved in shoulder flexion/abduction.
- PREs for the rotator cuff, progressing from side lying to elastic band exercises.
- Forward elevation in the plane of the scapula—full can—is initiated with evidence of good scapulohumeral rhythm.
- Hydrotherapy exercises are utilized for its buoyancy and hydrostatic properties.
- Upper body ergometry.

Neuromuscular Dynamic Stability Exercises

- Continue with rhythmic stabilization exercises, progressing to more challenging positions such as at shoulder height
- Perturbation in latter phase with adequate strength base with arm close to side

Functional Exercises

- Begin scapula plane elevation—full can position—to shoulder height when good, pain-free scapulohumeral rhythm is evident (no shrug)
- Hydrotherapy may be used initially to provide environment for active-assistive exercise
- Pushing activities such as wall pushups

Sport-Specific Exercises

- Introduced based on the demands of the sport that the athlete is returning to

Milestones for Progression to the Next Phase

- Normal scapulo-humeral rhythm with PoS shoulder flexion to shoulder height and to 120° of flexion
- ROM WNLs
- 0/10 pain with exercise progression, and ADLs
- Compliance with home exercise program

Phase IV (weeks 10 to 14)

Clinical Pearls

- At this point, communication with the physician to ensure that healing is complete is important.
- The patient should be monitored for symptoms of pain and should be progressing.
- An adequate strength base is required for progression to plyometrics.

Goals

- Achieve full range of motion
- Normal S-H rhythm throughout full ROM
- Overhead activities with adequate strength base, and normal shoulder mechanics
- Avoid pain with exercise: progressive shoulder strengthening
- Monitor for increase in symptoms

Management of Pain and Swelling

- Avoid pain with exercise
- Activity modification
- Cryotherapy
- Monitor for swelling

Techniques for Progressive Increase in Range of Motion

Manual Therapy Techniques

- Evaluation-based, treat as needed

Soft Tissue Techniques

- Evaluation-based, treat as needed

Stretching and Flexibility Techniques for the Musculotendinous Unit

- Evaluation-based, treat as needed
- Monitor flexibility of posterior cuff and posterior capsule and address accordingly.

Other Therapeutic Exercises

- Stationary cycling, elliptical, utilization of upper body with c-v equipment, pain-free

Core

- Lower abdominals, bridging, gluteals

TAS

- Avoid carrying heavy weights and traction forces with training program.
- Perform pain-free exercise within the available ROM such as biceps curls, triceps curls, scapular retraction, scapular protraction, extension (dumbbell row).
- Upper body ergometry, use of arms in c-v equipment (row, elliptical, bicycle) progresses pain-free.

TLS

- Emphasize sports specific training exercises including:
- Squats, RDLs, knee extension, knee flexion, side lying hip abduction.
- Machines for hip abduction/adduction, gluteals.

Activation of Primary Muscles Involved in Injury Area or Surgical Structures

- Chest press/bench press/pushups
- Forward flexion in the plane of the scapula, full can position

Sensorimotor Exercises

- PNF diagonal pattern progressions from supine to standing; from no resistance to manual resistance and resistance with elastic bands

Open and Closed Kinetic Chain Exercises

- Rotator cuff full Can exercise with progression to single arm ball stabilization
- Push up progressions
- Quadruped position

Techniques to Increase Muscle Strength, Power, and Endurance

- Progressive rotator cuff strengthening from modified neutral to 90/90 position
- Advanced periscapular strengthening: prone exercises for middle trapezius, lower trapezius, latissimus
- Upper body ergometry, use of arms in c-v equipment (row, elliptical, bicycle)
- Isokinetic training

Neuromuscular Dynamic Stability Exercises

- Body blade©
- Ball stabilization
- Manual
- Quadruped position
- PNF diagonal pattern progression

Plyometrics

- Activity-specific plyometrics, ball tosses: chest pass, overhead pass;
- Progress from double arm to single arm

Functional Exercises

- PNF diagonal pattern progressions

Sport-Specific Exercises

- These are introduced based on the demands of the sport that the athlete is returning to and arm dominance: throwing, catching, swimming, and stability.
- Throwing program

Milestones for Progression to the Next Phase

- 2:3 ER:IR strength ratio
- Strength 85% of non-involved extremity
- ROM WNLs
- Normal scapulohumeral rhythm above shoulder height

Phase V (weeks 14 to 24)

Clinical Pearls

- Overhead athletes with involvement of their dominant arm in overhead athletes may require more time before returning to sport.
- Caution should be taken in early return to play, as refracture has been reported.
- Return to play criteria can vary by the athlete's sport.
- Hardware removal can be performed at **12 to 16 weeks**, after confirmation of radiographic union.
- Reasons for hardware removal:
  - Painful or prominent hardware
  - Cosmesis or patient preference
  - Prevention of impingement on the rotator cuff and acromial fractures (for distal clavicle hook plates)
- After removal of hardware (Figure 7-61), the clavicle is susceptible to refracture
- Rehabilitation guidelines after hardware removal are as follows:
  - Sling immobilization for 1 week
  - Isometric strengthening of rotator cuff, deltoid, biceps, triceps
  - Progressive ROM exercises
  - No contact sports or heavy lifting for a minimum of 6 weeks

Criteria for Return to Sport

General

- Radiographic signs of fracture union
- Full, painless range of motion of involved shoulder
- 85% strength of contralateral shoulder
- Normal scapulohumeral rhythm above shoulder height

Sport-Specific

- Football and contact sports
- Baseball and overhead throwing athletes
- Swimming and overhead athletes

FIGURE 7-61. Removal of implants can weaken the healed clavicle. Lifting and overhead restrictions are recommended after hardware removal.

After Return to Sport

Continuing Fitness or Rehabilitation Exercises

- Maintain symmetry in strength and ROM and flexibility

Exercises and Other Techniques for Prevention of Recurrent Injury

- Donut pads or fiberglass shoulder shell can be used to protect the healing clavicle during participation in contact sports
- If applicable, educate the athlete in proper falling, landing techniques

Evidence

Canadian Orthopaedic Trauma Society: Nonoperative treatment compared with plate fixation of displaced midshaft clavicular fractures. A multicenter, randomized clinical trial. *J Bone Joint Surg Am* 89:1–10, 2007.

The authors performed a prospective study on outcomes and complication rates following nonoperative vs. plate fixation of displaced midshaft clavicle fractures. A total of 132 patients were randomized to treatment and outcomes were assessed using the Constant score, DASH score, and radiographs. The mean time to radiographic union was 16.4 weeks in the group with plate fixation, versus 28.4 weeks in the nonoperative group. Nine symptomatic malunions and seven nonunions were noted in the nonoperative group, versus two nonunions and no malunions in those with plate fixation. The operative group showed higher satisfaction rates than the nonoperative group at one year.

Golish SR, Oliviero JA, Francke EI, et al: A biomechanical study of plate versus intramedullary devices for midshaft clavicle fixation. *J Orthop Surg* 3:28, 2008.

The authors performed a biomechanical study comparing the biomechanical performance of plate versus intramedullary fixation under cyclic bending forces in eight sets of matched cadaveric clavicles. A midshaft clavicle osteotomy was fixed with a 3.5 mm dynamic compression plate or a 3.8 or 4.5 mm intramedullary device and increasingly loaded for 3000 cycles. The plate constructs showed less displacement at fixed loads. The authors concluded that plate fixation may provide a stronger construct for early rehab protocols with repetitive motions.

Iannotti MR, Crosby LA, Stafford P, et al: Effects of plate location and selection on the stability of midshaft clavicle osteotomies: a biomechanical study. *J Shoulder Elbow Surg* 11:457–462, 2002.

The authors reported the effects of plate location and selection on the stability of midshaft clavicle fractures using 30 matched pairs of cadaver clavicles. Midshaft osteotomies were fixed with 3.5 mm reconstruction, 3.5 mm limited contact dynamic compression (LCDC) or 2.7 mm dynamic compression (DC) plates and loaded to failure in compression. They found that superior plating constructs had greater fracture rigidity and mean retained stiffness than the anterior location. They also found that LCDC plate constructs were superior to DC plates constructs in torsional rigidity and to reconstruction plates in compressive load.

Judd DB, Pallis MP, Smith E, et al: Acute operative stabilization versus nonoperative management of clavicle fractures. *Am J Orthop* 38:341–345, 2009.

This was prospective, randomized study of 57 subjects with midshaft clavicle fractures which were either treated nonoperatively (28 subjects) or with intramedullary fixation (29 subjects) with a modified Hagie pin. The authors reported that one subject in each group sustained a refracture within one year of the original injury.

Liu HH, Chang CH, Chia WT, et al: Comparison of plates versus intramedullary nails for fixation of displaced midshaft clavicular fractures. *J Trauma* 69:E82–E87, 2010.

The authors performed a retrospective review of 110 patients who underwent plate fixation (59 patients) or intramedullary nail fixation (51 patients) who were similar in demographics and fracture characteristics. They found that there was no significant difference in operative time, time to union, restoration of mobility, functional scores, or occurrence of complications such as malunion, nonunion, infection and need for hardware removal.

Morgan RJ, Bankston LS, Jr, Hoenig MP, et al: Evolving management of middle-third clavicle fractures in the National Football League. *Am J Sports Med* 38:2092–2096, 2010.

Of 13 100% displaced midshaft clavicle fractures in the National Football League, six underwent open reduction internal fixation with plating and seven were treated nonoperatively. Of those treated operatively, players returned to play within the same season, whereas four of the seven treated nonoperatively sustained refracture of their clavicle within 1 year and missed an average of 1.5 seasons.

Verborgt O, Pittoors K, Van Glabbeek F, et al: Plate fixation of middle-third fractures of the clavicle in the semi-professional athlete. *Acta Orthop Belg* 71:17–21, 2005.

The authors reported on their study of 39 semiprofessional athletes in various sports (mountain bike racers, soccer players, swimmers, cyclists) with displaced midshaft clavicle fractures that were treated with open reduction and plating with a 3.5 mm LCDC plate. Five percent had a complication with refracture due to new trauma while the hardware in place. The authors reported that these were treated with revision fixation and grafting with good results. The authors also reported that the most common complication was wound infection (18%).

Multiple-Choice Questions

QUESTION 1. In the first 6 weeks postoperatively after clavicle ORIF, limitations in rehabilitation should include

A. Strict immobilization
B. No strengthening
C. No limitations
D. <90° of abduction

QUESTION 2. In the first 6 weeks after surgery, exercises of the rotator cuff and deltoid should involve:

A. Unlimited passive ROM
B. Resisted strengthening
C. Isometric strengthening
D. Strict immobilization

QUESTION 3. Unlimited range of motion exercises should typically begin after signs of clinical or radiographic union, typically after:

A. 2 weeks
B. 4 weeks
C. 6 weeks
D. 12 weeks

QUESTION 4. Following removal of hardware:

A. there are no precautions
B. there are no risks for fracture
C. overhead strengthening may begin immediately
D. overhead strengthening may begin at 6 weeks, evaluation-based

Answer Key

QUESTION 1. Correct answer: **D** (see Phase II)

QUESTION 2. Correct answer: **C** (see Phase II)

QUESTION 3. Correct answer: **C** (see Phase III)

QUESTION 4. Correct answer: **D** (see Phase V)

BEYOND BASIC REHABILITATION: RETURN TO MOTOCROSS AFTER CLAVICLE FRACTURE

Kahl Goldfarb, PT, DPT, OCS, OMT, CSCS, and Paul C. Murphy, MD

Introduction

ASPECTS OF MOTOCROSS THAT REQUIRE SPECIAL ATTENTION IN REHABILITATION

- Clavicle fractures are common injuries and represent 4% to 10% of all adult fractures and 35% to 40% of all fractures of the shoulder girdle area. The most frequent location for a clavicular fracture is the middle one-third which accounts for 72% to 80% of all clavicle fractures.[1]
- The literature regarding nonoperative versus operative treatment has been extensive over the years, and there is much written about complications and functional results with both forms of treatment. Current literature has now determined that surgical management may indeed be more effective than previously thought, especially in displaced fractures.[2,3,4] Therefore, we are focusing on the surgical management and rehabilitation of clavicle fractures in this chapter.
- Returning to motocross after surgery can be challenging if not properly implemented. The treatment of these fractures should be determined by the clinical judgment of the treating surgeon and the athlete. Once surgery has been determined to be the treatment of choice, rehabilitation should be tailored to the athlete's fracture and its surgical stability. It is imperative that the fracture have rigid fixation in order to progress with early aggressive physical therapy treatments.
- Motocross riders are unique athletes. They require not only upper body strength and athleticism, but also lower extremity balance and aerobic fitness, as they can have three or four consecutive motos of 20 minutes or longer. Clavicle fractures in these athletes create a special set of circumstances for the surgeon and therapist in that the physical requirements of these athletes are not only strength, but very sport-specific proprioceptive demands that are required. Therefore, the rehabilitation of these athletes must not only focus on the shoulder clavicle fracture, but also incorporate core body fitness and aerobic capacity simultaneously.

- Motocross requires an inordinate need for functional postural endurance and aerobic fitness.
- The athlete must also demonstrate explosive strength of the upper extremity (UE) and lower extremity (LE) to control the bike (Figure 7-62).

FIGURE 7-62. Significant upper body requirements for controlling the bike in midair.

- Spinal motor control and extremity proprioception for afferent and efferent feedback are of utmost importance in order to control the bike under precarious circumstances during events and trainings.

Phase I: Advanced Strength and Conditioning Programs

Periodization

- Phase I of this periodization program for the postoperative patient will take approximately 6 weeks.[5]
- This mesocycle will utilize a linear design.
- The rehabilitation timeline is outlined in detail at the end of this chapter and describes the progression through this 6-week protocol. Pain and radiology findings are always the guide in progressing the athlete to the next stage.
- Typically we would rehabilitate our athletes in proper postural position with regard to glenohumeral and scapulothoracic position, but with these athletes, exercises should be performed in a postural position that mimics the riding position that these athletes must maintain for prolonged periods of time. Flexibility and joint mobility are not critical as compared to joint stability. Multi-planer exercises are needed to mimic motocross activities.

TIMELINE 7-9: Advanced Postoperative Rehabilitation for Clavicle Fracture with Internal Fixation for the Motocross Athlete

PHASE I (weeks 0 to 6)

- Repetitions: 15–30
- Sets: two to three
- Rest interval: 30 seconds
- Intensity: low
- Repetition tempo: slow with control
- Training frequency: 3–5 days per week
- Training duration: 30–60 minutes

Week 1

- Sling worn at all times except when exercising
- PT modalities and cryotherapy for controlling, pain and swelling
- No Continuous Passive Motion device (CPM) because there is a rare incidence of frozen shoulders post clavicle ORIF (Open Reduction Internal Fixation)
- Active assistive Codman's exercises
- Range of Motion(ROM)-scapular plane elevation to 90°
- Ball squeeze
- Resisted tricep and bicep TheraBand(TB) exercises
- Active assisted ROM below 90° of flexion and abduction
- Isometric shoulder external rotation(ER), internal rotation(IR), extension, abduction, adduction at side pain-free: early exercise can assist in muscular activity to avoid neuromuscular functional delay
- Manual therapy; mobilize soft tissue (pectoralis major and minor, upper trapezius, sternocleidomastoid, subclavius) decrease lymphedema, decrease trauma from surgery

Week 2

- Progressive weight bearing onto hands in riding position-weight shifting: use pain as guide
- PT Modalities as needed
- Active assisted range of motion (AAROM) 90° flexion and abduction
- Pulley flexion and scaption
- Proprioceptive Neuromuscular Facilitation(PNF): elbow, wrist, and periscapular exercises
- TB shoulder IR/ER at 0° abduction
- TB elbow and wrist flexion, extension, supination, pronation, radial and ulnar deviation
- Wall plank progress to standing table plank
- Scapular clocks against wall progress to standing at a table
- Isometric wall Ts (scapular retraction with arms at 90° of abduction), and Ms (scapular retraction with arms at sides)* Radiographs must indicate rigid internal fixation without loosening of the screws or movement of the plates in order to progress to week 3.
- At week 2–4 theoretically there could be some stress shielding on superior cortex and therefore repetitive load on the fixation and this type of load may need to be monitored with X-rays.

Week 3

- Discharge sling
- Closed chain activity is stressed due to functional needs. ROM needed for riding is 30° to 120° of flexion, extension 30°, ER 30°, IR 60°, horizontal abd 30°, horizontal add 30° (all stabilization exercises will encompass the above ROM. We are not training in a correct postural position because we want to mimic the riding posture during exercise)
- Towel wall active range of motion(AROM) within 120° of flexion with wall pressure
- Use TB around elbows during wall clocks with wall pressure
- Floor planks on knees and elbows progress as tolerated to normal plank position
- Floor plank clocks on knees and elbows
- Floor serratus punch on knees (quadruped)
- TB serratus punch
- TB/pulley IR/ER at 45° to 90° flexion, 0° abduction
- TB or TRX Ms, Ts rows
- PNF exercises
- Rhythmic stabilization exercises
- Closed Kinetic Chain manual perturbation exercises

WEEK 4–6

- Plank
- Plank with shoulder ER
- Physioball plank with perturbations: therapist tries to move ball, bouncing to simulate riding
- Lat pull down (avoiding ROM > 160* of flexion)
- Pushups (for endurance and control without pain)
- Ball toss to ground and up
- Horizontal adduction ball toss into trampoline
- Ball self catch at 90° of abduction moving in all ranges of horizontal adduction and abduction
- IR/ER at 90° abduction all ranges of horizontal adduction and abduction
- Body blade in all functional ranges

*Perform alternating sets with eyes open and then closed

TIMELINE 7-9: **Advanced Postoperative Rehabilitation for Clavicle Fracture with Internal Fixation for the Motocross Athlete** (Continued)

PHASE II (weeks 6 to 12)

- Repetitions: at least 30 but push until fatigue
- Sets: One set before training runs in order to prepare the athlete for the sport from a neuromuscular control standpoint, and then three sets greater than 30 repetitions each after they complete the training run in order to improve endurance.
- Rest interval: 30 seconds in order to stress the cardio respiratory system
- Intensity: moderate
- Repetition tempo: moderate to high
- Training frequency: 3–4 days per week (alternating days)
- Training duration: 60 minutes
  - Prone physioball LE on ball (LE curl up/pike and oblique curl up)
  - Supine physioball LE curl up (progress from full foot touch to just heel touch and from UE support to arms across chest)
  - UE step ups onto step
  - Humeral head depression dips

PHASE III (weeks 4 to 6 in preseason)

- Repetitions: 3–6 for Olympic lifts and 8–12 for all other exercises
- Sets: 3–5
- Rest interval: 60 seconds
- Intensity: moderate to high
- Repetition tempo: moderate to high
- Training frequency: 2 times per week with 2 day break
- Training duration: 30–80 minutes
- Training volume: total amount of repetitions and sets performed during one session
- Olympic lift (power clean)
- Plyometrics: double leg box jumps, single leg box jumps, drop-catch pushups, medicine ball plyopass from chest and progress to above head and incorporate rotation
- Bosu ball dumbell deadlifts
- Bear crawl exercise
- Three or four consecutive motos for >20 minutes each

Program Design/Performance Training Program

Sport-Specific Concepts of Integrated Training

- Training with optimum posture (functional riding position)
- Core training
- Multiplanar training activities
- Sensorimotor and balance training
- Training for optimum muscle balance
- Neuromuscular dynamic stability exercises
- Functional training

Training Principles Used in the Design of the Program

- Principle of progression

Application of Acute Training Variables

Phase I is the range of motion and stabilization phase. The focus is on regaining full range of motion (ROM), stabilizing the scapulothoracic and glenohumeral joints, and then functional strengthening exercises that mimic the angle and force that is required to perform motocross activities.

- Repetitions: 15 to 30
- Sets: 2 to 3
- Rest interval: 30 seconds
- Intensity: low
- Repetition tempo: slow with control
- Training frequency: 3 to 5 days per week
- Training duration: 30 to 60 minutes
- Training volume: total amount of repetitions and sets performed during one session
- Specific exercises used in the training:
  - Shoulder girdle and core
  - Active assisted ROM in flexion, abduction and scaption within permissible range
  - Passive pulley flexion and scaption ROM within pain-free range.
  - Isometrics for rotator cuff: internal rotation (IR) and external rotation (ER) at 0° and progressing to 90° of shoulder flexion and abduction,
  - Isometrics shoulder flexion, extension and abduction within pain-free range. Scapula stabilizers Ms (scapular retraction with arms at sides) and Ts (scapular retraction with arms at 90° of abduction)
  - Progressive weight bearing onto upper extremity (UE) with weight shifting and clocks
  - TheraBand (TB) internal rotation (IR) and external rotation (ER) at 0° and progressing to 90° of shoulder flexion and abduction; TB resisted extension
  - Wall towel slides with progressive resistance; pushing body weight into the wall not to exceed 120° of flexion
  - TB or TRX (Total body Resistance eXercise suspension system) Ts and Ms and serratus punch and wall clocks with TB around elbows
  - Proprioceptive neuromuscular facilitation (PNF) and rhythmic stabilization exercises
  - Plank progressions from the wall to a table to the ground. Progress on the ground from knees and elbows to normal plank. Then add variations such as shoulder ER and/or physioball under elbows with perterbations
  - Pushups (for endurance and control without pain)
  - Latismus dorsi pull downs (avoiding ROM > 160° of flexion)[6]
  - Ball tossing to ground and up
  - Self catching the ball at 90° of flexion and in all ranges of horizontal abduction and adduction.
  - Body blade in all functional ranges
  - Elbow/wrist/hand
  - TB elbow and wrist flexion and extension pronation and supination, radial and ulnar deviation
  - PNF in all directions
  - Ball squeezes

Application of Chronic Training Variables

At this stage in the rehabilitation process, intensity level will be low but total volume will be performed at a high level.

In order to progress to Phase II and to ride on flat surfaces, the following criteria must be met:

- Radiographic and clinical healing
  - Radiographs must indicate rigid internal fixation without loosening of the screws or movement of the plates. Minimal periosteal healing must be present unless under the age of 18 years old.
  - At weeks 2 to 4 theoretically there could be some stress shielding on superior cortex and therefore repetitive load on the fixation, and this type of load may need to be monitored with X-rays.
- Pushups: Able to perform 80% of the maximum amount of pushups without pain that the athlete was able to achieve prior to injury
- Laser pointer test: Able to perform 80% of the maximum time to maintain the laser beam within a 2-inch radius circle as compared to the uninvolved extremity during the laser pointer test (Figure 7-63). The athlete must be asymptomatic during this exercise in order to progress to Phase II.[7]
- Plank Proprioception Testing: Able to perform 80% of the maximum amount of UE reaches with uninvolved extremity as involved extremity without pain (Figures 7-64 and 7-65).

If the athlete is unable to pass all four criteria listed above, he/she will continue with the Phase 1 program and be reassessed by the surgeon until criteria is passed.

Phase II: Performance Enhancement Training Techniques

Periodization

- After our athlete progresses successfully through the Phase I rehabilitation program, and after the athlete passes all of the objective tests discussed, an advanced training and conditioning program is initiated. Phase II is initiated at about 6 weeks after surgery. This mesocycle will utilize a linear design.
- Careful monitoring of healing: weekly radiographs monitoring internal fixation until week 9 and then the final X-ray at week 12.

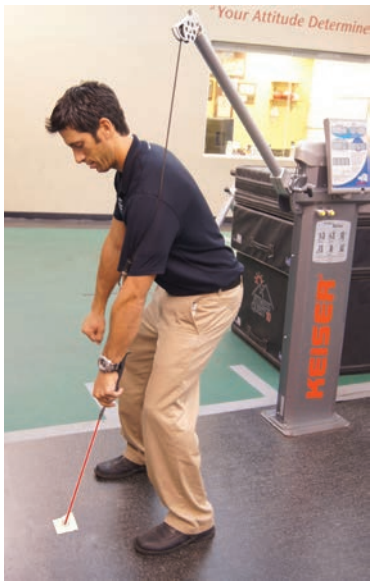

FIGURE 7-63. Laser Pointer test: Stand in a position that mimics the riding position and place the pulley and a laser in the uninvolved hand so the force is directed up through the arm and into the shoulder and thorax. Choose a weight on the pulley stack that mimics flat riding to test endurance. Attempt to keep the laser beam inside of a 2-inch radius circle on a sticky note. Time how long it takes until the subject can no longer isometrically maintain the laser in the 2 inch radius circle and then test the involved extremity in same manner. Subject must be able to keep the laser within the 2-inch circle 80% of the time in order to be cleared to ride on flat surfaces and 100% of the time in order to return to competition. The athlete must be asymptomatic in this exercise in order to progress forward.

FIGURE 7-64. Plank Proprioceptive Testing Level 1: In a plank position, weight bear through the involved extremity as seen with the red arrow. Slowly move the other extremity forward and back and to the side, as seen with the black arrow, while being sure to keep the body still through the entire motion. This test demonstrates stability of the shoulder in the riding position without dynamic stress (i.e., bumps and hills).

Program Design/Performance Training Program

Sport-Specific Concepts of Integrated Training

All of the specific exercises listed below are sports specific and can be performed with minimal equipment and without supervision. They incorporate all of the training variables listed.

- Core training
- Cardiorespiratory training

FIGURE 7-65. Plank Proprioceptive Testing level 2: similar to level 1 except with the uninvolved extremity on a slider (or using a towel) reach as far as possible away from the body in all directions. This time try to move the body over the involved shoulder during the maximal reach in order to stress the involved shoulder in different positions mimicking shoulder motions during dynamic riding (bumps, hills, etc.).

- Multi-planar training activities
- Training for optimum muscle functional strength
- Training for speed, agility, quickness (SAQ)
- Sport-specific training
- Neuromuscular dynamic stability
- Sensorimotor and balance training

Training Principles Used in the Design of the Program

- Principle of progression
- Principle of individualization

Application of Acute Training Variables

Phase II is a combination of the endurance phase with a progressive strengthening component to mimic the needs of a motocross athlete. The load is increased as compared to Phase I and the volume is increased to enhance the fatigue threshold.

- Repetitions: at least 30, but push until fatigue results
- Sets: 1 set before training runs in order to prepare the athlete for the sport from a neuromuscular control standpoint, and then 3 sets greater than 30 repetitions each after they complete the training run in order to improve endurance.
- Rest interval: 30 seconds in order to stress the cardio respiratory system
- Intensity: moderate
- Repetition tempo: moderate to high
- Training frequency: 3 to 4 days per week (alternating days)
- Training duration: 60 to 90 minutes
- Training volume: training volume varies but should be documented in order to improve the repetitions and or time/endurance
- Specific exercises used in the training
  - Prone physioball LE on ball (LE curl up/pike and oblique curl up) (Figures 7-66 and 7-67). This exercise mimics the coordination, strength (core, UE and LE) and endurance needed to control the bike when riding over bumps or when airborne. Slowly increase

FIGURE 7-66. Pike on Ball: With hands placed on ground and toes on ball, simultaneously pull your upper body and lower body together to reach a final pike position.

FIGURE 7-67. Physioball oblique curl up: With hands on the ground and toes on the ball begin to pull your upper and lower body together but curl to one side so to incorporate rotation and repeat on both sides.

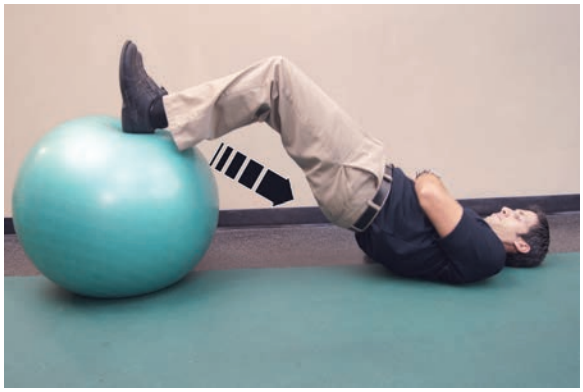

FIGURE 7-68. Supine bridge physioball hamstring curl up. Level 1. Place both feet on the ball so the entire sole is touching the ball, place hands on the floor at your sides to increase stability, and bridge body into the air. Slowly raise and lower your body but do not touch the ground until fatigue or control is an issue. Progression: Progress so heels only touch the ball and final progression is to place arms across chest to increase demand.

FIGURE 7-69. Upper extremity step ups: Put as much weight as comfortable through the involved extremity and slowly step opposite hand onto step. Then elevate involved extremity onto step and then slowly control the opposite arm during its descent down from the step. Make sure that shoulder blade does not wing.

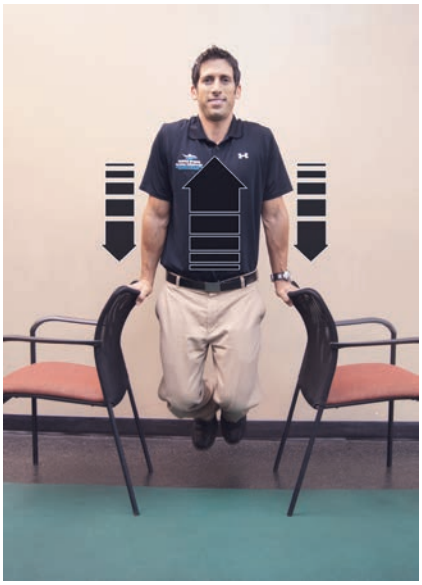

FIGURE 7-70. Humeral head depression dips: Using two chairs that are placed shoulder width apart, hold your full body weight in the air and then elevate your body higher by pressing your shoulders down toward the ground. Slowly lower your body until your shoulders reach your chin and then elevate your body up again. Repeat until fatigue or control is compromised.

speed to focus on speed, agility, and quickness and to stress the cardio respiratory system.

- Supine physioball bridge hamstring curl (progress from full foot touch to just heel touch and from UE support to arms across chest) (Figure 7-68). This activity directly stresses the posterior chain, which is essential in kickstarting and controlling the bike. This exercise assists in training for optimum muscle functional strength and sensorimotor and balance systems.
- UE step ups onto step (Figure 7-69), which utilizes scapular stability and shoulder girdle strength in order to mimic the force attenuated by the UE during riding and during bumpy rides. These exercises incorporate sport-specific training and neuromuscular dynamic stability
- Humeral head depression dips (Figure 7-70) focus on rotator cuff dynamic stability and scapular strength in order to provide the ability for the shoulder and UE to control the bike during rough rides.

Application of Chronic Training Variables

- Chronic training variables are manipulated over the mesocycle with a continued increase in volume and intensity as per the athlete's maximal ability and endurance allows.
- In contrast to most team sports where a trainer, strength coach, and physical therapist, as well as a training room are readily available, motocross athletes do not have access to these privileges. In our experience, once the rider returns to full competition, the rider often does not continue with rehab or neuromuscular reeducation and strength training under supervision. Therefore, the program that we prescribe can be completed in any location, as it only requires a physioball, two chairs, and 12 feet by 12 feet open space. This simple program will help with patient compliance. The exercises are performed once before a training run and again three times after the run is complete in order to improve functional capacity, strength, motor control and endurance. For optimal recovery and performance, it is recommended that the athlete continue with a supervised sports-specific training program. If the athlete complies, we then progress them to Phase III.

Phase III: Sport-Specific Training

Periodization

- Phase III takes place during the preseason and would stress the development of maximum aerobic capacity, strength/motor control and flexibility. Training will be a linear. Periodization for the length of one mesocycle (approximately 4 to 6 weeks).

Program Design/Performance Training Program

Sport-Specific Concepts of Integrated Training

- Flexibility/joint mobility for joint stability
- Core training
- Cardiorespiratory training
- Multiplanar training activities
- Training for optimum muscle functional strength
- Neuromuscular dynamic stability exercises
- Training for speed, agility, quickness
- Plyometric training
- Functional training
- Sport-specific training

Olympic Lifts Used in the Training Program

- Power clean: In a power clean, the athlete pulls the barbell from shin level and must receive it on the shoulders and stop moving downward before sinking past a parallel squat.

Training Principles Used in the Design of the Program

- Principle of progression
- Principle of overload
- Principle of variation
- Principle of individualization
- Principles of specificity–specific adaptation to imposed demands (SAID)

Application of Acute Training Variables

This mesocycle is a strength phase. If the athlete does not have a strength coach or appropriate supervision to assure that form is correct, we recommend omitting power lifting. The power clean should be done with heavy weights so that the athlete can perform a maximum of 3 to 6 repetitions. Plyometrics should follow power cleans after a 60-second rest time and should be done 8 to 12 times.

Repetitions: three to six for Olympic lifts and eight to twelve for all other exercises

- Sets: three to five
- Rest interval: 60 seconds
- Intensity: moderate to high (athlete should only be able to speak in short phrases, should be sweating, and breathing is deep and rapid due to exercise intensity)
- Repetition tempo: moderate to high
- Training frequency: two times per week with a 2-day break
- Training duration: 30 to 90 minutes
- Training volume: total amount of repetitions and sets performed during one session
- Specific exercises used in the training:
  - Olympic lift (Power Clean) which will assist in the force production needed to push the bike off of terrain and utilizes training for optimum muscle functional strength
  - Plyometrics: double leg box jumps, single leg box jumps, drop-catch pushups, medicine ball plyopass from chest and progress to above head and incorporate rotation. These plyometric exercises incorporate core training, cardiorespiratory training and multiplanar training activities to reproduce the forces that the UE and LE must absorb during riding.
  - Dumbell deadlifts on BOSU ball to stress the neuromuscular dynamic stability system while strengthening the posterior chain eccentrically.
  - Bear crawl exercise (crawling on hands and feet with pelvis as low to the ground as possible without allowing knees to touch the ground). This multiplanar and core exercise assists in functional strengthening of the shoulders and hips during spinal stabilization.
  - Three or four consecutive motos for > 20 minutes each.

Application of Chronic Training Variables

- Power is generally not a primary focus for motocross athletes. The primary muscles that are worked for power are the posterior chain muscles such as hamstrings and gluteals which are used to kick start and push off the bike. Back muscular strength is needed in the form of neuromuscular control and movement patterns to control the weight of the bike. Shoulder and chest motor control is needed to manipulate the bike. We recommend that the athlete perform this exercise program 2 days per week. Day 1 would consist of this

exercise program, Day 2 would consist of functional riding for sports specific training and Day 3 should be the HEP from phase II. Day 4 would be a rest day and then the entire cycle would be repeated.

Sports Performance Testing

General Information

- General history
- Subjective questionnaires
- Medical history
- Sports injury history
- Surgical history—history of related or unrelated surgeries
- Chronic conditions/medication—check for respiratory and cardiac condition, head injuries, concussions, vestibular disorders, systemic diseases

Objective Tests

- Radiographic healing
- Laser pointer test for endurance and control (see Figure 7-63)
- Plank proprioceptive testing PPT 1 and 2 (see Figures 7-64 and 7-65)
- Body weight tests: pushups
- Balance and proprioception (eyes open vs closed with HEP)
- Objective questionnaires: DASH.

Specific Criteria for Progression to the Next Stage to Determine Readiness for Motocross

- There must be rigid internal fixation (no movement of the screws or the plate) and minimal periosteal healing in order to progress to week 3.
- In order to progress to week 4, patient must pass the laser pointer test. Athlete must be able to keep laser within the two-inch radius circle 80% of the time as compared to uninvolved side. The athlete must be asymptomatic during this exercise.
- In order to ride on flats (approximately week 4), the athlete must pass the Plank Proprioception Test 1: In the plank position, slowly move the other extremity forward, back, and to the side, while being sure to keep the body still through the entire motion. Able to perform 80% of the maximum amount of UE reaches with uninvolved extremity as involved extremity without pain.
- In order to be cleared to ride on flat surfaces (approximately week 4), the athlete must perform 80% of the maximum amount of pushups without pain that the athlete was able to achieve prior to injury.

Specific Criteria for Release to Unsupervised Complete Participation in Motocross

- Radiographic and clinical healing (athletes under the age of 18 may present with periosteal callus which would not indicate an issue with fixation):
  - Fracture line is no longer present.
  - Periosteal healing is minimal.
  - Endosteal healing is clearly visible; sclerosis of the fracture line in the medullary canal.
  - Internal fixation is rigid without any movement of the screws or plate.
- Athlete must perform 100% of the maximum amount of pushups (pain free) that the athlete was able to achieve prior to injury.
- Athlete must pass the laser pointer test: Able to perform 100% of the maximum time to maintain the laser beam within a 2-inch radius circle as compared to the uninvolved extremity during the laser pointer test.
- Athlete must pass the Plank Proprioception Test 2: Able to perform 100% of the maximum amount of UE reaches with uninvolved extremity as involved extremity (pain-free)
- Careful monitoring of healing: weekly radiographs monitoring internal fixation until week 9, and then final x-ray at week 12.

Recommended Ongoing Exercises

- The authors recommend that the athlete continue with the Phase II program indefinitely.

Evidence

There are no evidence-based trials to support techniques to return patients to motocross after clavicle fracture.

Multiple-Choice Questions

QUESTION 1. At what week do we increase flexion ROM past 90°?

A. Week 1
B. Week 2
C. Week 3
D. Week 4

QUESTION 2. What is the functional criteria in order to progress to (non-competitive) riding?

A. Perform 10 pushups without pain and 20 pull-ups without pain
B. Pain-free full ROM and pain-free with putting weight through arms in a pushup position
C. Able to perform 20 pushups with pain and perform 30 serratus punches with 20 lbs per arm without pain
D. Perform 80% of the maximum amount of pushups (pain-free) that the athlete was able to achieve prior to injury.

QUESTION 3. Which Olympic lift is most appropriate for motocross athletes?

A. Clean and jerk
B. Snatch
C. Power clean
D. Dead lift

QUESTION 4. In order to perform advanced rehabilitation on a patient with a clavicle fracture who has had internal fixation, what is the most critical objective factor in determining when the athlete can begin rehab?

A. Motivated athlete
B. Main free with all movements
C. Rigid internal fixation via radiograph
D. Pain-free with weight lifting

QUESTION 5. Which of the following is a part of Phase II training?

A. Olympic lifting
B. Physioball dynamic exercises
C. Plyometrics
D. Isometrics

Answer Key

QUESTION 1. Correct answer: **C** (Week 3, as long as bony healing is occurring)

QUESTION 2. Correct answer: **D** (Perform 80% of the maximum number of pushups)

QUESTION 3. Correct answer: **C** (Power clean)

QUESTION 4. Correct answer: **C** (Rigid internal fixation via radiograph)

QUESTION 5. Correct answer: **B** (Physioball dynamic exercises)

Chapter 8

Adhesive Capsulitis and Glenohumeral Arthritis

INTRODUCTION

Jo A. Hannafin, MD, PhD, Theresa A. Chiaia, PT, DPT, and A. Simone Maybin, BS, NSCA-CPT

Epidemiology

- Primary adhesive capsulitis affects 2% to 5% of the general population
- Patient age, 40 to 65 years old
- Incidence, higher in females than in males
- Nondominant arm is more frequently involved
- Athletes (not sport specific) and nonathletes equally affected

Pathophysiology

Intrinsic Factors

- The following intrinsic factors may play a role in the development of primary adhesive capsulitis:
  - Angiogenesis and synovitis consistent with inflammation
- Secondary adhesive capsulitis and restriction of glenohumeral range of motion may result from:
  - Rotator cuff tendonitis
  - Rotator cuff tears
  - Calcific tendonitis
  - Contracture of the rotator cuff interval
  - Subacromial scarring
  - Inflammation of the long head of the biceps tendon and its synovial sheath

Extrinsic Factors

- Trauma is the only known extrinsic factor implicated in the development of adhesive capsulitis.
- Patients with diabetes mellitus are at greater risk of developing adhesive capsulitis, with a prevalence between 10% and 20%[1-3]
- Although more rare, both thyroid dysfunction and Parkinson disease are also associated with the development of adhesive capsulitis[4-6]

Classic Pathological Findings

- General pathological findings are synovial hyperplasia and capsular fibrosis[7] further characterized by:
  - Elevated cytokine expression in shoulder capsule including transforming growth factor-β (TGF-β), platelet-derived growth factor, and hepatocyte growth factor[7]
  - Excess accumulation and propagation of fibroblasts (Type I and II collagen)[7,8]
- Specific pathological findings vary dependent upon the current stage of the patient. These are further described in Table 8-1.[9,10]

Table 8-1 Stages of Adhesive Capsulitis

	Arthroscopic Appearance	Biopsy
Stage 1 (Preadhesive)	Fibrinous synovial inflammatory reaction No adhesions or capsular contracture	Rare inflammatory cell infiltrate Hypervascular, hypertrophic synovitis Normal capsular tissue
Stage 2 (Freezing)	Christmas tree synovitis Some loss of axillary fold	Hypertrophic, hypervascular synovitis Perivascular, subsynovial capsular scar
Stage 3 (Frozen)	Complete loss of axillary fold Minimal synovitis	Hypercellular, collagenous tissue with a thin synovial layer Similar features to other fibrosing conditions
Stage 4 (Thawing)	Fully mature adhesions Identification of intraarticular structures difficult	Not reported

Clinical Presentation

History

- Insidious onset without a definitive action or event causing symptoms
- Progressive increase in pain with development of sleep-disturbing night pain
- Deep achy pain at rest with acute intense pain associated with quick motion or rapid stretch
- ROM is initially limited by pain, not capsular contracture. It then progresses to global stiffness shoulder.
- Initial loss of external and internal rotation
- Passive and active motions are more restricted owing to pain at or before end range secondary to muscle guarding.

Physical Examination

Abnormal Findings

- Patients with adhesive capsulitis will differ in motion limitations dependent upon their current stage (1 through 4) (Table 8-2).

Pertinent Normal Findings

- Strength deficits are generally not present, in contrast to impingement and rotator cuff disease.
- No significant muscle atrophy

Imaging

- Plain radiographs (X-rays) are routinely performed to rule out calcific tendinitis or glenohumeral arthritis.
- Osteopenia is a common radiographic finding.
- Magnetic resonance imaging (MRI) is not essential for diagnosis but can rule out confounding pathology.
- Hallmark of adhesive capsulitis on MRI is thickening and loss of volume of the axillary pouch.
- MRI in stages 1 and 2 demonstrates increased signal in capsule and synovium consistent with hyperemia and synovitis.
- MRI in stages 3 and 4 demonstrates low signal capsule with increased capsular thickness in anterior capsule, posterior capsule, and axillary pouch.
- One-third of stage 2 adhesive capsulitis patients show some form of supraspinatus pathology on magnetic resonance arthrography.[11] The clinical significance is unknown but should be correlated with physical examination.
- Axillary recess thickening up to 1.3 cm or more compared with normal measurement of less than 4 mm[11]
- Rotator interval thickening[12]
- Glenohumeral ligament thickening[12]

Differential Diagnosis

- Shoulder stiffness is a common symptom of many glenohumeral joint conditions. It is critical to distinguish

Table 8-2 Clinical Signs and Symptoms of Adhesive Capsulitis

	Symptoms	Signs
Stage 1 (Preadhesive)	Achy pain at rest referred to deltoid insertion; sharp pain with movement Pain at night	Capsular sign on deep palpation Empty end feel = pain stops PROM before resistance felt by clinician Full motion under anesthesia
Stage 2 (Freezing)	Persistence of pain; increased night pain Pain extends to upper trapezius secondary to compensatory shrugging Progressive limitation of motion with ADLs	Motion restricted in capsular pattern; ROM reveals a capsular end feel. Forward flexion, abduction, internal and external rotation Pain at the end of the ROM Some improvement in motion under anesthesia
Stage 3 (Frozen)	Profound limitation of motion with ADLs Pain present at the end of range of motion only	Resistance to ROM felt before pain Significant loss of motion Tethering at ends of motion No improvement under anesthesia
Stage 4 (Thawing)	Minimal pain Slow, steady improvement in ROM with ADLs	Significant motion loss Gradual improvement in motion

Table 8-3 Possible Differential Diagnoses for Primary Adhesive Capsulitis

Possible Differential Diagnoses	Primary Factor to Supporting Differential vs. Primary Adhesive Capsulitis
Impingement Syndrome (Stage 1)[12]	Positive Neer, Hawkins tests Shoulder musculature may be tender upon palpation
Cervical spine and neurological pathologies	Character of pain is described as burning/stinging. Pain may follow a radicular pattern Deficit in strength, sensation, and/or reflexes may exist. Pain may change with motion of cervical spine
Calcific Tendonitis/Bursitis	Rotator cuff tendon(s) present with calcium deposits in radiography Pain is more sudden in onset. Pain with glenohumeral abduction, may be minimal with rotation in 0° abduction
Acromioclavicular arthritis	Tenderness present upon palpation of AC joint Positive crossover test
Bicep tendonitis	Tenderness present upon palpation of bicep tendon Local crepitus with humeral rotation
Severe glenohumeral osteoarthritis	Loss of joint space, osteophytes present on X-ray.
Rotator cuff tendonopathy	Pain present with internal rotation, abduction, and strength testing. MRI (+) for tendonosis.

between primary adhesive capsulitis and other disorders because the treatment is time sensitive. The common differential diagnoses are listed in Table 8-3.

Treatment

Nonoperative Management

- Physical therapy[13] including patient education, manual therapy,[13] therapeutic ROM exercises and periscapular strengthening, neuromuscular re-education and modalities for pain, relaxation, and tissue extensibility (moist heat, cryotherapy, TENS, low power laser)
- Oral nonsteroidal antiinflammatory medications (NSAIDs)
- Oral corticosteroid
- Intraarticular corticosteroid injection[14]
- Distension arthrography or hydrodilation
- Closed manipulation

Guidelines for Choosing Among Nonoperative Treatments

- Optimal treatment options should be selected according to:
  - The presenting stage of adhesive capsulitis
  - The degree of irritability
  - The pain level
  - The degree of restricted motion
  - The duration of symptoms and signs
  - The goals of the patient
- A combination of nonsurgical treatments may be ideal.

Surgical Indications

- When physical and pharmacological therapies have failed, surgical options should be considered and discussed with the patient.
- Failed therapy should be considered when a patient has reached a plateau or progress in increased ROM is extremely slow.
- Surgery may be indicated for a painful shoulder that has failed to respond to intraarticular corticosteroids.
- Surgery is indicated when the patient is failing to improve with a minimum of 6 months of conservative treatment.

Aspects of History, Demographics, or Exam Findings that Affect Choice of Treatment

- Surgical options are dependent on the stage of adhesive capsulitis and other concomitant pathology.
- Surgery is elective and based on patient pain, arm dominance, and goals.
- Failure to progress with physical therapy goals is a relative indication for surgical treatment.

Aspects of Clinical Decision Making When Surgery Is Indicated

- Options for surgical treatment include: (1) closed manipulation under anesthesia; (2) manipulation under anesthesia followed by arthroscopy; and (3) arthroscopy, capsular release, and manipulation.
- Surgeon preference, degree of osteopenia, and imaging studies guide decision making.
- Arthroscopy permits identification and treatment of associated pathology.
- Synovectomy is indicated when significant synovitis is present.
- Arthroscopic division of the capsule permits a more controlled and precise release than manipulation. The anterior and posterior capsule is released prior to manipulation. The axillary pouch can be released but care must be taken to avoid injury to the axillary nerve.
- Performing the manipulation prior to arthroscopy may result in intraarticular bleeding and an obscured view, as well as a risk for fracture.
- Patients with idiopathic adhesive capsulitis who have failed arthroscopic and closed manipulation procedures may benefit from an open release.
- Patients with secondary adhesive capsulitis may require lysis of adhesions in the subacromial space and release of the coracohumeral ligament.

Evidence

Carette S, Moffet H, Tardif J, et al: Intraarticular corticosteroids, supervised physiotherapy, or a combination of the two in

the treatment of adhesive capsulitis of the shoulder. *Arth Rheum* 48(3):829–838, 2003.

This controlled prospective study randomized 93 patients to compare the efficacy of intraarticular injection, supervised PT, the combo of PT and injection, and placebo. Utilizing the SPADI, the injection and PT group demonstrated faster results; however, injection alone yields better results than supervised PT alone. (Level II evidence)

Hazelman BD: The painful stiff shoulder. *Rheumatol Phys Med* 11:413–421, 1972.

This retrospective review of 130 patients noted that the efficacy of intraarticular hydrocortisone injections inversely correlates with the duration of symptoms. Further, discrimination between stage 1 and 2 disease can be determined based on the patient's response to the local anesthetic, and thus can be used for future treatment options. (Level III evidence)

Jewell DV, Riddle DL, Thacker LR: Interventions associated with an increased or decreased likelihood of pain reduction and improved function in patients with adhesive capsulitis: A retrospective cohort study. *Phys Ther* 89:419–429, 2009.

This retrospective cohort study examined the data from 2370 patients to determine whether physical therapy interventions predicted meaningful short-term improvement in four measures of physical health, pain, and function in patients with adhesive capsulitis who had completed outpatient physical therapy. Joint mobilization and mobility, and exercise increased the odds of increased the odds of meaningful improvement in bodily pain, and hybrid function, respectively. (Level III evidence)

Nevaiser AS, Hannafin JA: Adhesive capsulitis: A review of current treatment. *Am J Sports Med* 38(11):2346–2356, 2010.

This is a paper illustrating the histopathologic progression of disease in capsular biopsies from patients with Neviaser stages 1 through 3. (Level I evidence)

Neviaser RJ, Neviaser TJ: The frozen shoulder. Diagnosis and management. *Clin Orthop Relat Res* 223:59–64, 1987.

This is a paper describing the four stages of adhesive capsulitis—the preadhesive stage, the freezing stage, the frozen or maturation stage, and the thawing stage—by correlating the physical exam with the arthroscopic findings. (Level V evidence)

Oh JH, et al: Comparison of glenohumeral and subacromial steroid injection in primary frozen shoulder: A prospective, randomized short-term comparison study. *J Shoulder Elbow Surg* 20(7):1034–1040, 2011.

This prospective, randomized trial randomly divided 71 patients with primary adhesive capsulitis into glenohumeral or subacromial ultrasound guided injection. The GH steroid injection led to earlier pain relief. (Level II evidence)

Multiple-Choice Questions

QUESTION 1. Which intrinsic factor can lead to primary adhesive capsulitis?

A. Calcific tendinitis
B. Contracture of RCI
C. Subacromial scarring
D. None of the above

QUESTION 2. Which stage of adhesive capsulitis is characterized by a Christmas tree (synovium is pedunculated and thickened) synovitis by arthroscopy?

A. Stage 1 Preadhesive
B. Stage 2 Freezing
C. Stage 3 Frozen
D. Stage 4 Thawing

QUESTION 3. Stage 3 adhesive capsulitis signs and symptoms include the following:

A. Pain at the end range of motion and no improvement under anesthesia
B. Profound stiffness and gradual improvement in motion
C. Severe night pain and gradual improvement in motion
D. Pain referred to deltoid insertion and full motion under anesthesia

QUESTION 4. What nonsurgical treatment for adhesive capsulitis can also be used as a diagnostic tool?

A. Oral NSAIDs
B. Oral corticosteroids
C. Intraarticular steroid injections
D. Distention arthrography

QUESTION 5. When is surgery indicated for patients diagnosed with primary adhesive capsulitis?

A. As soon as the patient's physical exam indicates Stage 2 signs and symptoms
B. When other physical and pharmacological therapies have failed
C. Anytime radiography demonstrates axillary recess thickening greater than 4 mm
D. After significant motion loss and stiffness has persisted longer than 4 months

Answer Key

QUESTION 1. Correct answer: **D** (see Pathophysiology)

QUESTION 2. Correct answer: **B** (see Pathophysiology)

QUESTION 3. Correct answer: **A** (see Clinical Presentation)

QUESTION 4. Correct answer: **C** (see Treatment)

QUESTION 5. Correct answer: **B** (see Treatment)

NONOPERATIVE REHABILITATION OF ADHESIVE CAPSULITIS

Theresa A. Chiaia, PT, DPT, Jo A. Hannafin, MD, PhD, and A. Simone Maybin, BS, NSCA-CPT

GUIDING PRINCIPLES OF NONOPERATIVE REHABILITATION

- Understand the stages of adhesive capsulitis.
- The stage of presentation will guide rehabilitation to optimize results.
- The stage of presentation will determine the duration of each phase of rehabilitation.
- The patient's response to initial treatment (injection) will determine the duration of each phase.
- Achievement of phase-specific goals will determine advancement.
- Irritability of the shoulder will guide prescription for range of motion.
- Perform reassessment of the patient's response to treatment to avoid joint inflammation.
- Understand the patient's individual goals will determine discharge planning.
- Patient education will help increase compliance with HEP, activity modification, and decrease frustration.

Introduction

- The phases of rehabilitation for adhesive capsulitis have typically been written to coincide with the stages of adhesive capsulitis.
- These guidelines are written in phases for a patient presenting with stage 2 adhesive capsulitis, because this is when the majority of patients seek treatment.
- Stage 1 is characterized by pain, inflammation, and an active synovitis.
- Stage 3 is characterized by a stiff shoulder resulting from loss of capsular volume.
- Stage 2 is a continuum/transition from stage 1 to 3 and thus has characteristics of both stages.
- Five phases of rehabilitation are presented: 1, Symptom Control; 2, Mobility; 3, Optimization of ROM; 4, Strengthening; 5, Functional Activity/Return to Sport.
- Regardless of the stage at presentation, the patient will pass through all these phases. The duration of each phase will vary according to the stage of presentation, initial treatment and response, goals of the patient, as well as shoulder dominance.

Phase I (weeks 1 to 4): Symptom Control

Management of Pain and Swelling

- NSAIDs
- Intraarticular injection
- Patient education
- Activity modification
- Positioning (Figure 8-1)
- Cryotherapy
- TENS
- Hydrotherapy
- Manual therapy
- Moist heat
- Low power laser therapy

Techniques for Progressive Increase in Range of Motion

CLINICAL PEARL

Understand the irritability of the shoulder and monitor the shoulder's response to treatment. ROM should improve, not regress.

Manual Therapy Techniques

- Gentle shaking of the extremity. Gently grasp the patient's wrist and gently oscillate the upper extremity

FIGURE 8-1. Positioning of the UE in the plane of the scapula with the elbow higher than shoulder. Also support limitations in IR ROM.

in a comfortable, neutral position. This will allow the patient to relax and help to control pain.

- Joint mobilizations in the posterior/dorsal direction, inferior, and caudal, lateral distraction direction. The glenohumeral joint is mobilized using Grade I mobilizations to help modulate pain, progressing to Grade II mobilization. Distraction/traction can be performed in combination with the glides. The sternoclavicular, acromioclavicular, and scapulothoracic articulations are assessed for restrictions and addressed, as needed.
- ROM: Pain-free physiological movements such as scapular plane elevation with the arm in modified neutral, IR/ER in the plane of the scapula (PoS), and abduction will help modulate pain by stimulating mechanoreceptors. These movements are performed in a slow, consistent tempo by the therapist to promote relaxation. The hold time begins as a pause with gradual increase in duration as tolerance and irritability permits.

Soft Tissue Techniques

- Therapeutic massage for myofascial release of pectorals, triceps, latissimus, and subscapularis

Stretching and Flexibility Techniques for the Musculotendinous Unit

- Pendulum exercises produce joint distraction and increase the arc of pain-free movement. Pendulum exercises should be pain free. This is achieved when the patient bends forward and uses body momentum to create arm movement. The arc of motion should be within an arc that is pain free and allows the upper extremity (UE) to relax. The patient chooses the direction of movement. These are performed three times for 10 to 30 seconds. This should be a "go-to" exercise during the day.
- Pain-free physiological movements using the opposite extremity with low load (intensity) and low duration performed three to five times per day. For example: supine forward flexion in modified neutral, supine IR, supine ER using a cane in the plane of the scapula. The patient is instructed to perform these ROM exercises to the edge of pain, not into pain. Irritability of the shoulder will help the PT instruct the patient regarding frequency, duration, and intensity. A good starting point is to hold for 5 to 10 seconds, and perform 10 repetitions. The shoulder's response to treatment will determine irritability and will guide parameters, in terms of duration of stretch and repetitions.
- Supine "T towel" positioning, with a towel roll positioned along the spine, and a second along the base of the head, is recommended to promote thoracic extension and allow the anterior positioned humeral head to sit back. This position is used to achieve thoracic mobility and to open up the anterior chest. The patient rests in this position for 10 minutes with her arms supported on pillows. The "T towel" can be performed two times per day.
- Continuous passive motion (CPM) in the PoS for IR/ER in modified neutral can be used. This modality allows the patient to relax as the shoulder is cycled through internal and external rotation. It can be used at comfortable, slow speeds—a pause can be used for a patient who can tolerate a longer time at end range. The duration of each session is 10 to 15 minutes.
- Hydrotherapy provides an environment for active-assistive exercise. To address any ROM deficits and/or maintain ROM: The water temperature is warm to create an environment that promotes relaxation. The patient is instructed to perform modified breast stroke movements (horizontal abduction and adduction), flexion in the plane of the scapula, and gentle internal and external rotation.

Other Therapeutic Exercises

- TLS to tolerance. Monitor and avoid exercises that involve loading the shoulder and upper extremity.
- Core stability emphasizing the lower abdominals can be performed using the legs to challenge the core. At this time, avoid exercises that load the shoulder with weight through the elbows.
- TAS: can perform scapular retraction, scapular elevation to tolerance, biceps curls, triceps extension with arm in neutral position. Avoid heavy weights that will cause compensatory anterior translation of the humeral head.

Activation of Primary Muscles Involved

- Strengthening of the scapular muscles can be initiated to tolerance such as retraction, elevation, protraction. Side lying position with the involved arm on top and supported by pillows can be used to decrease gravity for increased tolerance to exercise. Tactile cues can be helpful to ensure proper movement. Manual resistance can be given by the physical therapist. With increased strength, the patient can perform scapular retraction in sitting, scapular protraction in supine. Resistance can be added with elastic bands or hand weights. Perform

10 reps, 3 sets; however, the emphasis is on quality of movement.
- Hydrotherapy, because the buoyancy provides an environment for active-assistive exercise. The patient is instructed to perform modified breast stroke movements (horizontal abduction and adduction), flexion in the plane of the scapula, and gentle internal and external rotation. The water temperature is warm to create an environment that promotes relaxation.

Sensorimotor Exercises

- Hydrotherapy can be used for its hydrostatic properties, which create a "glove-like" effect stimulating the proprioceptors of the skin.

Open and Closed Kinetic Chain Exercises

- Pain-free, closed kinetic chain (CKC) exercises below shoulder height, such as physioball scapular stabilization exercises can be initiated with adequate ROM/soft tissue length. A physioball is placed on a stable surface (chair, resting on a toss back) so that the UEs are positioned below shoulder height and slightly wider than her body. With the elbows straight, the patient then compresses the ball and performs small movements as instructed by the therapist.

Techniques to Increase Muscle Strength, Power, and Endurance

- Strengthening of the scapular muscles can be initiated as described previously.

Neuromuscular Dynamic Stability Exercises

- Rhythmic stabilization exercise for IR/ER in the PoS in modified neutral to tolerance. With the patient lying in supine, the patient's upper extremity is positioned in the plane of the scapula and the elbow is supported on a towel roll with the elbow flexed to 90°. The therapist applies gentle pressure at the wrist in the direction of

TIMELINE 8-1: **Nonoperative Rehabilitation of Adhesive Capsulitis**

PHASE I (weeks 1 to 4)	PHASE II (weeks 5 to 8)

• PT modalities for pain and inflammation, relaxation: TENS, cryotherapy, moist heat, low-level laser therapy
• PT modalities to promote tissue extensibility and relaxation
• Oral NSAIDs, intraarticular injection
• Patient education: activity modification, disease progression, positioning
• Home exercise program: pendulums, ROM for supine scapular plane elevation, supine PoS ER, in modified neutral with cane, supine PoS IR, in modified neutral with opposite extremity
• Manual therapy: grade I and II joint mobilizations in posterior direction, inferior direction, distraction; pain-free ROM exercises; gentle shaking of the UE
• Soft tissue techniques: myofascial release latissimus, pectorals, subscapularis
• Codman's/pendulum exercises
• Initiate periscapular strengthening
• Rhythmic stabilization for IR/ER in the PoS
• Postural reeducation
• Continuous passive motion (CPM) for IR/ER (PoS) TBS/TAS/TLS activities as recommended and tolerated, for example:
  • TLS/ TBS: avoid exercises that avoid loading the shoulder and UE
  • Core stability emphasizing the lower abdominals can be performed using the legs to challenge the core.
  • TAS: Can perform scapular retraction, scapular elevation to tolerance, biceps curls, triceps extension with arm in neutral position
	• PT modalities to control pain, inflammation
	• PT modalities to promote tissue extensibility, relaxation
	• Oral NSAIDs, intraarticular injection
	• Patient education: activity modification, disease progression, positioning
	• Home exercise program: pendulums, ROM for supine shoulder elevation in PoS, supine ER in PoS, in modified neutral with cane, supine IR in PoS, in modified neutral with opposite extremity, standing ER doorway stretch with the arm in modified neutral.
	• Manual therapy (evaluation-based): Grade II joint mobs in posterior direction, inferior, distraction; mobilization of thoracic spine, scapula mobilization; pain-free ROM including IR/ER (PoS), and with gradually increasing abduction, elevation
	• Therapeutic massage for pectorals, latissimus, teres, subscapularis, triceps, rotator interval.
	• CPM for IR/ER (in the PoS) in modified neutral
	• Self-stretching: ROM exercises, as tolerated
	• Pendulums
	• Introduce pulleys when evidence of humeral head control and ≈130° elevation
	• Postural education
	• Upper body ergometry for active warmup
	• Neuromuscular reeducation: rhythmic stabilization in supine for IR/ER in the PoS and at shoulder height with elbow straight
	• Hydrotherapy
	• Strengthening of the periscapular muscles: scapular retraction, scapular protraction, shoulder extension to neutral
	• Pain-free RC isotonics to neutral in side-lying position
	• CKC scapular stabilization with physioball (bilateral UEs)
	• TBS/TAS/TLS activities as recommended and tolerated, for example:
	  • TBS using stationary bicycle, elliptical using arms to shoulder's tolerance
	  • Core strengthening can include lower abdominal strengthening, bridging.
	  • TAS: Avoid overhead exercise. Perform pain-free exercise within the available ROM such as biceps curls, triceps curls, scapular retraction, scapular protraction. Upper body ergometry can be incorporated as a warmup.
	  • TLS: Can perform squats, knee extension, knee flexion, side-lying hip abduction. Machines for hip abduction/adduction

internal and external rotation in alternating fashion to work on humeral head control. The patient is instructed to hold the arm stable, thus working on coordination. This can be performed for 10 seconds initially for three to four sets.

Milestones for Progression to the Next Phase

- Control of pain/inflammation
- Resolution of resting pain, and decreased irritability of the shoulder allows for progression of ROM exercises
- Patient compliance with home exercise program
- Minimize ROM loss
- Retard/halt the progression from synovitis to capsular fibroplasias, which is determined by end feel and pain. An empty end feel is more indicative of synovitis, whereas a capsular, firm end feel is more indicative of fibroplasia.
- Maximize function. During each phase the therapist wants to maximize the patient's functional strength within the available pain-free ROM. This allows the patient to then use the extremity during ADLs in the available ROM without compensatory movements. If the functional strength is not sufficient, and the patient continues to use the arm during ADLs, impingement symptoms will occur. This in turn will slow the return of ROM because the shoulder will be painful and inflamed. Use of the arm in pain-free arcs of motion will help the patient gain ROM.
- Avoid symptoms of impingement. The patient is not encouraged to use the arm outside available ROM/AROM.

Phase II (weeks 5 to 8): Mobility

Clinical Pearl

> The patient is encouraged to use the arm during the day in pain-free motions.

TIMELINE 8-1: Nonoperative Rehabilitation of Adhesive Capsulitis (Continued)

PHASE III (weeks 9 to 16)	PHASE IV (weeks 17 to 22)	PHASE V (weeks 23+)
• Patient education • Home exercise program: pendulums, supine forward elevation in the plane of the scapula (PoS), supine external rotation in the PoS and at 90° abduction with cane, internal rotation behind back with opposite hand, posterior capsule stretch as tolerated • Modalities: moist heat, cryotherapy • Upper body ergometry for an active warmup • Hydrotherapy: horizontal abduction/adduction, modified breast stroke, chest press with paddle • ROM: increase total end range time; initiate IR behind back with opposite hand or strap without compensatory movements, pulleys • Strengthening: periscapular muscles; rotator cuff PREs side-lying ER to TBIR/ER in the PoS • Manual therapy (evaluation-based): PNF contract-relax for IR in the PoS, ER in the PoS; joint mobilization; physiological movements • Therapeutic massage for length of subscapularis, teres, pectorals; mobilization for thoracic spine extension • CKC exercises progressing from double to single support • TBS/TAS/TLS activities as recommended & tolerated	• Patient education: activity modification; avoid "too much, too soon"; functional progression • Home exercise program, as instructed • Modalities, prn: moist heat, cryotherapy • Manual therapy: prn: contract-relax, joint mobilizations • Upper body ergometry for active warmup, endurance training • Advanced periscapular strengthening: prone exercises for middle trapezius, lower traps, latissimus • RC PREs, pain free • Upper body weight training • Soft tissue techniques for subscapularis, latissimus, pectorals, teres, posterior capsule • Hydrotherapy • Rhythmic stabilization • Ball stabilization • PNF diagonal patterns • ROM exercises: cane ER at 90° abduction; strap IR behind back • Flexibility exercises: door stretch for pectorals, sleeper stretch, chicken wing • TBS/TAS/TLS activities as recommended & tolerated	• Patient education • Modalities: cryotherapy • Home exercise program: as instructed • Upper body ergometry for warmup, endurance • Flexibility exercises for posterior cuff, posterior capsule, pectorals ROM exercises for maintenance • Manual therapy (evaluation-based): prn • Soft tissue techniques (evaluation-based): prn • Advanced periscapular strengthening continues • Advanced stabilization exercises • Rotator cuff strengthening: IR/ER at 90° abduction • Upper body weight training • PNF diagonal patterns • Isokinetic training • Plyometrics progression: ball toss • Sport-specific exercises • TBS/TAS/TLS activities as recommended and tolerated

Management of Pain and Swelling

- Oral NSAIDs
- Intraarticular injection
- Patient education
- Activity modification
- Positioning
- Modalities: cryotherapy, TENS
- Hydrotherapy
- Manual therapy
- Moist heat will promote relaxation and tissue extensibility and can assist with controlling pain.

Techniques for Progressive Increase in Range of Motion

Manual Therapy Techniques

- Joint mobilizations in the A-P direction, caudal direction, distraction techniques. The shoulder is supported by the physical therapist in the resting position with the patient in supine-lying, then the glenohumeral joint is mobilized using Grade II mobilizations. Distraction/traction can be performed in combination with the glides. The sternoclavicular, acromioclavicular, and scapulothoracic articulations are assessed for restrictions and addressed, as needed.
- Gentle shaking of the UE for 10 to 15 seconds. The physical therapist gently grasps the patient's wrist and gently oscillates her upper extremity in a comfortable, neutral position. This will allow the patient to relax and help to control pain.
- Pain-free ROM using physiological movements are performed in the plane of the scapula for shoulder elevation, IR/ER, and abduction. The physical therapist "ranges" the patient's shoulder through shoulder abduction in the plane of the scapula, shoulder flexion in the plane of the scapula, internal rotation in the plane of the scapula, and external rotation in the plane of the scapula. During internal and external rotation, the proximal humerus is stabilized with one hand to avoid compensatory movements. The shoulder's response to treatment will guide how far the shoulder is stretched and how long the stretch is held. Decreased irritability of the shoulder will allow for a longer stretch.
- Mobilization of the scapula. Scapulohumeral dissociation is often limited, and is observed with scapular motion greater than humeral motion in arcs less than 90°. This is assessed during observation of posture and observation with passive and active shoulder elevation, and can be measured more objectively by measuring the distance between the spinous process and medial border of scapula and spine and inferior scapular angle, respectively. More formal assessment using the Lateral Scapular Slide Test can be instituted,
- Mobilization of the thoracic spine to promote thoracic extension can be performed by the physical therapist in the position that is most comfortable for the patient, and in which the PT is most comfortable in performing—sitting upright, sitting and leaning forward supported by a table, or prone.

FIGURE 8-2. Therapeutic massage. Subscapularis release.

Soft Tissue Techniques

- Therapeutic massage emphasizing the subscapularis, triceps, rotator interval, pectorals (minor and major), latissimus (Figure 8-2)

Stretching and Flexibility Techniques for the Musculotendinous Unit

- Stretching exercises are performed daily, two to three times per day.
- Pendulum exercises produce joint distraction and increase the arc of pain-free movement. Pendulum exercises should be pain free. This is achieved when the patient bends forward and uses body momentum to create arm movement. The arc of motion should be within an arc that is pain free and allows the UE to relax. The patient chooses the direction of movement—the only criterion is that it is pain free. These are performed for 10 to 30 seconds, two or three sets, two to three times per day.
- Self-stretching using the opposite extremity for supine scapular plane elevation in modified neutral, supine internal rotation with the opposite extremity, and external rotation with a cane in the PoS. The arm can be positioned, as ROM allows, into greater abduction while performing ER with a cane.
- The dosage of ROM exercise can be increased and is dependent on the patient's response to treatment. ROM exercises can be performed more frequently and held for a longer duration.
- Pulley exercise can be performed with adequate ROM (≈130° flexion) and humeral head control to avoid shrug and impingement symptoms. The patient sits facing the pulley. The patient stretches the involved shoulder into flexion in the plane of the scapula. The involved elbow moves from a position of flexion to extension as it is stretched overhead to keep a short lever arm. The stretch is held for 10 seconds, and the exercise is continued as long as the patient is not experiencing impingement symptoms. As tolerated, the patient may hold the stretch longer. With increased duration of the stretch, the number of repetitions can decrease.

- Self-stretching in a doorway for ER in modified neutral affords the patient frequent stretching opportunities. The patient faces a door jam. With the elbow flexed to a right angle and held close to her side, the patient slowly turns to the direction opposite the shoulder (i.e., right shoulder, turn towards left) and holds the position to duration recommended by physical therapist—initially for 10 seconds, 10 reps.
- As IR in the PoS improves toward normal, AAROM for IR behind the back can be initiated using the opposite extremity for assistance (5- to 10-seconds hold for 5 to 10 reps)
- Hydrotherapy can be used to interrupt the pain-inflammation-spasm cycle and to provide an environment for active-assistive exercise. The water temperature is warm to create an environment that promotes relaxation. Supine abduction with buoyancy-assisted device at surface of water, ER ROM with paddle, and pass behind the back with buoyancy device for functional IR. If the patient is willing, the patient can go under water to increase arc of buoyancy.
- CPM for IR/ ER, PoS, in modified neutral

Other Therapeutic Exercises

- Strengthening exercises are performed two to three times per week.
- TBS
  - Stationary bicycle, elliptical. As the patient is comfortable using the UE for balance, the stationary bike and elliptical can be used. The bicycle will be introduced first followed by the elliptical without UE movement. Use of the UEs can be started progressively on an interval basis (30 seconds work, 1 minute rest). The individual will move the shoulder in a pain-free ROM, below shoulder height. Pain and progression of ROM will guide tolerance to these exercises.
  - Use of the arms below shoulder height with cardiovascular equipment (elliptical, bicycle) can be introduced for a short duration, as tolerated.
- Core strengthening
  - Lower abdominal strengthening using Sahrmann progression, bridging bilateral to marching in place, to single leg bridge. Avoid loading the elbow as in a plank position.
- TAS
  - Avoid overhead exercise.
  - Perform pain-free exercise within the available ROM such as biceps curls, triceps extensions, scapular retraction, and scapular protraction. While performing biceps curls and triceps extensions, it is important that the patient avoid forcing the humeral head anterior. This is achieved by making sure that the weight is not too heavy causing the patient to not go through the full ROM at the elbow. Upper body ergometry can be incorporated as a warmup.
- TLS
  - Squats, knee extension, knee flexion, side lying hip abduction
  - Machines for hip abduction/adduction

Activation of Primary Muscles Involved

- Emphasis is on periscapular muscles—rhomboids, serratus, latissimus, trapezius—to provide a proximal stable base for distal mobility and to reestablish force couples necessary for shoulder elevation: scapular retraction, protraction, extension to neutral. Scapular retraction can be performed in sitting—resistance with elastic bands can be added; scapular protraction in supine—resistance with hand weights can be added; lower trapezius isometrics in an upright position, which will also be postural cues, shoulder extension to neutral with elastic bands progressing from ≈45° flexion to 0° (side of body). These exercises will be performed three times per week. Three times 10 reps progressing to two times 15 reps before increasing resistance
- Progress from submaximal RC isometrics in modified neutral: 5-second hold, 5-second rest for 10 reps, two times per day to isotonics in S/L position to neutral. Five reps, three sets, two-three times per week.
- Active exercise is performed in the plane of the scapula.

Sensorimotor Exercises

- Hydrotherapy for its hydrostatic properties

Open and Closed Kinetic Chain Exercises

- CKC physioball stabilization exercises can be performed below shoulder height with double arm support. CKC exercise causes contraction of the force couples, allows the rotator cuff to work as a compressor, and creates an axial load (weightbearing). A physioball is positioned on a secured surface (chair, resting on a toss back) so that the UE is positioned below shoulder height. The size of the ball allows the patient to position her arms slightly wider than her body. With the elbows straight, the patient then compresses the ball and performs small movements in the coronal plane (side to side), the sagittal plane (up and down) with the shoulder girdle positioned, as instructed by the therapist, in retraction, protraction, or neutral. Three sets of 10 repetitions can be performed in each direction, as tolerated.
- OKC exercises such as pain-free forward flexion—full can position—in the plane of the scapula can be initiated with good scapulohumeral rhythm; dumbbell row with hand weights, shoulder extension in prone with hand weights, single arm cable column pulldown in plane of scapula.

Techniques to Increase Muscle Strength, Power, and Endurance

- These exercises should be pain-free and performed two to three times per week. Exercising into pain or with pain will further irritate the shoulder and cause loss of motion, and thus function. There is a balance of enough resistance to stimulate the muscle without aggravating the joint.
- Upper body ergometry can be incorporated: Airdyne (arms only) with elevated seat height for 5 minutes, as

tolerated; upper extremity bicycle also with high seat height.
- Use of arms below shoulder height with cardiovascular equipment (elliptical, bicycle) can be introduced for a short duration.
- Strengthening of the periscapular muscles for retraction in sitting or standing with elastic bands or manual resistance, protraction in supine with weight of arm, then progressing to hand weights, and extension in standing with elastic bands or prone with weight of arm against gravity progressing to hand weights to neutral is important to reestablish force couples for synchronous arm elevation.

Neuromuscular Dynamic Stability Exercises

- Proprioceptive neuromuscular facilitation (PNF) exercise such as rhythmic stabilization in supine is performed for IR/ER (PoS) in modified neutral and at shoulder height with the elbow as tolerated. This can be performed for 10 seconds initially for three to four sets.

FIGURE 8-3. Mobilization of the thoracic spine.

Functional Exercises

- Begin pain-free scapula plane elevation—full can position—to shoulder height when good scapulohumeral rhythm is evident.
- Hydrotherapy may be used initially to provide environment for active-assistive exercise.

Sport-Specific Exercises

- N/A with the exception of progressive ROM exercises.
- Incorporating exercises for core, TBS, TAS, and TLS is encouraged, keeping in mind the limitations and precautions associated with the involved shoulder.

Milestones for Progression to the Next Phase

- Control pain/inflammation
- Resolution of rest and night pain
- Compliance with home exercise program
- Avoid subacromial impingement
- Avoid rotator cuff inhibition, which is determined by increased pain with therapeutic exercise, pain at rest, and increased compensatory movements.
- Minimize loss of ROM
- Minimize capsular contracture. This can be determined by assessing joint play, end feel with humeral head glides, as well as by postural habitus and ROM deficits.
- Normalize scapulohumeral rhythm to shoulder height in the plane of the scapula, pain-free

Phase III (weeks 9 to 16): Optimization of ROM

Management of Pain and Swelling

- Patient education
- Oral NSAIDs
- Intrarticular injection
- Avoid pain with strengthening
- ROM exercises to the shoulder's tolerance
- Cryotherapy
- Moist heat
- Activity modification.

Techniques for Progressive Increase in Range of Motion

Manual Therapy Techniques

- Joint mobilization techniques in the posterior direction, inferior direction, and distraction. Mobilization can be performed at end range positions.
- Pain-free ROM using physiological movements for scapula plane elevation, IR/ER, abduction, ER/IR at 90° abduction
- PNF such as hold-relax for IR ROM in the PoS; at 90° abduction; for ER ROM at the PoS; at 90° abduction
- Thoracic spine mobilization (Figure 8-3)

Soft Tissue Techniques

- Therapeutic massage for dissociation of the shoulder girdle: subscapularis, latissimus, teres, and pectorals

Stretching and Flexibility Techniques for the Musculotendinous Unit

- In this phase, as irritability of the shoulder decreases, ROM can be performed at end range and held for longer duration. Stretching exercises are performed two to three times per day.
- Pendulum exercise
- Pulley exercise can be performed with adequate ROM (≈130° flexion) and humeral head control to avoid shrug and impingement. The patient can use pulleys at home daily.

- Self-stretching using the opposite extremity or cane for supine scapular plane elevation: The patient lies on her back with the cane in her left hand steering/assisting the right arm into flexion—the right arm is positioned with the right palm facing the toward the body. Supine internal rotation with the opposite extremity or cane: The patient lies with the arm in the plane of the scapula or at 90° abduction. With the left hand or with a cane in the left hand, rotate the right arm in the direction of internal rotation; and supine external rotation with a cane in the PoS and at 90° abduction. With the left hand or with a cane in the left hand, rotate the right arm in the direction of external rotation.
- Low load, long duration stretching is recommended, with decreased irritability characteristic of the latter stage. The total end range time is increased to affect capsular extensibility and remodeling.
- *These stretches can be initiated for 10 second holds for 10 reps, two times per day.*
- Initiate posterior capsule stretching with avoidance of impingement symptoms.
- IR behind the back with a strap
- Inferior capsule stretch
- Chicken wing stretch: Lie on your back with hands behind head and arms positioned in horizontal abduction/ER.
- Pectoral stretch in doorway: Stand in the doorway.
- Sleeper stretch performed without impingement symptoms
- Cane forward flexion: The patient lies on her back with the cane in her left hand steering/assisting the right arm into flexion—the right arm is positioned with the right palm facing towards the body.
- Trunk rotation in supine hook-lying position or with legs supported by a physioball
- Hip stretching

Clinical Pearl

When introducing self-stretches, it is imperative that the patient feel the stretch in the targeted tissue. Avoid symptoms of impingement with horizontal adduction, sleeper stretch, etc.

Other Therapeutic Exercises

- Strengthening exercises are performed two to three times per week.
- TBS
  - Stationary bicycle
  - Elliptical
  - Use of the UE during cardiovascular exercise can be initiated to tolerance such as bike with arms, elliptical with arms.
  - The patient can perform a modified breast stroke.
- Core strengthening
  - Lower abdominal strengthening
  - Bridging
  - Introduce trunk rotation strengthening.
- TAS
  - Avoid overhead exercise.
  - Perform pain-free exercise within the available ROM such as biceps curls, triceps curls, scapular retraction, and scapular protraction.
  - Upper body ergometry, use of arms in c-v equipment progresses to tolerance.
- TLS
  - Squats, RDLs, knee extension, knee flexion, side-lying hip abduction
  - Machines for hip abduction/adduction, gluteals
  - Lunges, lunges with rotation

Activation of Primary Muscles Involved

- Perform two to three times per week.
  - With adequate ROM and no pain with muscle activation, rotator cuff exercises in the PoS are progressed from side-lying position to the upright position with elastic resistance in modified neutral.
  - With adequate ROM, advanced, progressive scapular strengthening can be performed. These exercises can include: single arm pull down with cable column from overhead, chest press, latissimus pulldown, and prone horizontal abduction for middle trapezius with adequate length of pectorals.

Sensorimotor Exercises

- Hydrotherapy for its hydrostatic properties: The water temperature is warm to create an environment that promotes relaxation. Supine abduction with buoyancy-assisted device at surface of water, ER ROM with paddle, and pass behind the back with buoyancy device for functional IR. If the patient is willing, the patient can go under water to increase arc of buoyancy. Walking forwards with arms abducted will help stretch the anterior chest. Gentle strengthening of proximal scapular musculature can be achieved with scapular retraction/protraction with dumbbells or paddle board; shoulder extension with gloves or paddles, scaption to surface of water with appropriate resistance as tolerated, as well as IR/ER with appropriate resistance of paddle. Walking backward in water will facilitate scapular retractors,
- Hydrotherapy exercises will replace one day of strengthening on land.

Open and Closed Kinetic Chain Exercises

- Quadruped can be initiated to tolerance for scapular stabilization.
- Physioball exercises below shoulder height can be progressed from double arm support to single support, as tolerated.

Techniques to Increase Muscle Strength, Power, and Endurance

- Upper body ergometry for 5 minutes
- Strengthening of the biceps and triceps with comfortable resistance.

FIGURE 8-4. Wall slides to assist with AROM.

- Reestablish force couples for arm elevation above shoulder height.
- Bench/chest press can be performed in water with a paddle, on land with dumbbells, and wall pushups.

Neuromuscular Dynamic Stability Exercises

- PNF such as PoS rhythmic stabilization for IR/ ER in modified neutral, and shoulder height elevation will be progressed to more challenging positions.
- Initiate PNF D2 flexion in supine for 10 reps, one set, three times per week.

Functional Exercises

- Scapular plane elevation (full can position) to shoulder height with good scapula-humeral rhythm
- Hydrotherapy
- Wall slides (Figure 8-4) are performed in the PoS.

Milestones for Progression to the Next Phase

- Resolution of night pain, pain with ADLs, therapeutic exercise
- AROM = PROM
- Maximize function. This is measured using an outcomes scale (DASH), and by observation of movement patterns such as raising the arm, reaching behind the back, reaching out to the side, as well as patient willingness to use the arm. This is also achieved when AROM = PROM.
- Normalize scapulohumeral rhythm above shoulder height—measured by observation as the patient raises the arm. In the middle of the arc of motion, scapular motion should be greater than humeral motion so that the glenoid is positioned to receive the humeral head.
- Reestablish force couples for arm elevation. Manual muscle testing allows the physical therapist to assess muscle strength; however, timing is assessed with observation.
- Avoid impingement.
- Compliance with home exercise program

Phase IV (weeks 17 to 22): Strengthening

Management of Pain and Swelling

- Cryotherapy
- Functional progression
- Avoid pain with exercise.
- Patient education: activity modification; avoid too much, too soon; avoid subacromial impingement
- Emphasize quality of movement.

Techniques for Progressive Increase in Range of Motion

Manual Therapy Techniques

- Evaluation-based
- Pain-free ROM using physiological movements for scapula plane elevation, IR/ ER, abduction, ER/ IR at 90° abduction.
- Proprioceptive neuromuscular facilitation (PNF) such as hold-relax (Figure 8-5)

Soft Tissue Techniques

- Evaluation-based; maintenance of ROM

Stretching and Flexibility Techniques for the Musculotendinous Unit

- These stretches will be held for 30 seconds, three reps, two times per day:
  - Pectoral stretch in doorway
  - Sleeper stretch (avoid impingement)
  - Posterior capsule stretch (avoid impingement)
  - Cane forward flexion
  - Towel IR stretch behind back
  - Chicken wing

FIGURE 8-5. Hold-relax for internal rotation ROM at 90° abduction.

Other Therapeutic Exercises

- As described previously

Activation of Primary Muscles Involved

- These exercises are performed two to three times per week, emphasizing quality of movement:
  - Advanced periscapular strengthening such as prone exercises for lower trapezius, middle trapezius, and latissimus. These exercises are performed with scapular setting before upper extremity movement.
  - Pain-free RC PREs IR/ ER with elastic resistance. Place a towel roll under the arm and rotate only to neutral position.

Sensorimotor Exercises

- PNF diagonal pattern D2 flexion progressions from supine to standing

Open and Closed Kinetic Chain Exercises

- Wall pushup progression to pushups beginning with an upright position and gradually progressing to floor, single arm ball stabilization

Techniques to Increase Muscle Strength, Power, and Endurance

- Upper body ergometry
- Cardiovascular equipment with UEs
- Upper body weight training: row, lat pulldown, chest press

Neuromuscular Dynamic Stability Exercises

- PNF diagonal patterns D2 flexion progressing from supine to standing progression
- Bodyblade can be introduced in modified neutral position with IR/ER oscillations for 30 seconds.

Plyometrics

- Latter part of phase: Ball toss such as chest pass, overhead toss, and side to side toss can be introduced.

Functional Exercises

- PNF diagonal patterns D2 flexion initiated in supine for 10 reps
- Scapular plane elevation—full can position—with good scapula-humeral rhythm, pain-free (emphasize quality of movement). Emphasize posture and stabilization through core. Do not perform more than 10 reps in a set. May perform three sets.

Sport-Specific Exercises

- These are introduced based on the demands of the sport that the athlete is returning to.

Milestones for Progression to Advanced Sport-Specific Training and Conditioning

- Resolution of pain with ADLs, therapeutic exercise
- AROM/ flexibility to meet demands of sport
- Strength to meet the demands of sport; 85% of uninvolved shoulder with isokinetic dynamometer or manual muscle tester
- Pain-free progression of exercises
- Normalized S-H Rhythm throughout the ROM via observation. In the early part of the ROM (0° to 60°), humeral motion is greater than scapular motion. Between 60° and 120°, scapula motion is greater than humeral motion, and in the final phases of elevation (120° to180°), humeral motion is greater than scapular motion.

Phase V (weeks 23+): Return to Sport

Management of Pain and Swelling

- Cryotherapy
- Patient education: Avoid too much, too soon; emphasize quality of movement, functional progression. As described above, as patient demonstrates decreased irritability, improved ROM, and strength, exercise progressions will build on previous reached milestones.

Techniques for Progressive Increase in Range of Motion

Manual Therapy Techniques

- Evaluation-based

Soft Tissue Techniques

- Evaluation-based; maintenance of ROM

Stretching and Flexibility Techniques for the Musculotendinous Unit

- These stretches are held for 30 seconds, and performed three times, twice daily:
  - Pectoral stretch in doorway: Stand in the doorway.
  - Sleeper stretch
  - Posterior capsule stretch
  - Cane forward flexion: The patient lies on her back with the cane in her left hand steering/assisting the right arm into flexion—the right arm is positioned with the right palm facing towards the body.
  - Towel IR stretch behind back. Stand
  - Chicken wing

Other Therapeutic Exercises

- As described previously

Activation of Primary Muscles Involved

- Advanced periscapular strengthening such as prone exercises for lower trapezius, middle trapezius, latissimus
- RC PREs: IR/ ER at 90° abduction as tolerated

Sensorimotor Exercises

- These are initially performed for 10 repetitions and then progresses to three sets:
  - PNF diagonal pattern progressions from supine to standing; from no resistance to manual resistance and resistance with elastic bands.

Open and Closed Kinetic Chain Exercises

- Wall pushup progression to pushups
- Single arm ball stabilization
- Quadruped activities continue

Techniques to Increase Muscle Strength, Power, and Endurance

- Upper body ergometry: can be incorporated using a rowing ergometer, upper body bicycle, or Airdyne beginning with 5 minutes and progressing to patient tolerance.
- Cardiovascular equipment with UEs: such as elliptical, rowing ergometer, Nordic track
- RC and periscapular strengthening: prone exercises such as prone horizontal abduction, prone lower traps
- Isokinetic training for IR/ER
- Upper body weight training: row, lat pulldown, chest press

Neuromuscular Dynamic Stability Exercises

- Beginning with 10 reps.
- PNF diagonal patterns progressing from supine to standing progression (Figure 8-6)
- Bodyblade with longer lever arm, in diagonal patterns
- Stabilization exercises
- RC strengthening at 90/90 position with rhythmic stabilization at end range for five reps
- Quadruped on unstable surfaces for 15 to 30 seconds, three reps

FIGURE 8-6. Proprioceptive neuromuscular facilitation performed manually in supine.

Plyometrics

- Ball tosses are performed for 10 reps each, two sets.
- Initiate ball toss—two-hand chest pass
- Activity-specific plyos
- Ball tosses: chest pass, overhead pass progressing from two-handed to single-handed, side passes

Functional Exercises

- PNF diagonal patterns progressing from supine to standing progression
- Deceleration exercises with cable column, ball toss

Sport-Specific Exercises

- These are introduced based on the demands of the sport and position that the athlete is returning to and will be introduced on an individual basis.
  - If the athlete is returning to throwing, an interval throwing program should be used to gradually introduce stresses.
- The program will be adjusted according to sport and position, and will begin with a day of rest in between throwing sessions. Soreness is expected, sharp pain should not be worked through.
  - Throwing
  - Catching/receiving
  - Tackling
  - Swimming
  - Swinging
  - Batting
  - Rowing
  - Lifting

Criteria for Abandoning Nonoperative Treatment and Proceeding to Surgery or More Intensive Intervention

- When physical and pharmacological therapies have failed, surgical options should be considered and discussed with the patient.
- Failed therapy should be considered when the patient has reached a plateau or progress in increasing ROM is extremely slow for the patient function.
- Painful shoulder that has failed to respond to intraarticular corticosteroids
- Surgery is indicated when the patient is failing to improve with minimum of 6 months of conservative treatment.

Tips and Guidelines for Transitioning to Performance Enhancement

- Transition to performance will begin in the latter phases (phases IV and V) with regard to training the upper extremity.

- When the patient has achieved the phase III milestones, transition to performance can be made.
- Core exercises and lower body transition to performance can be ongoing from the early phases. This will help keep the athlete engaged.
- As always, communication between the physical therapist and performance specialist must be ongoing.

Performance Enhancement and Beyond Rehabilitation: Training/ Trainer and Optimization of Athletic Performance

- Maintaining a solid foundation of strength is important for safe progression of functional exercises. This is monitored through observation of quality of movement and strength testing.
- Care is taken to monitor ROM and flexibility throughout to ensure proper shoulder mechanics.
- Lower extremity, and trunk strength and mobility will take stress off the shoulder.
- Adequate core strength will transfer power from the lower extremities to the upper extremities.
- Adequate rest is incorporated into the upper extremity training program to prevent flaring the joint.
- Close attention is paid to the volume of exercise. The performance specialist must recognize signs and symptoms of inflammation such as pain, loss of motion, and a decrease in strength, and readily communicate with the physical therapist. The athlete will not be pushed through pain and inflammation to avoid setbacks.
- Be careful not to perform more than two exercises per muscle isolation.

Specific Criteria for Return to Sports Participation: Tests and Measurements

- ROM/flexibility to meet the demands of the sport
- Full, pain-free ROM
- IR/ ER strength 3:2 ratio in involved extremity. This can be measured with an isokinetic dynamometer or with a manual muscle tester.
- Strength 85% of uninvolved extremity. This can be measured with an isokinetic dynamometer or with a manual muscle tester.

Evidence

Carette S, Moffet H, Tardif J, et al: Intraarticular corticosteroids, supervised physiotherapy, or a combination of the two in the treatment of adhesive capsulitis of the shoulder. *Arth Rheum* 48(3):829–838, 2003.

This controlled prospective study randomized 93 patients to compare the efficacy of intraarticular injection, supervised PT, the combo of PT and injection, and placebo. Using the SPADI, the injection and PT group demonstrated faster results; however, injection alone yields better results than supervised PT alone. (Level II evidence)

Diercks RL, Stevens M: Gentle thawing of the frozen shoulder: a prospective study of supervised neglect versus intensive physical therapy in seventy-seven patients with frozen shoulder syndrome followed up for two years. *J Shoulder Elbow Surg* 13(5):499–502, 2004.

This prospective study of 77 patients randomized into supervised neglect (education, instructed not to exercise in excess of pain threshold, pendulums, AROM within pain threshold) and intensive physical therapy (executed by a physical therapist: AROM up to and beyond pain threshold, passive stretching and manipulation, and home stretching based on maximal stretching and reaching). A Constant score of ≥80 was reached by 89% at 24 months (64% at 12 months) in the supervised neglect group, and by 63% at 24 months in the intensive physical therapy group. (Level II evidence)

Griggs SM, Ahn A, Green A: Idiopathic adhesive capsulitis. A prospective functional outcome study of non-operative treatment. *J Bone Joint Surg* 10(82–A):1398–1407, 2000.

This prospective study evaluated the outcomes of patients with stage II idiopathic adhesive capsulitis who were treated with a four-direction shoulder-stretching program. Outcomes included assessment of pain, range of motion, and function. Ninety percent of the patients reported a satisfactory outcome with a significant decrease in pain at rest, with activity and increase in active and passive ROM. (Level IV evidence)

Hazelman BD: The painful stiff shoulder. *Rheumatol Phys Med* 11:413–421, 1972.

This retrospective review of 130 patients noted that the efficacy of intraarticular hydrocortisone injections inversely correlates with the duration of symptoms. Further, discrimination between stage 1 and 2 disease can be determined based on the patient's response to the local anesthetic and thus can be used for future treatment options. (Level III evidence)

Johnson AJ, Godges JJ, Zimmerman GJ, et al: The effect of anterior versus posterior glide joint mobilization on external rotation range of motion in patients with shoulder adhesive capsulitis. *J Orthop Sports Phys Ther* 37(3):88–99, 2007.

This randomized control trial (RCT) demonstrated a significant difference in ER ROM when posteriorly directed mobilization was added to the treatment as compared to anteriorly directed mobilization. (Level II evidence)

Light KE, Nuzik S, Personius W, et al: Low-load prolonged stretch vs. high-load brief stretch in treating knee contractures. *Phys Ther* 64(3):330–333, 1984.

Sequential medical trials were used to compare the results of high-load brief stretch to low-load prolonged stretch knee extension PROM. A 10° difference was noted in favor of LLPS. (Level II evidence)

McClure PW, Blackburn LG, Dusold C: The use of splints in the treatment of joint stiffness: Biologic rationale and an algorithm for making clinical decisions. *Phys Ther* 74(12):1101–1107, 1994.

This paper discusses the total end range time (TERT), the amount of time the joint is held at or near end-range position.

The total algorithm is based on pain and ROM. (Level VI evidence)

Neviaser RJ, Neviaser TJ: The frozen shoulder: diagnosis and Management. *Clin Orthop Rel Res* 223:59–64, 1987.

This evidence paper describes 4 stages of adhesive capsulitis—the preadhesive stage, the freezing stage, the frozen or maturation stage, and the thawing stage—by correlating physical exam with the arthroscopic findings. (Level V evidence)

Oh JH, et al: Comparison of glenohumeral and subacromial steroid injection in primary frozen shoulder: A prospective, randomized short-term comparison study. *J Shoulder Elbow Surg* 20(7):1034–1040, 2001.

This prospective, randomized trial randomly divided 71 patients with primary adhesive capsulitis into glenohumeral or subacromial ultrasound guided injection. The GH steroid injection led to earlier pain relief. (Level II evidence)

Multiple-Choice Questions

QUESTION 1. The optimal way to gain ROM

A. Push the shoulder into painful ROM.
B. Ignore the patient's response to treatment.
C. Determine the irritability of the shoulder and apply TERT principles.
D. A and C

QUESTION 2. Stage 2 adhesive capsulitis is characterized by

A. Pain in the early stage
B. Stiffness in the late stage
C. Transition from stage 1 to 3
D. All of the above

QUESTION 3. To increase ER ROM, the most effective direction for joint mobilization is

A. Inferior
B. Posterior to anterior
C. Anterior to posterior
D. Distractive

QUESTION 4. Abandonment of nonoperative treatment should be considered when

A. Physical and pharmacological therapies have failed
B. Failure to improve with a minimum of 6 weeks of conservative treatment
C. Failure to improve with a minimum of 6 months of conservative treatment
D. A and C

Answer Key

QUESTION 1. Correct answer: **C** (see Phase I)

QUESTION 2. Correct answer: **D** (see Introduction)

QUESTION 3. Correct answer: **C** (see Phase III)

QUESTION 4. Correct answer: **D** (see end of Phase IV)

POSTOPERATIVE REHABILITATION AFTER CAPSULAR RELEASE FOR GLENOHUMERAL ADHESIVE CAPSULITIS

Theresa A. Chiaia, PT, DPT, Jo A. Hannafin, MD, PhD, and A. Simone Maybin, BS, NSCA-CPT

Indications for Surgical Treatment

- When physical and pharmacological therapies have failed, surgical options should be considered and discussed with the patient.
- Failed therapy should be considered when patient has reached a plateau or progress in increased ROM is extremely slow for the patient's function.
- Painful shoulder that has failed to respond to intraarticular corticosteroids
- Surgery is indicated when the patient is failing to improve with a minimum of 6 months of conservative treatment.

Brief Summary of Surgical Treatment

Major Surgical Steps

- Examination under anesthesia to document glenohumeral and total ROM
- Shoulder arthroscopy in beach chair position (author preference)
- Diagnostic arthroscopy before manipulation
- Thorough diagnostic arthroscopy with synovectomy as needed
- Capsular release is performed using thermal device from 1 to 5 o'clock (right shoulder, medial to labrum)

- Adequate visualization of subscapularis muscle belly
- Beginning release superiorly permits better visualization for distal release
- Switch arthroscope to anterior portal and continue release from 11 to 7 o'clock
  - Pearl: Keep pump pressure at 25 mmHg to decrease shoulder swelling.
- Remove instruments and perform manipulation.
- Author's preference: external rotation, forward flexion, abduction and internal rotation

Factors That May Affect Rehabilitation

- Regional anesthesia is used to permit passive ROM.
- Pain management is critical to permit physical therapy on postoperative day 1.

Other Surgical Techniques and Options

- Some surgeons prefer to manipulate the shoulder before arthroscopy.
- If synovectomy is needed, time may be limited secondary to swelling.

Before Surgery: Overview of Goals, Milestones, and Guidelines[1]

GUIDING PRINCIPLES OF POSTOPERATIVE REHABILITATION

- Understand the procedure performed.
- Understand the duration of symptoms and preoperative ROM.
- Understand the anatomic structures.
- Achievement of phase-specific goals will determine advancement.
- Control pain and inflammation.
- Understand the goals of the patient.
- Attain ROM achieved post manipulation in the OR.
- Discourage the formation of adhesions.

Phase I (days 0-14): Immediate Postoperative Period

Clinical Pearls

- Pain management is the key to this phase of rehabilitation.
- Adequate pain control will allow the patient to attain post-manipulation ROM achieved in the OR.
- ROM exercises are performed with the goal of achieving postmanipulation ROM.
- The patient is seen five times per week for 2 weeks to meet this objective.

[1]*Prehabilitation, if appropriate, is described in the Nonoperative Rehabilitation section of this chapter.*

Goals

- Control postoperative pain and inflammation.
- Comply with activity modification, HEP, positioning.
- Attain ROM achieved postmanipulation in the OR.
- Discourage the formation of adhesions.
- Minimize rotator cuff inhibition.

Protection

- Sling is used until block wears off.

Management of Pain and Swelling

- For pain:
  - Block may be kept in overnight for pain control so intraoperative ROM can be achieved repeatedly. Also, it allows the patient to see their extremity move through the ROM.
  - TENS
  - Oral NSAIDs
  - Oral pain medication
  - Cryotherapy
- To decrease swelling:
  - Cryotherapy
  - Oral NSAIDs

Techniques for Progressive Increase in Range of Motion

Manual Therapy Techniques

- Gentle shaking of the extremity: Gently grasp the patient's wrist and gently oscillate her upper extremity in a comfortable, neutral position for 10 to 15 seconds. This will allow the patient to relax and help to control pain.
- Joint mobilizations: The glenohumeral joint is mobilized using Grade I mobilizations to help modulate pain in the posterior/dorsal direction, inferior, and caudal, lateral distraction direction. The sternoclavicular, acromioclavicular, and scapulothoracic articulations are assessed for restrictions and addressed, as needed.
- ROM: Physiological movements such as scapular plane elevation with the arm in modified neutral, IR/ ER in the plane of the scapula (PoS), and abduction will help modulate pain by stimulating mechanoreceptors. These movements are performed in a slow, consistent tempo by the therapist to promote relaxation. The duration is up to 10 seconds for 10 repetitions with gradual increase in duration and frequency as tolerance and irritability of the shoulder permit. The goal is to work toward ROM achieved following capsular release.

Soft Tissue Techniques

- Therapeutic massage for myofascial release of pectorals, triceps, latissimus, and subscapularis (Figure 8-7). Firm, consistent pressure is applied to soft tissue so that it surrenders and relaxes.

FIGURE 8-7. Demonstrating therapeutic massage: Myofascial release for pectorals.

Stretching and Flexibility Techniques for the Musculotendinous Unit

- Pendulum exercises produce joint distraction and increase the arc of pain-free movement. Pendulum exercises should be pain-free. This is achieved when the patient bends forward and uses body momentum to create arm movement. The arc of motion should be within an arc that is pain-free and allows the UE to relax. The patient chooses the direction of movement. These are performed three times for 10 to 30 seconds. This should be a "go-to" exercise during the day.
- Physiological movements using the opposite extremity with low load (intensity) and low duration exercises performed three to five times per day. For example: supine forward flexion, supine IR, supine ER in the plane of the scapula with a cane. There is a balance of moving the shoulder to increase ROM and flaring the shoulder and losing ROM. The goal is ROM achieved during capsular release.
- Supine "T towel" positioning, with a towel roll positioned along the spine and a second along the base of the head, is recommended to promote thoracic extension and allow the anterior positioned humeral head to sit back. It is recommended that the patient lie in this position for 10 minutes, twice a day.
- Continuous passive motion (CPM) in the PoS for IR/ER in modified neutral can be used. This modality allows the patient to relax as the shoulder is cycled through internal and external rotation. It can be used at comfortable, slow speeds—a pause can be used for a patient who can tolerate a longer time at end range. The duration of each session is 10 to 15 minutes.
- Hydrotherapy provides an environment for active-assistive exercise and can be initiated with occlusive dressing to protect the incisions, as per surgeon's recommendations and clearance. The water temperature is warm to create an environment that promotes relaxation. The patient is instructed to perform modified breast stroke movements (horizontal abduction and adduction), flexion in the plane of the scapula, and gentle internal and external rotation.

Other Therapeutic Exercises

- Light cardiovascular exercise such as stationary bicycle. Avoid perspiration in the surgical wounds.

Activation of Primary Muscles Involved in Injury Area or Surgical Structures

- Exercises for the distal extremity may be performed, such as gripping, wrist extension/flexion, forearm pronation/ supination, and elbow flexion/extension. These are performed with no resistance initially.
- Postural retraining. The patient is instructed in scapular retraction with the arms supported on her lap, as well as sternal lifts. The patient is encouraged to do posture checks throughout the day.
- Scapular mobility in side-lying with UE supported in the PoS. The patient actively moves the scapula in the direction of elevation, depression, retraction, and protraction—10 times each direction for two sets. Manual tactile cues can be given.

TIMELINE 8-2: **Postoperative Rehabilitation after Capsular Release for Glenohumeral Adhesive Capsulitis**

PHASE I (weeks 1 to 2)	PHASE II (weeks 3 to 6)
• Sling immobilization until block wears off • PT modalities for pain, inflammation • Codman's/ pendulum exercises • Manual therapy: mobilizations, ROM • Therapeutic massage • Self-stretching • Initiate scapula strengthening • Submaximal deltoid isometrics • Postural retraining • Hydrotherapy • CPM for IR/ER • Exercises for distal extremity • Home exercise program • TBS/TAS/TLS activities as recommended & tolerated	• PT modalities for pain, inflammation, relaxation • Manual therapy • Therapeutic massage • Home exercise program • Hydrotherapy • CPM for IR/ER • Upper body ergometry for active warm-up • Scapular exercises • RC isometrics to RC PREs • Neuromuscular reeducation: rhythmic stabilization exercise • TBS/TAS/TLS activities as recommended & tolerated

Techniques to Increase Muscle Strength, Power, and Endurance

- Light cardiovascular exercise

Neuromuscular Dynamic Stability Exercises

- With the patient lying in supine, the patient's upper extremity is positioned in the plane of the scapula and the elbow is supported on a towel roll with the elbow flexed to 90°. The therapist applies gentle pressure at the wrist in the direction of internal and external rotation in alternating fashion to work on humeral head control. The patient is instructed to hold the arm stable, thus working on coordination. This can be performed for 10 seconds initially for three to four sets.

Milestones for Progression to the Next Phase

- Control pain/ inflammation
- Resolution of rest pain
- Compliance with activity modification
- Achievement of postmanipulation ROM (i.e., full ROM).

Phase II (postoperative weeks 2 to 6)

Clinical Pearls

- Postmanipulation ROM should be maintained during this phase. Monitor the patient for loss of ROM and signs of increased shoulder irritability.
- Compliance with activity modification will control pain/inflammation and avoid impingement during use of the extremity, and thus assist with ROM goals.
- Scapular strengthening is progressed so that an adequate strength base is developed for functional use of the extremity and more advanced exercises.
- RC strengthening can be initiated if pain free.

Goals

- Control pain/inflammation
- Achieve/maintain post-manipulation ROM
  - Minimize rotator cuff inhibition, which is determined by increased pain with therapeutic exercise, pain at rest, and increased compensatory movements.
- Compliance with activity modification, and with home exercise program
- AROM in the PoS to shoulder height with good S-H rhythm

Management of Pain and Swelling

- Treatment for pain/analgesia
  - TENS
  - Oral NSAIDs
  - Oral pain medication
  - Cryotherapy

Clinical Pearl

The use of cryotherapy is continued to control post-operative pain, and inflammation, as patient activity level continues to increase.

- To decrease swelling
  - Cryotherapy
  - Oral NSAIDs

Techniques for Progressive Increase in Range of Motion

Manual Therapy Techniques

- Joint mobilizations are evaluation-based, Grade I to II (in the latter phase (evaluation-based), in the posterior direction, inferior, and caudal direction, and lateral

TIMELINE 8-2: **Postoperative Rehabilitation after Capsular Release for Glenohumeral Adhesive Capsulitis** (Continued)

PHASE III (weeks 6 to 10)

- Patient education: activity modification, avoid "too much, too soon," functional strengthening progression
- Home exercise program, as instructed
- Modalities, prn: moist heat, cryotherapy
- Manual therapy: prn: contract-relax, joint mobilizations
- Upper body ergometry for active warm-up, endurance training
- Advanced periscapular strengthening: prone exercises for middle trapezius, lower traps, latissimus
- RC PREs, pain-free
- Upper body weight training
- Soft tissue techniques for subscapularis, latissimus, pectorals, teres, posterior capsule
- Hydrotherapy
- Rhythmic stabilization
- Ball stabilization
- PNF diagonal patterns
- ROM exercises: cane ER at 90° abduction; strap IR behind back
- Flexibility exercises: door stretch for pectorals, sleeper stretch, chicken wing
- TBS/TAS/TLS activities as recommended & tolerated

PHASE V (weeks 10 to 14+)

- Patient education
- Modalities: cryotherapy
- Home exercise program: as instructed
- Upper body ergometry for warmup, endurance
- Flexibility exercises for posterior cuff, posterior capsule, pectorals
- ROM exercises for maintenance
- Manual therapy (evaluation-based): prn
- Soft tissue techniques (evaluation-based): prn
- Advanced periscapular strengthening continues
- Advanced stabilization exercises
- Rotator cuff strengthening: IR/ER at 90° abduction
- Upper body weight training
- PNF Diagonal patterns
- Isokinetic training
- Plyometrics progression: ball toss
- Sport-specific exercises
- TBS/TAS/TLS activities as recommended & tolerated

distraction. Distraction may be applied in combination. This is a healing capsule.
- ROM: Pain-free physiological movements such as PoS forward flexion, IR/ER at 0°, 45°, and 90° abduction. The goal is to achieve intraoperative ROM. May need to perform high intensity (into discomfort), low duration for 10 repetitions. Tempo should be consistent to promote trust and relaxation.
- PNF: Hold-relax techniques can be performed for increasing IR and ER in the PoS. The patient holds an isometric contraction against resistance (determined by the therapist) from the therapist for a few seconds then gently releases followed by the therapist moving the arm into greater ROM for a few seconds. This can performed for three to five reps.

Soft Tissue Techniques

- Therapeutic massage for myofascial release of pectorals (supine), triceps (prone), latissimus (side-lying), and subscapularis (supine or side-lying)
- Mobilization of the scapula

Stretching and Flexibility Techniques for the Musculotendinous Unit

- Pendulum exercises can be performed as described to produce joint distraction and increase the arc of pain-free movement. The duration of this exercise can be increased.
- Pulley exercise can be performed with adequate ROM (≈130° flexion) and humeral head control to avoid shrug and impingement (Figure 8-8). The patient sits facing the pulley. The patient stretches the involved shoulder into flexion in the plane of the scapula. The involved elbow moves from a position of flexion to extension as it is stretched overhead to keep a short lever arm. The stretch is held for 10 seconds, and the exercise is continued as long as the patient is not experiencing impingement symptoms. As tolerated, the patient may hold the stretch longer. With increased duration of the stretch, the number of repetitions can decrease.
- Physiological movements using the opposite extremity with increasing intensity and increasing duration exercises performed three to five times per day. For example, supine forward flexion, supine IR, supine ER in the plane of the scapula with a cane. Supine ER at 90° abduction is added, as well as supine IR at 90° abduction with a cane. Initially these new additions are held for 10 seconds, 10 repetitions, and performed twice/day.
- Abduction/ER position with hands behind head in supine for 10 seconds. The patient can adduct arms so elbows are pointed toward the ceiling for rest position.
- Supine "T towel" positioning, with a towel roll positioned along the spine, and a second along the base of the head, is recommended to promote thoracic extension, and to allow the anterior positioned humeral head to sit back. The patient can relax in this position for 10°, twice a day.
- CPM in the PoS for IR/ER in modified neutral can be used.
- Hydrotherapy provides an environment for active-assistive exercise (Figure 8-9).

Other Therapeutic Exercises

- TBS exercises are performed in a progressive fashion so as not to flare the shoulder. Monitor for this.
  - Stationary bicycle, elliptical
  - Use of the arms below shoulder height with cardiovascular equipment (elliptical, bicycle) can be introduced for a short duration, as tolerated.
- Core strengthening
  - Lower abdominal strengthening (Sahrmann progression), bridging. Avoid loading through the shoulder such as planks at this time.

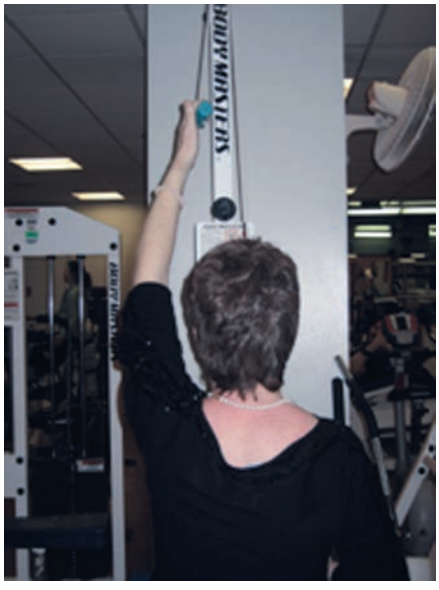

FIGURE 8-8. Pulleys are initiated when the athlete demonstrates ≈130° flexion and humeral head control to avoid a shrug and symptoms of impingement.

FIGURE 8-9. Hydrotherapy provides an environment for active-assistive exercise. Horizontal abduction is shown.

- TAS
  - Avoid overhead exercise.
  - Perform pain-free exercise within the available ROM such as biceps curls, triceps extensions, scapular retraction with elastic band resistance, and scapular protraction in supine with hand weights. Light resistance so full elbow flexion and extension occurs and compensatory anterior movement of the humeral head is avoided. These are performed thrice weekly for three sets of 10 repetitions.
  - Upper body ergometry can be incorporated as a warmup for 3 to 5 minutes. Adjust seat height to meet available AROM.
- TLS
  - Squats (no weight), knee extension, knee flexion, side lying hip abduction
  - Monster/crab walks, the clock

Activation of Primary Muscles Involved in Injury Area or Surgical Structures

- Submaximal rotator cuff isometrics are initiated if pain free in the early part of this phase (5 seconds on, 5 seconds off for 10 reps, twice daily). Pain-free RC strengthening is progressed from submaximal isometrics to isotonics (ER in side-lying in modified neutral) only if pain free and toward the middle or latter phase for three sets of 5 to 10 reps, two to three times per week.
- Periscapular muscles such as scapular retraction with elastic bands, scapular protraction performed in supine performed three times per week: three sets of 10 repetitions.
- Active exercise is performed in the plane of the scapula.

Sensorimotor Exercises

- Hydrotherapy can be used for its hydrostatic properties. The water temperature is warm to create an environment that promotes relaxation. Supine abduction with buoyancy-assisted device at surface of water, ER ROM with paddle, and pass behind the back with buoyancy device for functional IR. If the patient is willing, the patient can go under water to increase arc of buoyancy. Walking forward with arms abducted will help stretch the anterior chest. Gentle strengthening of proximal scapular musculature can be achieved with scapular retraction/ protraction with dumbbells or paddle board; shoulder extension with gloves or paddles, scaption to surface of water with appropriate resistance as tolerated, as well as IR/ER with appropriate resistance of paddle. Walking backward in water will facilitate scapular retractors.
- Hydrotherapy exercises will replace one day of strengthening on land.

Open and Closed Kinetic Chain Exercises

- CKC physioball stabilization exercises are performed below shoulder height with double arm support. CKC exercise causes contraction of the force couples, allows the rotator cuff to work as a compressor, and creates an axial load (weightbearing). Arms are held wider than shoulder width and are moved in a clockwise and counterclockwise direction for two sets of 10, three times per week.

Techniques to Increase Muscle Strength, Power, and Endurance

- Scapular strengthening is initiated in this phase to include rhomboids, serratus anterior, latissimus in the PoS (two to three sets of 10 to 15 repetitions, respectively, three times per week).
- Pain-free RC strengthening is progressed from submaximal isometrics to isotonics (ER in side-lying in modified neutral) only if pain free and toward the middle and latter phase for three sets of 5 to 10 reps, three times per week.
- Upper body ergometry may be initiated at this time for an active warmup for 5 minutes. Adjust seat height to work within available ROM without compensatory hiking of shoulder girdle.

Neuromuscular Dynamic Stability Exercises

- Rhythmic stabilization exercises performed in supine in the plane of the scapula and with the arm at shoulder height (supine) in the plane of the scapula for 10 seconds, three to four reps.

Functional Exercises

- Begin scapula plane elevation—full can position—to shoulder height when good, pain-free scapulohumeral rhythm is evident (no shrug). These are initiated with no weight and maximum volume is three sets of 10 reps, three times per week.
- Wall slides with physioball are begun in the PoS to achieve strength above shoulder height.
- Hydrotherapy may be used initially to provide environment for active-assistive exercise.

Sport-Specific Exercises

- N/A with the exception of progressive ROM exercises
- Incorporating exercises for core, TBS, TAS, TLS is encouraged, keeping in mind the limitations/precautions associated with the involved shoulder.
- Can initiate trunk rotation and hip ROM

Milestones for Progression to the Next Phase

- Resolution of resting pain, night pain
- PROM of the glenohumeral joint and scapulothoracic joint WNLs
- Normalize scapulohumeral rhythm with elevation to shoulder height in the PoS and observe for compensations (shrug, scapular winging, delayed movement).

Phase III (postoperative weeks 6 to 10)

Clinical Pearls

- Activity levels should be increased gradually in order to optimize muscular fitness and avoid aggravating the joint.
- Patients should be educated and monitored to avoid signs and symptoms of impingement.
- Scapular strengthening is progressed so that an adequate strength base is developed for more advanced exercises.
- Care is taken to follow a functional exercise progression.
- Cryotherapy is continued as activity levels increase.

Goals

- Control pain/inflammation
- ROM WNLs
- Normalize scapular plane elevation above shoulder height which is observed for compensations and timing. In the early part of the ROM (0° to 60°), humeral motion is greater than scapular motion. Between 60° and 120°, scapula motion is greater than humeral motion, and in the final phases of elevation (120° to 180°, humeral motion is greater than scapular motion.
- Avoid impingement.
- Avoid pain with strengthening, ADLs.
- Compliance with home exercise program

Management of Pain and Swelling

- Treatment for pain/analgesia
  - Cryotherapy
  - Patient education: activity modification, avoid too much, too soon pitfall
  - Functional progression
  - Avoid pain with active exercise, strengthening
  - Avoid impingement
- To decrease swelling
  - Cryotherapy

Techniques for Progressive Increase in Range of Motion

Manual Therapy Techniques

- Evaluation-based. Treat areas that have deficits.
- Pain-free ROM using physiological movements for scapula plane elevation, IR/ER, abduction, ER/IR at 90° abduction
- PNF: Hold-relax techniques are used for IR and ER in the PoS, 90° abduction as indicated.
- Joint mobilizations (evaluation-based) at end range will be used, as needed.

FIGURE 8-10. Chicken wing. Horizontal abduction, external rotation.

Soft Tissue Techniques

- Evaluation-based: maintenance of ROM

Stretching and Flexibility Techniques for the Musculotendinous Unit

- These stretches are performed to patient's tolerance. Initially 10 seconds duration for ten repetitions two times per day progressing to 30 seconds duration for three repetitions, two times per day
  - Pectoral stretch in doorway at varying arm heights
  - Inferior capsule stretch
  - Sleeper stretch (avoid impingement which means stretch should be felt posteriorly, not anterior superior)
  - Posterior capsule stretch (avoid impingement as described)
  - Cane forward flexion
  - Towel IR stretch behind back
  - Horizontal abduction/ER with hands behind head = Chicken wing (Figure 8-10)

Other Therapeutic Exercises

- TBS:
  - Stationary bicycle
  - Running
  - Elliptical, using arms to shoulder's tolerance
  - Use of the UE during cardiovascular exercise can be incorporated to tolerance such as rowing ergometer, elliptical with arms, etc.
  - The patient can perform a modified breast stroke.
- Core strengthening
  - Quadruped position using alternating arm lifts, then alternating leg lifts, then rocking back to forward for transitional movements at the core. This will provide added benefit of scapular stabilization.
  - Lower abdominal strengthening using Sahrmann progression with pressure cuff from 10 reps to 1 minute
  - Bridging (bilateral to marching to single leg progression)

FIGURE 8-11. Advanced strengthening of the periscapular muscles.

  - Trunk rotation with cable column resistance, Theraband resistance, or medicine ball resistance
- TAS
  - Avoid overhead exercise such as military press.
  - Perform pain-free exercise within the available ROM such as biceps curls, triceps curls, scapular retraction, scapular protraction, extension (dumbbell row), lat pulldown, or chest press.
  - Upper body ergometry, use of arms in c-v equipment (row, elliptical, bicycle) progresses pain free
- TLS
  - Squats, RDLs, knee extension, knee flexion, sidelying hip abduction
  - Dead lifts, monster walks, clocks for hip stability
  - Lunges, lunges with rotation

Activation of Primary Muscles Involved in Injury Area or Surgical Structures

- These exercises are performed two to three times per week, emphasizing quality of movement:
  - Advanced periscapular strengthening such as prone exercises for lower trapezius, middle trapezius, latissimus (Figure 8-11). These exercises are performed with scapular setting before upper extremity movement.
  - Pain-free rotator cuff PREs progressing from sidelying to standing with elastic resistance. This is performed in modified neutral with towel roll under arm—ER is performed to neutral.

Sensorimotor Exercises

- Hydrotherapy
- PNF diagonal patterns D2 flexion are introduced in supine and progressed to standing.

Open and Closed Kinetic Chain Exercises

- CKC physioball stabilization exercises progressing from bilateral to single arm at shoulder height performed for time or repetitions (1 minute or 10 repetitions, three sets)
- Wall pushup progression from upright position to progressively lower position and ultimately to floor
- Quadruped position as described

Techniques to Increase Muscle Strength, Power, and Endurance

- Upper body ergometry (5 to 10 minutes)
- Cardiovascular equipment with UEs (gradually progress—leg component will be for longer duration than arm component, which will be used in intervals)
- Upper body weight training: chest press, row, lat pull down
- Introduce Bodyblade in modified neutral with oscillations for IR/ER for 30 seconds, three sets.

Neuromuscular Dynamic Stability Exercises

- PNF diagonal patterns D2 flexion in supine to manual resistance to standing to tubing resistance (progressing from 1 to 2 sets of 10 to 15 reps)
- Bodyblade can be introduced in modified neutral position with oscillations for IR/ER, 30 seconds, three sets.

Plyometrics

- Ball toss such as chest pass, side to side pass, and overhead pass can be introduced in latter phase.

Functional Exercises

- PNF diagonal patterns initiated in supine D2 flexion in supine to manual resistance to standing to tubing resistance (progressing from one to two sets of 10 to 15 reps, three times per week)
- Scapular plane elevation performed with no resistance to light resistance for maximum of three sets of 10 reps with good S-H rhythm observed, three times per week. Emphasize posture and stabilization through core.

Sport-Specific Exercises

- These are introduced based on the demands of the sport that the athlete is returning to. Incorporate hip mobility and trunk rotation.

Milestones for Progression to the Next Phase

- Absence of pain with ADLs, therapeutic exercise
- AROM/flexibility to meet demands of sport
- Strength to meet the demands of sport; 85% of uninvolved shoulder measured with isokinetic dynamometer or manual muscle testing dynamometer. Pain-free progression of exercises
- Normalized S-H Rhythm throughout the ROM, which is observed for timing and compensations measured by observation as the patient raises the arm. In the middle of the arc of motion, scapular motion should be greater than humeral motion so that the glenoid is positioned to receive the humeral head.

Phase IV (postoperative weeks 10 to 14+)

Clinical Pearls

- Communication with the surgeon is imperative to begin return to play activities.
- An adequate strength base is required for progression to plyometrics.
- The patient should be monitored for symptoms of pain and inflammation.

Goals

- ROM/flexibility to meet the demands of the sport
- Full, pain-free ROM
- IR/ER strength 3:2 ratio in involved extremity measured with dynamometer, either isokinetic or manual muscle tester

Management of Pain and Swelling

- Treatment for pain/analgesia
  - Cryotherapy continued as exercise increases
  - Monitor volume of exercise: No more than two to three exercises should be performed for specific muscle.
  - Functional progression as outlined in chapter: ROM progression with initiation of strengthening of scapular muscles. Introduction of RC strengthening begins with isometric training and is progressed. With solid foundation of ROM and strength, more challenging exercises (incorporate diagonal patterns, planes of motion) are introduced and endurance is added.
- Decrease swelling
  - Cryotherapy

Techniques for Progressive Increase in Range of Motion

Manual Therapy Techniques

- Evaluation-based

Soft Tissue Techniques

- Evaluation-based

Stretching and Flexibility Techniques for the Musculotendinous Unit

- Evaluation-based: as needed, and as tolerated progressing from 10 seconds duration for 10 repetitions to 30 second duration for three repetitions
- Pectoral stretch in doorway with varying degrees of abduction
- Inferior capsule stretch
- Sleeper stretch (avoid impingement)
- Posterior capsule stretch (avoid impingement)
- Cane forward flexion
- Towel IR stretch behind back
- Horizontal abduction/ER with hands behind head (chicken wing)

Other Therapeutic Exercises

- As described previously

Activation of Primary Muscles Involved in Injury Area or Surgical Structures

- Advanced periscapular strengthening such as prone exercises for lower trapezius, middle trapezius, and latissimus. The goal is three sets of 10 repetitions, twice a week. It is imperative that the patient stabilizes the scapula before performing movement of the extremity.
- RC PREs: IR/ER at 90° abduction as tolerated with elastic tubing in standing or prone. Three sets of 10 repetitions are performed, three times per week.

Sensorimotor Exercises

- PNF diagonal pattern progressions from supine to standing, from no resistance to manual resistance and resistance with elastic bands.
- Quadruped exercises are performed for alternating shoulder elevation in the PoS, to alternating LE lifts.
- Rhythmic stabilization is added to resistance exercises at end range.

Open and Closed Kinetic Chain Exercises

- Wall pushup progression to pushups as described
- Single arm ball stabilization
- Quadruped position

Techniques to Increase Muscle Strength, Power, and Endurance

- Upper body ergometry
- Cardiovascular equipment with UEs
- RC and periscapular strengthening
- Isokinetic training
- Upper weight training
- Wall/ball dribbles

Neuromuscular Dynamic Stability Exercises

- PNF diagonal patterns progressing from supine to standing progression
- Bodyblade progressing to away from body but with arm in the PoS; mimicking path of follow through in throwing
- Quadruped training
- RC strengthening at 90/90 position with rhythmic stabilization at end range for five reps
- Quadruped on unstable surfaces for 15 to 30 seconds, three reps

Plyometrics

- Ball tosses are performed for 10 reps each, two sets.
  - Initiate ball toss—2 hand chest pass
  - Activity-specific plyos

- Ball tosses: chest pass, overhead pass progressing from two handed to single-handed, side throws with trunk rotation; two sets of 10 for each

Functional Exercises

- PNF diagonal patterns progressing from supine to standing progression
- Deceleration exercises with cable column, ball toss

Sport-Specific Exercises

- These are introduced based on the demands of the sport that the athlete is returning to. If the athlete is returning to throwing, an interval throwing program should be used to gradually introduce stresses. The program will be adjusted according to sport and position, and will begin with a day of rest in between throwing sessions. Soreness is expected; sharp pain should not be worked through.
  - Throwing
  - Catching/ receiving
  - Tackling
  - Swimming
  - Swinging
  - Batting
  - Rowing
  - Lifting

Evidence

Anderson NH, Sojbjerg JO, Johanssen HV, et al: Frozen shoulder: Arthroscopy and manipulation under general anesthesia and early passive motion. *J Shoulder Elbow Surg* 7(3):218–222, 1998.

This paper discusses the advantages to performing an arthroscopic examination before capsular release or manipulation: Diagnosis and staging can be confirmed, a therapeutic synovectomy can be performed, and potential secondary causes of symptoms can be recognized. (Level III evidence)

Driscoll SW, Kumar A, Salter RB: The effect of continuous passive motion on the clearance of a hemarthrosis from a synovial joint. An experimental investigation in the rabbit. *Clin Orthop Rel Res* 176:305–311, 1983.

(Level X evidence)

Lin JJ, Wu YT, Wang SF, et al: Trapezius muscle imbalance in individuals suffering from frozen shoulder syndrome. *Clin Rheumatol* 24:569–575, 2005.

This study compared upper and lower trapezius muscle activity in 15 asymptomatic subjects to 15 patients with frozen shoulder. It demonstrates that patients with adhesive capsulitis have greater EMG activity in their upper trapezius as compared to their lower trapezius. (Level II evidence.)

Olgilvie-Harris DJ, Biggs BJ, Fitsialos DP: The resistant frozen shoulder: manipulation versus arthroscopic release. *Clin Orthop Rel Res* 319:238–248, 1995.

This prospective cohort study divided 50 patients with persistent pain, stiffness, functional loss for at least 1 year into arthroscopy before and after manipulation, and arthroscopic division of the contracted tissue. Patients treated with arthroscopic division had significantly better pain relief and restoration of function. (Level III evidence.)

Rizk TE, Christopher RP, Pinal RS, et al: Adhesive capsulitis (frozen shoulder): A new approach to its management. *Arch Phys Med Rehabil* 64:29–33, 1983.

This study divided 50 outpatients with adhesive capsulitis into Group A (heat modalities, therapeutic exercise, and gentle manipulation) and Group B (prolonged pulley traction accompanied by TENS). Group B demonstrated greater improvements in ROM. (Level II evidence)

Salter RB: The biologic concept of continuous passive motion of synovial joints: The first 18 years of basic research and its clinical application. *Clin Orthop Rel Res* 242:12–25, 1989.

This paper presents an overview of 18 years experience with basic animal research relevant to the biological concept of CPM of synovial joints in vivo, and 10 years of clinical application to joints in humans. (Level I evidence)

Multiple-Choice Questions

QUESTION 1. Which of the following statements is true?

A. MUA is the favored method to achieve ROM intraoperatively.
B. Capsular release is performed before manipulation.
C. Manipulation is performed before capsular release.
D. B and C

QUESTION 2. Which of the following is NOT true?

A. A block may be kept in for 24 hours.
B. Sling immobilization is used for 6 weeks.
C. ROM exercises are initiated immediately.
D. The sling is discharged when the block wears off.

QUESTION 3. The 6 week postoperative goals include all of the following except

A. Return to sport
B. Resolution of pain at rest
C. PROM WNLs
D. PoS elevation to shoulder height: without a shrug, without pain

QUESTION 4. The advantages of performing arthroscopy before capsular release include:

A. Diagnosis and staging can be confirmed.
B. Therapeutic synovectomy can be performed.
C. Potential secondary causes of symptoms can be recognized.
D. All of the above

QUESTION 5. Abandonment of nonoperative treatment should be considered when

A. Physical and pharmacological therapies have failed.
B. Failure to improve with a minimum of 6 weeks of conservative treatment.
C. Failure to improve with a minimum of 6 months of conservative treatment.
D. A and C

Answer Key

QUESTION 1. Correct answer: **B** (see Surgical Technique)

QUESTION 2. Correct answer: **B** (see Phase I)

QUESTION 3. Correct answer: **A** (see Phase II)

QUESTION 4. Correct answer: **D** (see Evidence)

QUESTION 5. Correct answer: **D** (see Failed Conservative Treatment)

POSTOPERATIVE REHABILITATION AFTER ARTHROPLASTY (REPLACEMENT), HEMIARTHROPLASTY, AND TOTAL SHOULDER OR JOINT RECONSTRUCTION

David S. Bailie, MD, and Todd S. Ellenbecker, DPT, MS, SCS, OCS, CSCS

Indications for Surgical Treatment

- Glenohumeral degenerative osteoarthritis
- Secondary degenerative osteoarthritis
- Capsulorraphy arthropathy
- Rheumatoid arthritis
- Shoulder fracture
- Avascular necrosis

Brief Summary of Surgical Treatment

Major Surgical Steps

- A standard deltopectoral approach is used.
- The pectoralis tendon is released no more than 1 cm if additional exposure is required.
- The subscapularis (SSC) tendon is released 1 cm lateral to the myotendinous junction from the rotator interval to the ligated anterior circumflex vessels. Adequate tendon stump is left on the lesser tuberosity for later repair.
- The entire SSC tendon is then mobilized by releasing the superior aspect to the base of the coracoid and included release of the coracohumeral ligament. Any loose bodies within the subcoracoid space are carefully removed.
- The inferior SSC border is released by incising the capsule inferiorly to the glenoid rim. The anterior capsule is then released from the anterior glenoid leaving a square patch of capsule firmly attached to the posterior side of the SSC.
- Adequate release was determined by the ability to "bounce" the tendon using two traction sutures in the lateral edge of the tendon. The myotendinous unit should be mobilized easily to the lateral tendon stump with the arm in a minimum of 60° of external rotation with the arm adducted. In cases of total shoulder arthroplasty (TSA), additional releases are performed for placement of the glenoid component, if needed.
- The long head of the biceps is routinely tenotomized or tenodesed. If a tenodesis was performed, it was done at the lower border of the bicipital groove by sewing it to the pectoralis major tendon with a locking No. 2 high-strength polyester braided suture (Fiberwire, Arthrex, Naples, FL). The portion proximal to this is then excised.
- Shoulder arthroplasty is then performed using component specific technique. Anatomic replacement is performed regardless of implant chosen. For stemmed hemiarthroplasty (SHA) or TSA, the humeral head is removed without the use of a guide along the anatomical neck. This allows for preservation of the patient's specific humeral rotation (version) and neck inclination.
- An anatomical humeral implant is then used with the head diameter determined from the size of the humeral osteotomy neck surface. All stemmed prostheses are of a noncemented design. If a glenoid component is used (TSA), it is a nonconforming, cemented all polyethylene pegged design. Resurfacing humeral head replacement arthroplasty is performed in many cases using a noncemented hydroxyapatite-coated cobalt chromium implant placed in anatomical fashion preserving humeral head inclination, offset, and version.
- An extensive capsular release on the humeral neck is performed for all cases, with additional capsular release performed on the glenoid side for TSA cases. The

capsule is not excised in any case and no capsular plications were performed.
- SSC repair is then performed using four No. 5 nonabsorbable sutures in a Mason-Allen suture configuration on the medial side and the lateral side. In cases of SHA or TSA, the lateral limbs of the sutures are passed through drill holes in the lesser tuberosity and are then pulled through the cancellous bone of the humeral neck until they reach the anterior humeral cortex. Laterally, these sutures are passed at the medial edge of the bicipital groove. The placement of these sutures allows the medial SSC tendon to approximate the lateral stump in a side-side fashion, thus resulting in a tendon-tendon repair without lengthening or medialization. A running, locking No. 2 polyester braided suture is then used (Fiberwire, Arthex, Naples, FL) from the rotator interval to the inferior aspect of the SSC.
- For humeral head replacement cases, a tendon-tendon repair is performed in a similar fashion but without using transosseous drill holes in the lesser tuberosity. In cases in which there had been an SSC tear noted before tenotomy or when tissue quality is a concern, PEEK 5.5 mm suture anchors with braided No. 2 polyester suture (PEEK FT anchors, No. 2 Fiberwire, Arthrex, Naples, FL) are used along the lesser tuberosity. If anchors are used, a total of three anchors (six sutures) are used. Sutures are passed by placing the anchor at the level of the tenotomy and passing one limb of each suture through opposing sides of the tendon with a Mason-Allen suture configuration.
- The tendon is not medialized to the anatomical neck, lengthened by coronal "Z" lengthening, or released from the lesser tuberosity.
- After SSC repair all patients are required to have a minimum of 60° of external rotation (ER) with arm at the side and 90° ER in 90° of abduction without tension on the repair.
- Wounds are then closed using absorbable suture in a standard fashion. A drain is not used routinely.

Before Surgery: Overview of Goals, Milestones, and Guidelines[2]

GUIDING PRINCIPLES OF POSTOPERATIVE REHABILITATION

- Initial protection of the subscapularis repair while allowing early range of motion to optimize range of motion recovery postoperatively
- Early activation of the scapular stabilizers and rotator cuff to improve glenohumeral stabilization and scapulohumeral rhythm.
- Progressive resistive exercise to improve shoulder function via enhanced muscular strength and endurance

[2]*Prehabilitation, if appropriate, is described in the Nonoperative Rehabilitation section of this chapter.*

Phase I (days 0–14): Immediate Postoperative Period

Clinical Pearls

- It is imperative at this time of the rehabilitation following arthroplasty that patients be educated on the key limitations and contraindications pertaining to early ROM and functional activity.
- Because of the subscapularis repair, no external rotation beyond 30° should be performed, as well as no internal rotation resistance.
- Additionally, there should be no elbow resistive exercise or lifting because of the concomitant biceps tenodesis that is performed during the procedure.

Goals

- Protect subscapularis repair while facilitating passive movement of the glenohumeral joint to minimize range of motion loss.
- Encourage movement of the distal upper extremity to minimize disuse atrophy and range of motion loss/stiffness.
- Initiate scapular stabilization exercise to enhance proximal stability of the upper extremity.

Protection

- The patient uses a sling with abduction pillow during this phase during waking hours and also at night to maximally protect the shoulder and structures addressed during the surgical procedure.

Management of Pain and Swelling

- Treatment for pain/analgesia
  - Modalities consisting of cryotherapy and electrical stimulation are used during this phase for pain control. In our experience, interferential electrical stimulation is used.
- Decrease swelling
  - Swelling around the incision and ecchymosis in the upper arm and pectoral region are commonly encountered; however, unlike the knee or ankle, excessive swelling is not typically a major or primary complication of this procedure. Use of the modalities coupled with passive range of motion and gentle edema massage can be used when increased swelling is encountered.

Techniques for Progressive Increase in Range of Motion

Manual Therapy Techniques

- Mobilization of the glenohumeral and scapulothoracic joints is performed from the first postoperative visit moving forward. Range of motion limitations are for

the protection of the subscapularis, as mentioned, with no more than 30° to 45° of passive external rotation range of motion and likely more importantly no external rotation stretching or loading the extremity into external rotation.
- Care should be taken when interpositional arthroplasty is performed, with respect to accessory mobilization or glides.
- Protection of the graft jacket or soft tissue graft on the glenoid is recommended via limited humeral head shear activities and hence, less anterior/posterior accessory glide mobilization and less caudal glide mobilization use in these patients in the first 4 to 6 weeks of rehabilitation. A greater reliance on physiological movement and range of motion is warranted.

Soft Tissue Techniques

- Gentle soft tissue massage and scar tissue management for the anterior based scar can be applied at this phase as tissue healing progresses.

Stretching and Flexibility Techniques for the Musculotendinous Unit

- Passive range of motion activities as previously listed are the primary means of flexibility exercise applied postoperatively.
- The primary muscle tendon unit emphasized is the posterior shoulder (infraspinatus and teres minor) through the use of internal rotation range of motion and cross arm adduction stretching.
- Many patients present with internal rotation range of motion loss, and the use of stretching and passive motion during this phase is recommended to address often chronic shortening of the posterior shoulder from years of motion loss and disuse before arthroplasty.

Other Therapeutic Exercises

- Grip exercise and wrist flexion extension range of motion and active range of motion are encouraged in the first phase postoperatively.

Milestones for Progression to the Next Phase

- Initial tolerance to passive range of motion of the shoulder and scapulothoracic joint
- Tolerance of manual scapular stabilization exercise
- Decreased pain levels allowing for therapeutic exercise and manual therapy.

Phase II (postoperative weeks 2 to 6)

Clinical Pearls

- Continue use of subscapularis precautions to minimize rehabilitation stress to the healing subscapularis tendon.
- Use a low-load, long-duration range of motion concept to improve glenohumeral joint range of motion in this early phase of rehabilitation.

Goals

- Improve passive and active assisted range of motion of the glenohumeral joint.
- Initiate rotator cuff and scapular strengthening exercise.

TIMELINE 8-3: **Postoperative Rehabilitation after Arthroplasty (Replacement), Hemiarthroplasty, and Total Shoulder or Joint Reconstruction**

PHASE I (weeks 1 to 4)

- General guidelines
  - Sling use directed by surgeon in postoperative instructions
  - Immediate postoperative passive and active assistive range of motion consisting of stomach rubs, sawing movements, and elbow range of motion instructed following hospital discharge
  - Initial postoperative range of motion limitations may be set by surgeon based on underlying shoulder mobility status and range of motion obtained in the OR post implantation
- Modalities to decrease pain and inflammation
- Passive range of motion initiated with no limitation in flexion, abduction, or internal rotation. NO EXTERNAL ROTATION stretching or anterior capsular mobilization in this rehabilitation phase to protect the subscapularis repair. Gentle PROM into external rotation allowed without overpressure up to 30° to 45° with 45° abduction. NO EXTERNAL ROTATION ROM in 90° abduction during this phase.
- Elbow, wrist, and forearm range of motion/stretching
- Manually applied scapular resistive exercise for protraction/retraction strengthening and scapular mobilization
- No biceps manual resistance for initial 6 to 8 weeks because of bicep tenodesis performed with procedure
- Ball approximation (closed chain Codman's) using Swiss Ball or table top
- Initiation of active assistive range of motion using pulley for sagittal plane flexion and scapular plane elevation as well as supine active assistive exercise using a cane or stick

PHASE II (weeks 2 to 6)

- Continuation of Phase I program
- Initiation of submaximal multiple angle isometrics and manual resistive exercise for shoulder external rotation, ab/adduction, flexion/extension. No internal rotation resistive exercise for initial 6 weeks to protect the subscapularis repair
- Upper body ergometer (UBE)
- External rotation isotonic exercise using pulley or weight/tubing with elbow supported and glenohumeral joint in scapular plane and 10° to 20° of abduction (towel roll or pillow under axilla)
- Manual resisted external rotation exercise in scapular plane position by therapist in varying degrees of elevation (30° 60°) from full internal rotation position to neutral external rotation position

- Develop and advance a home exercise program to augment in-clinic activity for ROM and strengthening.
- Activate the entire upper extremity kinetic chain to minimize disuse atrophy of the regions both proximal and distal to the glenohumeral joint.

Protection

- Sling use continues in precarious situations outside the home, with gradual weaning of protection during seated and less stressful situations toward the 4- to 6-week stage of the recovery process.

Management of Pain and Swelling

- Treatment for pain/analgesia
  - Modality use continues with cryotherapy, electrical stimulation, heat, and joint mobilization being applied.
- Decrease swelling
  - Modality care and soft tissue work are used to address swelling if present.

Techniques for Progressive Increase in Range of Motion

Manual Therapy Techniques

- For the first 6 weeks, specific subscapularis precautions must be followed to protect this important structure postoperatively. This entails limitation of passive or active external rotation range of motion, and no active resistive exercise for internal rotation.
- Although gentle attempts at passive external rotation can occur to as far as 30° to 45° of external rotation beyond neutral, techniques which place increased or undue tension on the anterior capsule and subscapularis are avoided for the first 6 weeks following surgery.
- Additional precautions may be needed depending on the repair of additional rotator cuff tendons at the time of surgery, as well as whether bicep tenolysis, tenodesis, or tenotomy has been performed.
- To address selective capsular tightness, posterior glides of the humeral head relative to the glenoid, with varying degrees of internal rotation of the glenohumeral joint, are used to mobilize the posterior capsule and address limitations in internal glenohumeral joint rotation.
- Anterior glides of the humeral head are often used later in the rehabilitation process once initial subscapularis healing has occurred, to address limitations in external rotation if indicated. Optimization of capsular length between the anterior and posterior capsule is theoretically purported to minimize humeral head shear within the glenoid with glenohumeral joint movement.
- In addition to the use of glenohumeral joint mobilization, application of passive stretching using the low-load, long-duration stretching concept is also recommended.

Soft Tissue Techniques

- Soft tissue techniques to address the periscapular structures and upper arm are used for pain control and to improve circulation, but are not a main emphasis during this phase of the rehabilitation.
- Although these techniques can be comforting to the patient, their short-term response limits endorsement as a primary technique in shoulder rehabilitation.

TIMELINE 8-3: **Postoperative Rehabilitation after Arthroplasty (Replacement), Hemiarthroplasty, and Total Shoulder or Joint Reconstruction** (Continued)

PHASE III (weeks 6 to 12)

- Initiation of passive external rotation range of motion and stretching beyond 30° to 45° in 45° to 60° of abduction.
- Initiation of internal rotation submaximal resistive exercise progression
- Traditional rotator cuff isotonic exercise program
  - Side-lying external rotation
  - Prone extension
  - Prone horizontal abduction (limited from neutral to scapular plane position initially with progression to coronal plane as ROM and scapular control improves)
- Biceps/triceps curls in standing with glenohumeral joint in neutral resting position
- Oscillation exercise with flex bar or Bodyblade
- Rhythmic stabilization in open kinetic chain environments
- Scapular stabilization exercise progression including seated rows, external rotation with retraction, low rows and serratus presses/punches
- Initiation of elevation progression consisting of rhythmic stabilization with shoulder on small Swiss ball in 80° to 90° in the scapular plane

PHASE V (weeks 12 to 16)

- Continuation of rehabilitation
- Isometric Internal/external rotation strength testing assessment in neutral scapular plane position, functional rating scales SST, SANE, and ASES.
- Addition of ball dribbling and upper body plyometrics with small Swiss ball
- Advanced rotator cuff and scapular exercise progressions

FIGURE 8-12. External rotation manual resistance exercise performed by the physical therapist in 45° of elevation in the scapular plane.

Stretching and Flexibility Techniques for the Musculotendinous Unit

- As in preceding manual therapy techniques section.

Other Therapeutic Exercises

- Range of motion of the distal upper extremity occurs, specifically the elbow, wrist, and forearm to minimize loss of motion secondary to sling use. Additionally, the use of ball squeezing exercise and wrist flexion and extension curls can be applied to minimize disuse atrophy of the distal upper extremity during this phase.
- Care must be taken to respect proximal tissue healing while selecting isolated wrist and forearm exercises as well as grip strengthening during this initial postoperative phase.

Activation of Primary Muscles Involved in Injury Area or Surgical Structures

- Initial activation of the posterior rotator cuff begins in the first 10 days following surgery.
- Manual resistance for glenohumeral external rotation at 30° to 45° of abduction (Figure. 8-12) and the use of side-lying external rotation exercise are used.

FIGURE 8-13. Side-lying scapular exercise with manual resistance provided by the therapist.

- Additionally, manual scapular stabilization exercise in side-lying (Figure 8-13) is used from the first postoperative visit onward to ensure activation of the important scapular stabilizers.

Sensorimotor Exercises

- Rhythmic stabilization techniques are used in the balance point (90° of flexion) position.
- Scapular protraction is used during this technique to enhance activation of the serratus anterior via the "plus" position[1,2] with initially very gentle perturbations applied by the therapist to activate the stabilizing musculature and also provide proprioceptive input.

Techniques to Increase Muscle Strength, Power, and Endurance

- Early strengthening following glenohumeral arthroplasty focuses on the scapular stabilizers and safe, submaximal rotator cuff activation. As mentioned earlier, manual scapular stabilization is used in side-lying with manual contact from the therapist to the scapula. This technique allows for early contraction of the lower trapezius and serratus anterior force couple components without stressing the glenohumeral joint. Multiple sets to induce muscular fatigue of these important muscles are indicated.[3]
- In addition to the scapular stabilization exercise, early application of external rotation exercise is initiated. As mentioned throughout this chapter, internal rotation strengthening cannot commence before 6 weeks postop to protect the subscapularis muscle tendon unit.
- Progression of rotator cuff strengthening follows patterns outlined in the literature with documented high levels of activation of the posterior rotator cuff to enhance recruitment, and to improve local muscular endurance in formats of multiple sets of 15 to 20 repetitions.[4-7]
- Additionally in this early stage, external rotation isometrics with elastic resistance (Theraband, Performance Health Corp., Akron, OH) are performed as pictured in Figure 8-14. The neutral position is used with a towel roll placed under the axilla. This neutral starting position is maintained during the exercise wherein the patient steps laterally away from the attachment point of the tubing. After a several-second pause at the point of increased tension, the patient is directed to step again back toward the attachment point of the tubing. Actual motion at the glenohumeral joint does not occur, yet variable loading during this isometric exercise is transmitted to the glenohumeral and scapulothoracic muscles. This exercise is well tolerated, safe, and can be used as a home program exercise to begin to facilitate development of the posterior rotator cuff and scapular stabilizers.
- Gradual progressions in rotator cuff and scapular strengthening occur with increased intensity and variety following 4 to 6 weeks postop. The important role of the rotator cuff muscle-tendon units in controlling and centering the humeral head, especially during midrange movement patterns, cannot be underestimated.

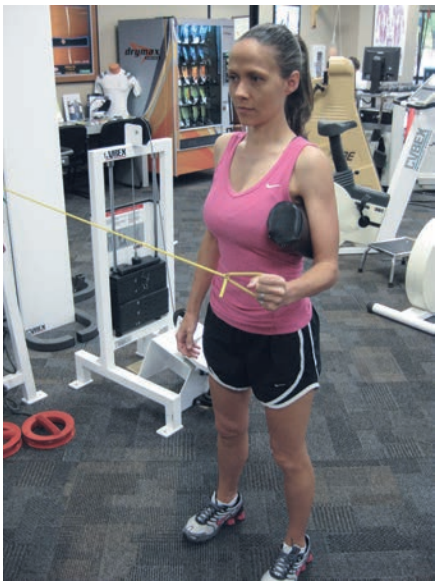

FIGURE 8-14. External rotation isometric with elastic resistance.

- The use of submaximal strengthening methods to selectively recruit the rotator cuff musculature, using exercise patterns placing the shoulder in neutral, non-impinging positions, forms the basis for in-clinic and home-based rehabilitative exercise.
- Exercises such as side-lying external rotation, prone extension, and prone horizontal abduction are used and recommended and are based on research using EMG that documented high levels of posterior rotator cuff activation.[4-7]
- As a general rule, exercises for the shoulder that keep the shoulder below 90° of elevation and the arm slightly anterior to, and in the scapular plane, are recommended.[8]
- Progressive advances in exercise for the muscles that stabilize the scapula are also indicated. Exercises that strengthen the serratus anterior and lower trapezius are particularly recommended to improve scapular upward rotation during elevation.[9] Resistance patterns with light weights, medicine balls, or Thera-Band can be used to perform shoulder punches, with emphasis on the position of maximal scapular protraction (termed the "plus" position) to recruit the serratus anterior.[1,2]
- Scapular retraction exercises, such as rowing with multiple positions of arm abduction, are also indicated.
- Lower resistance levels allow rotator cuff activation, with less compensation and shoulder girdle elevation that often accompanies independent exercise programs with higher resistance levels and movement patterns characterized by full, end range, overhead elevation. Care must be taken to ensure that resistive exercise does not elevate pain levels, which leads to muscular inhibition and compensation.
- The restoration of optimal muscle balance is imperative during the rehabilitation of all shoulder injury and pathologies; however, it is particularly important following shoulder arthroplasty.
- The effect of unbalanced muscular forces during shoulder muscular contraction and volitional movement is important to point out and is a concept that underlies the clinical application of the initial exercise prescription during postoperative rehabilitation in this early phase. Unbalanced internal rotation strength or dominant anterior muscular strength development can lead to anterior translation of the humeral head relative to the glenoid.[10]
- Likewise, excessive posterior development could accentuate posterior subluxation from an eroded posterior glenoid and overly tight anterior structures (obligate translation) and produce posterior instability.
- Optimal muscle balance between the external and internal rotators has been reported and recommended in the range between 66% and 75% ER/IR.[11] This can be assessed with a hand-held dynamometer or isometric function of an isokinetic dynamometer system in the later stages of rehabilitation to ensure proper restoration of this optimal muscle balance.[11]
- Patients frequently present with overly dominant anterior muscular strength, which can jeopardize glenohumeral mechanics and lead to complications and functional impairment.
- Rockwood et al. have demonstrated the concept of the "rocking horse" phenomenon, which can lead to implant loosening, one of the most frequently encountered complications following total shoulder arthroplasty.[12]
- Unbalanced muscular contractions creating humeral head shear can lead to implant loosening and failure of the glenoid implant. Restoration of proper muscular balance via monitoring and addressing the ER/IR strength ratio, as well as application of the range of motion, physiological stretching, and use of accessory mobilization techniques during postoperative rehabilitation ensure proper capsular excursion and minimize the effect from obligate translation.

Milestones for Progression to the Next Phase

- Enhanced glenohumeral joint passive range of motion to allow for progression of resistive exercise and functional range of motion
- Tolerance of initial submaximal exercise progression for rotator cuff and scapular strengthening
- Improved shoulder function in supine gravity eliminated position for shoulder elevation. The patient's ability to move from the 90° flexed position on the supine position termed the "balance point" position is evaluated based on scapular substitution and pain in addition to the overall quality of the motion. As the patient progresses, they are able to move further into flexion beyond 90° as well as into extension from the 90° flexed position. This is used as a precursor to standing against gravity exercise progressions and assures that the patient can engage the appropriate musculature without undue compensation from the upper trapezius and overall use of inappropriate motor patterns in this progression.

Phase III (postoperative weeks 6 to 12)

Clinical Pearls

- At 6 to 8 weeks postop, patients can begin internal rotation resistive exercise and receive external rotation passive overpressure stretching to complement the initial rehabilitation program initiated following surgery.
- Care is taken also at this stage to use techniques and positions appropriate for the patient's strength levels to begin successful attempts at initiating functional elevation.
- Early reliance on long lever arm techniques against resistances that exceed the patient's tolerance produce excessive scapular compensation and result in nonoptimal biomechanical movement patterns.

Goals

- Advance rotator cuff and scapular resistive exercise progressions.
- Progress against gravity elevation progressions using techniques and positions that minimize scapular compensation.
- Begin subscapularis and biceps strengthening at 6 to 8 weeks postop.
- Advance ROM to terminal ranges in all planes as the subscapularis precautions are lifted.

Protection

- Sling is removed for all patients and all activities at 6 weeks postop.

Management of Pain and Swelling

- Treatment for pain/analgesia
  - Modality application continues to facilitate healing and blood flow, decrease pain, and optimize recovery following increased resistive exercise interventions.
- Decrease swelling
  - Swelling at this phase is typically not encountered. If there are continued issues with swelling, soft tissue work and modality care coupled with edema control measures such as compression would be employed. This is not typically encountered, however.

Techniques for Progressive Increase in Range of Motion

Manual Therapy Techniques

- Glenohumeral joint mobilization continues during this phase to assist and facilitate passive range of motion and stretching in all planes.
- Restrictions in capsular mobility continue to be addressed to minimize the negative effects of obligate translation whereby excessive anterior translation can be produced from posterior capsular tightness as well as excessive posterior humeral head translation is produced from anterior capsular tightness.[13]
- This anterior capsular tightness can occur secondary to the initial protection of the subscapularis and anterior capsular protection afforded in the initial postoperative weeks.
- Great care and emphasis on the restoration of optimal passive and active range of motion to the postoperative extremity through directional accessory mobilization techniques continues during this phase of rehabilitation. Mobilization of the glenohumeral joint is performed with emphasis on the initial postoperative phases of rehabilitation on posterior glides to improve internal rotation as well as caudal glides. The posterior glides are initially applied in 30° to 45° of elevation in the scapular plane with progression toward 80° to 90° of elevation as the patient's range of motion improves. These posterior glides can be performed with the shoulder in varying amounts of internal rotation to increase tension in the posterior capsule and increase the intensity of the mobilization. Additionally, caudal glides are performed to improve humeral elevation. These are also initially performed in 40° to 50° of elevation with progression of the mobilization application to 80° to 90° of elevation as the patient's range of motion improves.
- Figure 8-15 shows a posterior glide performed with the glenohumeral joint in the scapular plane position.

Soft Tissue Techniques

- Soft tissue mobilization and massage are not emphasized during this phase of rehabilitation; however, in the presence of periscapular trigger points and muscular soreness, these can be applied to assist patients in recovery and pain relief.

Stretching and Flexibility Techniques for the Musculotendinous Unit

- Stretching of the glenohumeral joint as described commences to terminal range of motion in all planes.

FIGURE 8-15. Posterior glide of the humeral head with the shoulder placed in the scapular plane.

FIGURE 8-16. Upper-body ergometer.

FIGURE 8-17. "Ball on the wall" exercise with perturbations provided by the therapist and shoulder placed in the scapular plane.

- This stretching can occur in both adduction and abduction for external rotation beyond 30° to 45° to prepare the patient for a return to functional activity.
- Frequently these patients have had consideration range of motion loss before surgery and the reestablishment of greater arcs of glenohumeral joint range of motion in all planes is a desired outcome during this critical phase of postoperative rehabilitation.[14]

Other Therapeutic Exercises

- Exercise continues for the proximal and distal aspects of the upper extremity kinetic chain with fewer limitations during this phase because of the disappearance of the subscapularis precautions.
- Use of the upper body ergometer progresses during this phase to provide endurance-oriented scapular stabilization and entire extremity activation (Figure 8-16).

Activation of Primary Muscles Involved in Injury Area or Surgical Structures

- Activation continues as detailed above and below for the rotator cuff and scapular musculature.
- At this time activation of the subscapularis via internal rotation strengthening, as well as specific exercises for the biceps either in isolation or in combination (such as rowing), are employed.
- Internal rotation strengthening is performed using the scapular plane position and approximately 30° of elevation. This is achieved by placing a towel roll under the axilla to ensure that insolated internal rotation movement is performed and more optimally position the patient's extremity in the scapular plane in slight elevation. Starting position is initially from neutral rotation to full internal rotation toward the patient's stomach. Activation of the biceps can now commence after initially protecting against any bicep activity owing to the tenodesis.
- Elbow flexion curls with very light weight and controlled movement are used along with seated rows that do involve biceps contraction and upper body ergometry, which results in repetitive activation for endurance training.

Sensorimotor Exercises

- Perturbation exercises continue to be used, progressing from the 90° flexed (balance point) position to positions with greater amounts of humeral elevation and also external rotation to mimic functional positions required during sport and daily activities.
- Removal of visual cues and increasingly challenging intensities are used with the rhythmic stabilization interventions during this phase of rehabilitation.

Open and Closed Kinetic Chain Exercises

- The integration of close chain exercises are used during this phase of rehabilitation is recommended with the use of the "Ball on the wall" exercise (Figure 8-17).
- Progression to quadruped positions for perturbation as well as use of the BOSU ball or rocker platform to simulate weight bearing is applied to prepare patients for weight-bearing functional positions during this phase.
- It is important to emphasize that the weight-bearing (closed kinetic chain) exercise positions use distal upper extremity positions that create proximal glenohumeral joint positioning at or near the scapular plane (30° anterior to the coronal plane). Progression to closed kinetic chain exercises is followed. Initial closed chain exercise involves merely weight shifting in a standing position with the extremities on a table, progressing to rocker board or BAPS board type proprioceptive activation. As healing progresses and patient tolerance to exercise improves, the use of a quadruped position is recommended because of the functional position required from many patients during work and ADLs. Rhythmic stabilization in the quadruped position can be applied by the physical therapist to challenge the patient and create coactivation in the closed kinetic chain environment.
- Use of narrow, weight-bearing hand positions can align the glenohumeral joint closer to the sagittal plane, thereby creating a posterior shear position or situation within the glenohumeral joint.
- Careful alignment of the extremity during all exercise applications is warranted, but particularly when integrating closed kinetic chain exercises.

FIGURE 8-18. Upper extremity ranger exercise for active assisted elevation.

Techniques to Increase Muscle Strength, Power, and Endurance

- Progression to elevated positions of rotator cuff and scapular stabilization are indicated to assist patients with the return of against-gravity elevation following these extensive surgical procedures.
- Figure 8-17 shows an exercise position using the scapular plane and 80° to 90° of elevation and an exercise ball (Hygenic Corporation, Akron, OH). The patient is asked to maintain the position on the ball while the therapist provides challenges or perturbations to the extremity in all directions to elicit muscular activation in this functional position.
- As with all shoulder elevation exercises, great care is given to avoid the presence of excessive scapular elevation "hiking" the shoulder during exercise.[15] This compensatory pattern leads to the development of inappropriate motor patterns and produces long-term scapular pathology with arm elevation.
- Additional exercises used during this phase are assisted elevation exercises using the Upper Extremity Ranger device (Figure 8-18) and Thera-Flex device (Figure 8-19) to assist with arm elevation initially when the patient is unable to perform this motion against gravity without excessive scapular compensation.
- Figure 8-20 shows the typical shrug sign employed by patients when attempting arm elevation when limited rotator cuff strength is available.
- To allow patients to begin exercising at or near the functional position of 90° of scapular plane elevation, a sling device can be used (Figure 8-20) to provide elevation assistance while rotational exercise or perturbation/oscillation tasks are integrated to provide muscular activation.
- Figure 8-21 shows how a sling comprised of and elastic band (Thera-Band, Performance Health, Akron, OH) can be used to support the extremity with appropriate levels of assistance requiring muscular activation by the patient to maintain the elevated position without scapular compensation. As patients progress in their rehabilitation, the amount of resistance afforded by the elastic resistance is lessened both by the density or

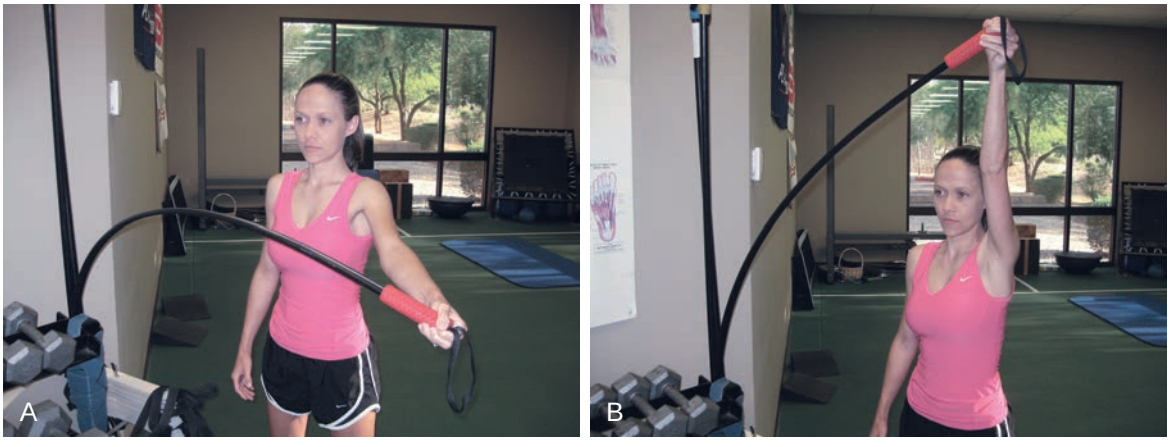

FIGURE 8-19. Thera-Flex assisted elevation in the scapular plane.

FIGURE 8-20. Abnormal compensation with arm elevation exercise. This characteristic compensation is to be avoided by modifying exercise techniques and loading strategies.

property inherent in the band as well as by the location of the band (proximal or distal aspect of the extremity) application to the extremity. A distal application of the assistive sling provides much greater overall assistance to the patient compared to a more proximal position of the band application.

Plyometrics

- During the later stages of this phase of rehabilitation, two-hand plyometric exercise is applied using a small physio ball or basketball. These two-hand plyometric exercises involve movement patterns that simulate functional exercise like a chest pass plyometric, golf swing plyometric, as well as forehand and backhand plyometric.
- The timing of application of these exercises is based on the successful progression of rotator cuff and scapular resistive exercise as well as available range of motion in the patient's postoperative extremity.
- Multiple sets of 15 to 30 repetitions using very light loads to minimize joint loading and provide an initial functional arc of lightly resisted motion are recommended.

FIGURE 8-21. Supported oscillation exercise in the scapular plane with 90° of elevation.

- See Beyond Basic Rehabilitation: Return to Golf, Swimming, and Tennis after Shoulder Arthroplasty for photos of these exercises.

Functional Exercises

- The use of exercise progressions in the stage of rehabilitation discussed includes the integration of shoulder elevation progressions and plyometrics.
- The use of wall pushups and quadruped exercise positioning is based on the functional goals and occupational demands of the individual patients. Traditional pushups and dips are not recommended for obvious reasons because of the inappropriate joint loading that these exercises would produce.
- Other traditional exercises like seated rowing, bent-over rows, and triceps and biceps exercises for the upper extremity can be integrated cautiously during this phase of rehabilitation to provide additional strength training stimuli to the upper extremity kinetic chain.
- Loading on these exercises has to be rehabilitation appropriate to avoid nonoptimal loading for joint and soft tissue protection.

Sport-Specific Exercises

- See previous Plyometrics exercise section.

Milestones for Progression to the Next Phase

- Tolerance of isotonic rotator cuff and scapular resistive exercise. Patient is able to perform isotonic resistive exercise for the rotator cuff and scapular muscles without pain and uses appropriate movement strategies without compensation to repetitive loading.
- Ability to attain against gravity elevation with minimal scapular compensation
- Ability to perform functional movement patterns of ADLs and sport simulation
- Objective testing of shoulder active and passive range of motion; isometric shoulder internal and external rotation strength, using a hand-held dynamometer, manual muscle testing, or the isometric mode of an isokinetic dynamometer (i.e., Biodex); and functional rating scales such as the Simple Shoulder Test (SST) and modified American Shoulder and Elbow Surgeons (ASES) are also completed at 12 weeks to provide clinicians with valuable objective information to base future exercise prescription, and manual mobilization and ROM interventions.

Phase IV (postoperative weeks 12–16)

Clinical Pearls

- Continued use of resistive exercise progressions to improve elevation control without scapular compensation is warranted as well as the use of the 90°

elevated position for rotational exercise in the younger, more active patient whose goal is to also return to sport activity or elevated work environments with repetitive movement.
- Mobilization and passive stretching to attain as full an arc as possible continues using the low-load long-duration stretching concepts coupled with in-clinic muscle tendon unit stretching and accessory mobilization techniques.

Goals

- Advance rotator cuff and scapular exercise and provide objective measurement and quantification of ER/IR muscle balance.
- Continue to address ROM limitations via aggressive mobilization and passive stretching techniques.
- Prepare the patient for gradual weaning of formal PT and incorporation of end stage ROM and strength activity for a return to full activity.

Management of Pain and Swelling

- Modality applications weaned but still used for recovery and to address joint pain or muscle soreness as needed
- Treatment to address swelling is not typically needed.

Techniques for Progressive Increase in Range of Motion

Manual Therapy Techniques

- Continued use of end range of motion passive stretching coupled with accessory mobilization to regain as full an arc of motion as possible in all planes. Continued use of passive range of motion and glenohumeral joint mobilization is applied in all planes and directions based on range of motion response from the patient. This includes posterior, anterior, and caudal glides as well as joint distraction techniques if there is continued joint hypomobility encountered.
- There are no ROM limitations and using the goal of achieving both active and passive range of motion values equal to the contralateral side remains.

Soft Tissue Techniques

- This is not an emphasis during this phase of the rehabilitation program.

Stretching and Flexibility Techniques for the Musculotendinous Unit

- Continues as listed above with prolonged holds at end ROM to enhance joint ROM

Other Therapeutic Exercises

- Specific exercises for the core and distal upper extremity continue to be applied in in-clinic rehabilitation as well as in the home program as patients return to gym-based workout programs for all regions of their body. Examples of core exercises include the use of resisted trunk rotation with a light medicine ball to encourage trunk rotation in preparation for return to work, ADL, and sport activity.
- Education is given, however, to continue to minimize joint loading to the shoulder, and modification of traditional exercise programs is warranted to ensure that the shoulder joint is not loaded or positioned in a harmful way to exercise adjacent body structures or segments.[16]

Activation of Primary Muscles Involved in Injury Area or Surgical Structures

- Rotator cuff and scapular exercise continue in this phase to be the primary emphasis for activation, and the application of specific exercises showing high levels of rotator cuff and scapular muscle EMG activity continues.[4-7]
- Rotational exercises coupled with proper scapular stabilization without compensation form are important exercises for inclusion during this phase. The use of prone rotator cuff and scapular stabilization exercises are also used in addition to the traditional humeral rotation exercise.

Sensorimotor Exercises

- Perturbation exercise and rhythmic stabilization progressions are used to challenge the sensorimotor system during this phase and have been outlined in the prior stages of rehab in this chapter.

Open and Closed Kinetic Chain Exercises

- Rehabilitation exercise continues to favor open kinetic chain rehabilitation for muscle group isolation and activation; however, some closed kinetic chain exercises in quadruped positions are used particularly in persons returning to either work environments in which crawling or upper extremity weightbearing is needed as well as for individuals who are involved in gardening or home based activities requiring upper body weight loading. Quadruped-based exercises with therapist perturbations as mentioned earlier continue as well as progression to tripod and pointer applications. It is important to point out that increased loading in the closed chain are not used and closed chain exercises are progressed very slowly in this population.
- Pushups are NOT recommended or used; however, placement of the extremity on a BOSU platform, or foam stability or rocker platforms is indicated to enhance proximal muscle activation and encourage proprioceptive input.

Techniques to Increase Muscle Strength, Power, and Endurance

- Exercise progressions in this final phase of formal rehabilitation progress to greater levels of resistive exercise intensity. Progression for the younger, more active patients to isokinetic internal and external rotation

training using a position with the shoulder placed in 30° of elevation in the scapular plane[11] allows for high-level activation of the rotator cuff at higher joint angular velocities.
- Additionally, isokinetic testing can be performed to allow for objective strength quantification to allow clinicians to know both bilateral comparisons and ER/IR muscle balance.
- In addition to isokinetic training, greater levels of manual resistance and external loading with elastic tubing and cuff weights or dumbbells are recommended. Loading schemes that allow for multiple sets of 15 repetitions to be performed without compensatory movements or exaggerated muscle compensation from the upper trapezius are used.

Plyometrics

- Two-hand plyometric exercise progressions continue with end stage application of one-hand plyometric exercises in only a small subset of patients who have regained appropriate range of motion levels for a return to throwing or swinging activity.
- These exercises are outlined and discussed in greater detail in the following section on Beyond Basic Rehabilitation: Return to Golf, Swimming, and Tennis after Shoulder Arthroplasty.
- The initial use of a basketball or soccer ball for two-hand plyometrics can be advanced gradually to light medicine balls to increase upper extremity loading for the performance of these plyometric functional exercises.

Functional Exercises

- Continued integration of overhead elevation activities, and limited weight-bearing postures in the rehabilitation program outlined during this phase provide functionally-based strength training stimuli for the patient in this important phase of rehabilitation.
- Modified return to traditional exercises such as the lat pulldown, rowing, chest press, and biceps and triceps curls are followed for individuals who are involved in these activities recreationally, as well as for those returning to manual labor type jobs.[16]

Sport-Specific Exercises

- See Beyond Basic Rehabilitation: Return to Golf, Swimming, and Tennis after Shoulder Arthroplasty for exercise progression and interval program specifics.
- Exercises listed earlier in this rehabilitation program detail the use of an elevated 90° scapular plane position used for strengthening, oscillation, and perturbation based exercise progression aimed at returning appropriate patients to overhead sport-specific activities.

Milestones for Progression to the Next Phase

- Stabilizing active and passive range of motion values despite continued interventions for mobilization and passive stretching. Deficits of 10° to 20° compared with the contralateral extremity can be expected; however, active range of motion should closely approximate passive range of motion before discharge.
- ER/IR ratio of 66% is a target. Deficits in strength compared with the contralateral uninjured extremity are common; however, a goal of returning equal IR and ER strength remains in the long-term functional outcome for the active patient following arthroplasty.
- Demonstrated independence with a home exercise program for range of motion maintenance and strengthening of the rotator cuff and scapular musculature
- Provision of initial guidance in an interval based functional or sport return program tolerated by the patient. This allows continued and gradual return to sport and functional activities in the ensuing months following discharge in an independent or consulting status for the patient.

Criteria for Return to Sport

- Unique challenges exist during the rehabilitation of the patient following shoulder arthroplasty. It is often not possible to achieve full, desired range of motion of the joint because of the chronic capsular changes and alterations of range of motion that existed pre-operatively; however, the use of an aggressive program of rehabilitation following surgery does strive to achieve a minimum of 70° of external rotation in the 90° abducted position.
- Active flexion and abduction (elevation) typically exceed 145° in these patients and are acceptable for the sports being discussed in this chapter.
- One additional consideration for the sport of golf is the achievement of optimal amounts of cross arm adduction to allow for either proper take back (e.g., left shoulder arthroplasty in a right handed golfer) or during following through (e.g., right shoulder arthroplasty in a right handed golfer).
- Careful monitoring of sport-specific movement patterns is needed by the physical therapist and physician during this phase of the rehabilitation because often some modifications (often shortening) of the stroke pattern is needed to facilitate the return to that sport.
- Although not always optimal from a performance enhancement standpoint, careful monitoring and use of video feedback to obtain the most efficacious movement pattern allowed by that patient's range of motion and strength levels is indicated.
- The use of computer programs such as Dartfish are indicated and used by these authors to monitor movement strategies and provide meaningful feedback to the patient during this critically important phase of the rehabilitation process.
- Objective criteria such as minimal pain-free range of motion characteristics, negative instability and impingement clinical tests, strength test within 15% to 20% of the contralateral limb in addition to acceptable unilateral strength ratios (optimal 66% to 75% ER/IR ratios, accepted minimal standards 55% to 65%) are used to guide the process objectively from a clinical standpoint.

Exercises and Other Techniques for Prevention of Recurrent Injury

- Maintenance programs given to the patients upon completion of their supervised rehabilitation include rotator cuff and scapular exercises to be performed using a low resistance high repletion format (multiple set training).
- These include exercise with elastic resistance for external and internal rotation both at the 30/30/30 position at the side and with 90° of elevation.
- Additionally, scapular stabilization exercises for the serratus anterior and lower trapezius are recommended.
- It is also recommended that range of motion exercises be continued to prevent range of motion loss including the cross arm and sleeper stretches for internal rotation as well as external rotation with a stick or implement and use of a pulley or external device such as a stick or cane for forward flexion.

Evidence

Bailie DS, Llinas PJ, Ellenbecker TS: Cementless humeral resurfacing arthroplasty in active patients less than fifty-five year of age. *J Bone Joint Surg* 90:110–117, 2008. doi: 10.2106/JBJS.F.01552.

Thirty six patients with a mean age of 42.3 years were tested at 38.1 months status post cementless humeral resurfacing hemiarthroplasty. All patients followed the rehabilitation protocol contained in this chapter. Significant improvements in single assessment numeric evaluation (SANE) scores, and ASES rating scales were reported just over 3 years postop. Visual pain rating scales changed from mean values of 7.5 preop to 1.3 at 2 years follow-up, ASES from 29.8 preoperative to 90.4 at 2 years follow-up. No signs of radiographic loosening were witnessed, and there was one complication of a subscapularis rupture form a traumatic incident and three cases of arthrofibrosis. These young, active patients reported high levels of satisfaction with their surgical outcome and returned to many forms of recreational and functional activities. (Level IV evidence)

Bartelt R, Sperling JW, Schleck CD, et al: Shoulder arthroplasty in patients aged fifty-five years or younger with osteoarthritis. *J Shoulder Elbow Surg* 20:123–130, 2011.

This study profiled 46 total shoulder arthroplasties and 20 hemiarthroplasties performed in 63 patients age 55 or younger. A minimum 2-year follow-up was used, and patients on average were followed up 7 years postop. The implant survival rate was 92% at 10 years for total shoulder arthroplasty in this young, active population and 72% for hemiarthroplasty. Patient satisfaction and feeling that they were better than before the operation was 87% for TSA and 65% for hemiarthroplasty. Patients receiving TSA had a 46° improvement in forward elevation from 105° preop to 151° at latest follow-up and 24° improvement in external rotation from 23° to 48°. This study also demonstrates significant range of motion and functional improvements in young active patients receiving either total or hemiarthroplasty. (Level IV evidence)

McCarty EC, Marx RG, Maerz D, et al: Sport participation after shoulder replacement surgery. *Am J Sports Med* 36:1577–1581, 2008.

This retrospective study described the return to sport outcomes of patients following shoulder arthroplasty. The frequency of returning to sports such as golf, tennis, fishing, and even kayaking shows the present ability of many patients to return to upper extremity sport activities following shoulder arthroplasty. (Level IV evidence)

Raiss P, Pape G, Becker S, et al: Cementless humeral surface replacement arthroplasty in patients less than 55 years of age. *Orthopade* 39(2):201–208, 2010.

This study followed 23 patients with 26 total implants using a cementless humeral resurfacing implant 1 to 6 years (mean 2.5 years) following surgery. Constant scores improved from a value of 33 to 61 points at last follow-up. Significant improvements were also noted in shoulder flexion, abduction, and external rotation range of motion in addition to the functional rating scale. This study shows excellent outcomes following humeral resurfacing in young active patients. (Level IV evidence)

Saltzman MD, Chamberlain AM, Mercer DM, et al: Shoulder hemiarthroplasty with concentric glenoid reaming in patients 55 years old or less. *J Shoulder Elbow Surgery* 20:609–615, 2011.

This study followed 65 young, active patients who underwent shoulder hemiarthroplasty with concentric glenoid reaming. A 2-year minimum follow-up was used to measure functional outcome and patient satisfaction following the procedure. Simple shoulder tests (SST) improved from 4.1 to 9.5/12 points at an average follow-up of 43 months. At final follow-up all patients with radiographic follow-up (N = 22) had centered humeral heads. Nine of the 65 patients did require revision surgery. Ninety-four percent of the patients felt their shoulder was functioning better following surgery. This study again shows the results of shoulder hemiarthroplasty in a younger patient base and its immediate outcomes following surgery at initial follow-up. (Level IV evidence)

Multiple-Choice Questions

QUESTION 1. The rehabilitation limitations commonly termed "subscapularis precautions" consist of which of the following restrictions?

A. No external rotation ROM and no internal rotation resistance application
B. No internal rotation ROM and no external rotation resistance application
C. No abduction and internal rotation ROM
D. No flexion and external rotation ROM

QUESTION 2. Which of the following structures is most affected during the deltopectoral surgical approach used during arthroplasty?

A. Triceps
B. Infraspinatus
C. Subscapularis
D. Deltoid

QUESTION 3. What characteristic compensation strategy is employed by patients with inadequate rotator cuff strength during humeral elevation?

A. Posterior subluxation of the humeral head
B. Superior scapular elevation or shrug sign
C. Elbow extension jutting
D. Ipsilateral cervical spine lateral flexion

Answer Key

QUESTION 1. Correct answer: **A** (see Phase I)

QUESTION 2. Correct answer: **C** (see Brief Summary of Surgical Technique)

QUESTION 3. Correct answer: **B** (see Phase II)

BEYOND BASIC REHABILITATION: RETURN TO GOLF, SWIMMING, AND TENNIS AFTER SHOULDER ARTHROPLASTY

Todd S. Ellenbecker, DPT, MS, SCS, OCS, CSCS, and David S. Bailie, MD

Introduction

ASPECTS OF GOLF, SWIMMING, AND TENNIS THAT REQUIRE SPECIAL ATTENTION IN REHABILITATION

- Swimming, golf, and tennis all require extensive ranges of motion as well as high levels of muscular stabilization in the rotator cuff and scapular musculature.
- Additionally, all three sports are very repetitive in nature and involve repeated muscular activations to train and perform, requiring high levels of muscular endurance.
- In golf, the movement of cross-arm adduction is required for the take-back portion of the golf swing and also on the contralateral extremity during the follow-through. This requires an acceptable range of pain-free motion for successful performance and return to sport.
- Likewise, in tennis and swimming, large arcs of rotational motion are needed to properly perform the biomechanical patterns of the serve and other strokes. This requires full rehabilitation following a progressive rehabilitation program to ensure optimal range of motion return as well as high levels of both muscular stabilization and endurance are in place before starting an interval program.

The athletic shoulder with glenohumeral arthritis is very common especially in patients following stabilization procedures. This has led to the terms *dislocation arthropathy* or *capsulorraphy arthropathy*. Athletic individuals requiring shoulder arthroplasty are becoming very popular patients in orthopaedic and sports medicine

clinics and require progressive rehabiltation protocols for their management in addition to a return to activity of return to sport program when applicable.

Literature Review

- Healy et al.[1] published a list of recommendations from the American Shoulder and Elbow Surgeons on recreational and sport activities to return to after shoulder arthroplasty. In their guidelines, they include upper extremity sports like golf and doubles tennis as well as swimming, bowling, canoeing, and shooting.
- General sports, like running, cross country skiing, and aerobics, were also included among the recommended activities following shoulder arthroplasty.
- McCarty et al.[2] performed a postsurgical survey of sport activities patients were successfully able to return to following shoulder arthroplasty. Their study found that the return rates for fishing (92%), swimming (86%), downhill skiing (81%), golf (76%), and tennis and squash/racquetball (75%) indicate a large majority of patients return to preoperative sport activity levels following shoulder arthroplasty.
- These studies provide evidence and guidance for the functional return programs that are incorporated into rehabilitation following shoulder arthroplasty.

Advanced Rehabilitation Program

- The advanced rehabilitation activities do vary based on the sport activity patients are involved in but do have certain commonalities beyond the interval sport return programs utilized following successful rehabilitation.[3]
- Several key components of the advanced rehabilitation progression for return to sport include exercises performed with 90° of elevation. Figure 8-22 shows the use of oscillation in 90° in the scapular plane, with Figure 8-23 depicting rhythmic stabilization performed by the therapist in 90° of elevation in the scapular plane with 70° of external rotation.
- In many patients following arthroplasty, external rotation range of motion may be limited to approximately 70° to 80° owing to the anterior approach, subscapularis repair, and chronic capsular changes occurring over years of osteoarthritis in the involved shoulder.[4]
- Therefore patients are progressed in this exercise with increasing amounts of external rotation in the abducted shoulder to utilize the newfound external rotation range of motion to prepare them for swimming and other overhead activities that require an abducted, externally rotated position.
- Closed chain exercises are not typically preferred because of the compressive forces incurred with this classification of exercise.
- Open chain exercises with increasing amounts of abduction/elevation are utilized to enable patients to transition to higher levels of function and their interval sport return program.[4]
- Plyometric exercises are recommended in the advanced stages following arthroplasty with the general progression from two-hand plyometric exercise drills such as the tennis groundstroke (Figure 8-24) or golf plyometric (Figure 8-25) with eventual progression to side-lying ball drops which elicit high levels of fatigue due their endurance format of multiple sets of 20 to 30 seconds of rapid repetitions of briefly letting go of the ball and then quickly regrabbing the ball (Figure 8-26).
- These exercise progressions along with continued rotator cuff and scapular isotonic exercises form the basis for many of the higher level rehabilitation activities during the end stages of rehabilitation following arthroplasty in the active patient.
- Continued focus on mobilization and passive stretching to improve and optimize glenohumeral joint range of motion are of critical importance throughout the rehabilitation process and continue to be indicated in this final phase of rehabilitation as well.[5]

FIGURE 8-22. External rotation oscillation exercise to improve endurance with the shoulder placed in the 90° abducted position in the scapular plane.

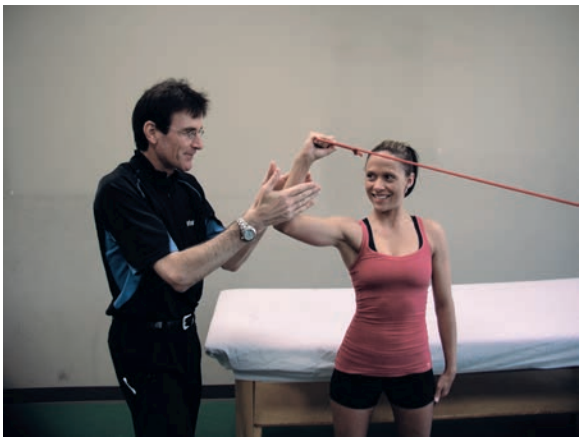

FIGURE 8-23. External rotation position with approximately 70° ER in 90° of abduction in the scapular plane. Therapist provides rhythmic stabilization in this position.

FIGURE 8-24. Plyometric exercise position simulating forehand and backhand ground strokes to provide a progression for a return to tennis.

Phase I: Advanced Strength and Conditioning Programs[3]

Periodization

- Undulating

Program Design/Performance Training Program

- Flexibility/joint mobility for joint stability
- Training with optimum posture
- Multi-planar training activities
- Training for optimum muscle balance
- Plyometric training
- Sport-specific training
- Training for optimum muscle functional strength

Training Principles Used in the Design of the Program

- Principle of progression
- Principle of overload
- Principle of variation
- Principle of individualization
- Principles of specificity—specific adaptation to imposed demands (SAID)

Application of Acute Training Variables

- For most of the exercises listed in the rehabilitation program following shoulder arthroplasty (see previous section of this chapter) with specific application for return to sport, two to three sets of 15 repetitions are followed to not only encourage the development of local muscular endurance but also to promote muscular fatigue with the use of lighter loads minimizing joint loading and stress to the tendinous repair to the subscapularis and bicep tenodesis.
- Rest intervals of 20 to 30 seconds are used again to promote muscular endurance, and are sport specific, for example in tennis wherein rest periods of 20 seconds are allowed between points.
- Rather than use what has traditionally been applied as repetition maximum loading schemes, these authors use clinical observation of loading (i.e., patient's ability to perform up to 15 repetitions per set without compensation), patient feedback (absence of joint or tendinous insertional pain) as well as ratings of perceived exertion such as the OMNI scale between 4 and 6 (0 being very easy resistance and 10 being very hard).[6]
- Training frequency consists of 3 training days per week with recovery days between.
- Duration of training consists of rehabilitation sessions lasting approximately 90 minutes in length over a 3- to

[3]See Postoperative Rehabilitation After Arthroplasty (Replacement), Hemiarthroplasty, and Total Shoulder or Joint Reconstruction for the rehabilitation timeline.

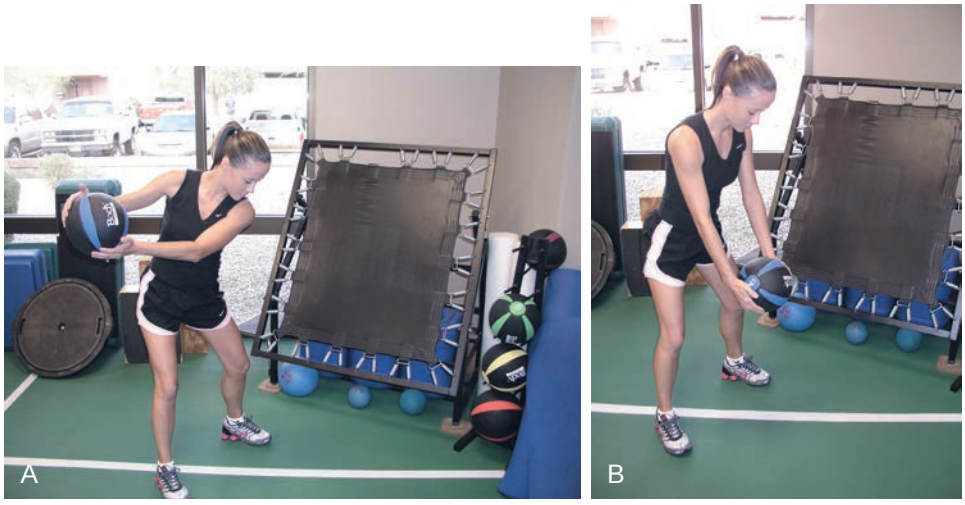

FIGURE 8-25. A,B, Plyometric exercise position simulating the golf swing to provide a progression for a return to golf.

FIGURE 8-26. Side-lying plyometric exercise to provide advanced rotator cuff strengthening following shoulder arthroplasty.

4-month period with 4 to 6 weeks dedicated to the return to activity programming and phase discussed in this chapter.

Application of Chronic Training Variables

- In addition to the exercises discussed earlier in this chapter, specific advanced training exercises are applied in this phase of training to improve rotator cuff strength and endurance and scapular stabilization.
- These include Jobe rotator cuff exercises such as side-lying external rotation, 90° abducted external rotation in the prone position, and prone extension and prone horizontal abduction exercise.
- These exercises are used to provide base rotator cuff and scapular muscle activation and are coupled with external rotation oscillation and "statue of liberty" exercises with elastic resistance (Figures 8-22 and 8-27).
- Isokinetic training for internal and external rotation (Figure 8-28) are also used to provide accommodative resistance in the modified base or "Davies" position. This position is also used for testing to compare bilateral strength variables of torque, work, and external/internal rotation unilateral strength ratios. Ratios ranging between 66% and 75% are desired to provide substantial posterior rotator cuff strength and stabilization.[7]
- Plyometric exercises described earlier in this chapter provide the sport-specific transitional exercise to simulate upper extremity and trunk segmental rotational movement patterns that are essentially precursors for patient initiation in a sport-specific interval return program.

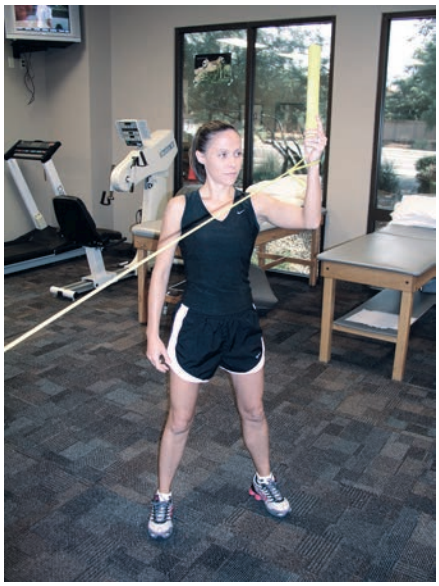

FIGURE 8-27. External rotation oscillation with arm in greater amounts of abduction to improve strength and endurance of the posterior rotator cuff and prepare the patient for a return to functional activity in this position.

FIGURE 8-28. Isokinetic internal and external rotation modified base (Davies Position) used for training and testing rotator cuff strength following shoulder arthroplasty on the Biodex Isokinetic Dynamometer.

Phase II: Sport-Specific Training (Interval Functional Return Programs)

Periodization

- Undulating

Program Design/Performance Training Program

Sport-Specific Concepts of Integrated Training

- Flexibility/joint mobility for joint stability
- Core training
- Multi-planar training activities

- Training for optimum muscle balance
- Training for optimum muscle functional strength
- Training for optimum muscle functional power
- Neuromuscular dynamic stability exercises
- Sport-specific training

Training Principles Used in the Design of the Program

- Principle of progression
- Principle of overload
- Principle of variation
- Principle of individualization
- Principles of specificity—specific adaptation to imposed demands (SAID)

Application of Acute Training Variables

- For the programs listed below, progression of the patient via each of the stages of increased functional overload is followed with alternate days of performance of the exercise to allow for rest and recovery of the upper extremity between sessions.
- The interval program (Box 8-1) is most often built into the rehabilitation session (tennis and throwing) as the patient undergoes a warmup on an upper body ergometer, and receives stretching and mobilization of the joint before performance of the interval program.
- Before performing significant amounts of resistive exercise for the rotator cuff and scapular musculature, the patient performs the interval tennis program or throwing program completing their exercises in the clinic after the interval sport program.
- Golf and swimming interval sport programs often cannot be performed in the clinic because of size and space limitations (lack of a pool in many clinics) and therefore must be guided by the therapist but cannot always occur under direct supervision of the therapist.
- Some golf related activity can be performed in the clinic with the use of netting, and/or wiffle balls.
- Tennis-related initial activity can be performed with the use of low compression tennis balls (e.g., Star ball, Penn Racquet Sports) or foam balls and tennis balls used during tennis instruction and development for children termed *red balls*, *orange balls*, and *green balls* that have remarkable characteristics for ball bounce without the heavier feel of a standard tennis ball impact, and also are easier to utilize inside clinic spaces for safety concerns.[8]
- For a detailed discussion of interval sport return programs, the reader is referred to Ellenbecker et al.[3,8]

Sports Performance Testing

General Information

- General history
- Subjective questionnaires
- Medical history
- Sports injury history
- Surgical history
- Chronic conditions/medication

Specific Tests

- Static and dynamic posture and scapular assessments begin very early in the rehabilitation program and continue throughout rehabilitation.
- Assessments and measurement of glenohumeral joint range of motion also begins on the first postoperative visit and is closely monitored throughout the rehab process.
- Isometric and isokinetic internal and external rotation testing is performed starting at approximately 12 weeks

BOX 8-1 Interval Tennis Program Guidelines

- Begin at a stage indicated by your physical therapist or physician.
- Do not progress or continue the program if joint pain is present.
- Always stretch your shoulder, elbow, and wrist before and after the interval program, and perform a whole-body dynamic warmup before performing the interval tennis program.
- Play on alternate days, giving your body a recovery day between sessions.
- Do not use a wall board or back board because it leads to exaggerated muscle contraction without rest between strokes. Ball feeds or a ball machine are preferred.
- Ice your injured arm after each session of the interval tennis program.
- It is highly recommended to have your stroke mechanics formally evaluated by a USPTA tennis teaching professional.
- Do not attempt to impart heavy topspin or underspin to your ground strokes until later stages in the interval program.
- Contact your therapist or doctor if you have questions or problems with the interval program.
- Do not continue to play if you encounter localized joint pain.

Interval Tennis Program

Perform each stage _____ times before progressing to the next stage. Do not progress to the next stage if you have pain or excessive fatigue on your previous outing—remain at the previous stage until you can perform that part of the program without fatigue or pain.

STAGE 1

a. Have a partner feed 20 forehand groundstrokes to you from the net using a foam ball. (Partner must use a slow, looping feed that results in a waist-high ball bounce for player contact.)

Continued on following page

BOX 8-1 Interval Tennis Program Guidelines *(Continued)*

b. Have a partner feed 20 backhand groundstrokes as in 1a above with a foam ball.
c. Rest 5 minutes.
d. Repeat 20 forehand and backhand feeds as above.

STAGE 2

Repeat Stage 1 with a low compression ball (e.g., Pro-Penn Star Ball, Penn Racquet Sports, Phoenix, AZ).

STAGE 3

Repeat Stage 1 with a real (regulation) tennis ball.

STAGE 4

a. Begin as in Stage 3 above, with a partner feeding 10 forehands and 10 backhands from the net as a warmup.
b. Rally with a partner from baseline, hitting controlled groundstrokes until you have hit 50 to 60 strokes. (Alternate between forehands and backhands and allow 20 to 30 seconds rest after every two or three rallies.)
c. Rest 5 minutes.
d. Repeat the rally instructions in 4b above.

STAGE 5

a. Rally groundstrokes (forehands and backhands) from the baseline for 15 minutes.
b. Rest 5 minutes.
c. Hit 10 to 15 forehand and 10 to 15 backhand volleys, emphasizing a contact point in front of your body.
d. Rally groundstrokes for 15 additional minutes from the baseline.
e. Hit 10 to 15 forehand and backhand volleys as listed above.

PRE-SERVE INTERVAL: (PERFORM BEFORE STAGE 6)

(Note: This can be performed off court and is meant solely to determine readiness for progression into stage 6 of the interval tennis program.)
a. After stretching, with racquet in hand, perform serving motion for 10 to 15 repetitions without a ball or any ball contact.
b. Using a foam ball, hit 10 to 15 serves without concern for performance result (only focusing on form, contact point, and the presence or absence of symptoms).
c. If successful and pain-free, progress to stage 6.

STAGE 6

a. Hit 20 to 30 minutes of groundstrokes, mixing in volleys using an 80% groundstroke/20% volley format.
b. Perform 5 to 10 simulated serves without a ball.
c. Perform 5 to 10 serves using a foam ball.
d. Perform 10 to 15 serves using a standard tennis ball at approximately 75% effort. (Note: It is important to hit flat or slice serves, not kick serves, in the initial phase of the interval tennis program)
e. Finish with 10 to 15 minutes of groundstrokes.

STAGE 7

a. Hit 30 minutes of groundstrokes, mixing in volleys using an 80% groundstroke/20% volley format.
b. Perform 5 to 10 serves using a foam ball.
c. Perform 10 to 15 serves using a standard tennis ball at approximately 75% effort.
d. Rest 5 minutes.
e. Perform 10 to 15 additional serves as in 7c above.
f. Finish with 15 to 20 minutes of groundstrokes.

STAGE 8

a. Repeat Stage 7 listed above, increasing the number of serves to 20 to 25 instead of 10 to 15.
b. Before resting between serving sessions, have a partner feed easy short lobs to attempt 4 to 5 controlled overheads.

STAGE 9

Before attempting match play, complete steps 1 to 8 without pain or excess fatigue in the upper extremity. Continue to progress the amount of time rallying with groundstrokes and volleys in addition to increasing the number of serves per workout until 60 to 80 overall serves can be performed interspersed throughout a workout. Initiate kick serves once the initial stages of the program have been completed. Remember that an average of up to 120 serves can be performed in a singles tennis match, therefore be prepared to gradually increase the number of serves in the interval program before full competitive play is engaged.

postop to determine IR and ER strength as well as muscular balance.
- Tolerance of the 90° abducted position during functional plyometric and elastic resistance exercises is also used as a precursor to beginning any functional activity interval sport return program (i.e., golf, tennis, swimming, throwing).

Objective Tests

- Static/dynamic postural assessments
- Dynamic muscle performance testing
- Movement performance testing
- Sport-specific testing

Specific Criteria for Progression to the Next Stage to Determine Readiness for Swimming, Golf and Tennis

- Unique challenges exist during the rehabilitation of the patient following shoulder arthroplasty. It is often not possible to achieve full, desired range of motion of the joint because of the chronic capsular changes and alterations of range of motion that existed preoperatively; however, the use of an aggressive program of rehabilitation following surgery does strive to achieve a minimum of 70° of external rotation in the 90° abducted position.
- Active flexion and abduction (elevation) typically exceed 145° in these patients and are acceptable for the sports being discussed in this chapter.
- One additional consideration for the sport of golf is the achievement of optimal amounts of cross-arm adduction to allow for either proper take back (e.g., left shoulder arthroplasty in a right handed golfer) or during following through (e.g., right shoulder arthroplasty in a right handed golfer).
- Careful monitoring of sport-specific movement patterns is needed by the physical therapist and physician during this phase of the rehabilitation because often some modifications (often shortening) of the stroke pattern are needed to facilitate the return to that sport.
- Although not always optimal from a performance enhancement standpoint, careful monitoring and use of video feedback to obtain the most efficacious movement pattern allowed by that patient's range of motion and strength levels are indicated.
- The use of computer programs such as Dartfish are indicated and used by these authors to monitor movement strategies and provide meaningful feedback to the patient during this critically important phase of the rehabilitation process.
- Objective criteria such as minimal pain-free range of motion characteristics, negative instability and impingement clinical tests, strength test within 15% to 20% of the contralateral limb in addition to acceptable unilateral strength ratios (optimal 66% to 75% ER/IR ratios, accepted minimal standards 55% to 65%) are used to guide the process objectively from a clinical standpoint.

Specific Criteria for Release to Unsupervised Complete Participation in Swimming, Golf, and Tennis

- Successful completion of a supervised rehabilitation program
- Isokinetically documented strength within 10 % of the contralateral side with acceptable (66–75%) ER/IR unilateral strength ratios
- Pain-free range of motion required for sport activity (i.e., negative cross-arm adduction range of motion for a golfer, etc.)
- Successful completion of a supervised interval sport return program

Recommended Ongoing Exercises

- Maintenance programs given to the patients upon completion of their supervised rehabilitation include rotator cuff and scapular exercises to be performed using a low-resistance high repletion format (multiple set training).
- These include exercise with elastic resistance for external and internal rotation both at the 30/30/30 position at the side and with 90° of elevation.
- Additionally, scapular stabilization exercises for the serratus anterior and lower trapezius are recommended.
- It is also recommended that range of motion exercises be continued to prevent range of motion loss including the cross-arm and sleeper stretches for internal rotation as well as external rotation with a stick or implement and use of a pulley or external device such as a stick or cane for forward flexion.

Evidence

Bailie DS, Llinas PJ, Ellenbecker TS: Cementless humeral resurfacing arthroplasty in active patients less than fifty-five years of age. *J Bone Joint Surg Am* 90:110–117, 2008. doi: 10.2106/JBJS.F.01552.

This retrospective study presented the outcome of shoulder arthroplasty in patients 55 years of age or less. Improvements in range of motion and functional outcomes were documented in this study with humeral resurfacing using the Biomet Copeland Humeral Resurfacing Prosthesis. (Level IV evidence)

Healy WL, Iorio R, Lemos MJ: Athletic activity after joint replacement. *Am J Sports Med* 29(3):377–388, 2001.

This publication involved interviewing 35 members of the American Shoulder and Elbow Surgeons Society regarding their recommendations for returning to sport after shoulder arthroplasty. The responses were analyzed statistically to determine a consensus recommendation. Recommended activities such as swimming, doubles tennis, bowling, low-impact aerobics, and bicycling were all recommended activities among the panel with golf, shooting, ice skating, and downhill skiing recommended if patients were experienced in that sport participation. Contact sports such as football and hockey were not recommended. (Level V evidence)

Jensen KL, Rockwood CA: Shoulder arthroplasty in recreational golfers. *J Shoulder Elbow Surg* 7:362–367, 1998.

This study consisted of a retrospective review of 24 patients who were recreational golfers who underwent shoulder arthroplasty. Three patients in this group had bilateral arthroplasty. The findings of this retrospective review were that 96% of the patients were able to return to playing golf after surgery. Six in this group of patients were hemiarthroplasties and 20 were total shoulder arthroplasties. The authors found that the average time to return to golf from time of surgery was 4.5 months, and of 18 patients who reported a preoperative handicap golf rating, an improvement of five shots postoperatively was noted. (Level IV evidence)

McCarty EC, Marx RG, Maerz D, et al: Sport participation after shoulder replacement surgery. *Am J Sports Med* 36:1577–1581, 2008.

This retrospective study described the return to sport outcomes of patients following shoulder arthroplasty. The frequency of returning to sports such as golf, tennis, fishing, and even kayaking and fishing shows the present ability of many patients to return to upper extremity sport activities following shoulder arthroplasty. (Level IV evidence)

Saltzman MD, Chamberlain AM, Mercer DM, et al: Shoulder hemiarthroplasty with concentric glenoid reaming in patients 55 years old or less. *J Shoulder Elbow Surgery* 20:609–615, 2011.

This article does not specifically review return to sport but does profile improvements in shoulder function in young active individuals who had shoulder arthroplasty and are less than 55 years of age. Improved functional outcomes scores are reported in this study, with a 44 month follow-up after surgery. (Level IV evidence)

Multiple-Choice Questions

QUESTION 1. According to research by McCarty et al., what percentage of patients following shoulder arthroplasty return to sports like golf, fishing, swimming, and softball?

A. Less than 20%
B. Approximately 50%
C. 75 to 90%
D. 100% return to these sports

QUESTION 2. Which of the following are objective criteria that can be used to determine whether a patient is ready to return to sport following arthroplasty?

A. Pain-free range of motion
B. Negative instability and impingement tests
C. Strength to within 15% to 20% of the contralateral limb with objective strength testing
D. All of the above would be indicators.

QUESTION 3. What characteristic would NOT be considered important for patients following shoulder arthroplasty?

A. Low load, high repetition training formats
B. Closed kinetic chain exercises
C. Rest periods of approximately 30 seconds between sets
D. Alternate day training (day of recovery between training sessions)

QUESTION 4. Regarding an interval tennis program, which statement does not accurately characterize the recommendations for successful return to sport?

A. Begin with forehand and backhand groundstrokes before serving.
B. Hit on alternate days to allow recovery between training sessions.
C. Use video and other feedback to ensure proper mechanics are used.
D. Begin with overhead serving before any other types of tennis activity.

QUESTION 5. Which of the following tests are important when evaluating a patient before returning to an interval sport program?

A. Static and dynamic posture with specific emphasis on scapular position
B. Glenohumeral joint active and passive range of motion
C. Repetition maximum testing for shoulder flexion in overhead position
D. A and B are correct

Answer Key

QUESTION 1. Correct answer: **C** (see Literature)

QUESTION 2. Correct answer: **D** (see Specific Criteria for Progression to the Next Stage to Determine Readiness for Swimming, Golf, and Tennis)

QUESTION 3. Correct answer: **B** (see Application of Chronic Training Variables)

QUESTION 4. Correct answrr: **D** (see Application of Acute Training Variables)

QUESTION 5. Correct answer: **D** (see Application of Acute Training Variables)

Chapter 9

Epicondylitis

INTRODUCTION

Michael Levinson, PT, CSCS, and David Altchek, MD

Epidemiology

Age/Sex

- Age: Those 35 to 50 years of age are at the highest risk
- Females and males

Sport

- Tennis
- Golf
- Occupations or hobbies with repetitive activities
- 1% to 3% of the general population affected
  - Adult players: 35% to 50%
  - Elite players: 11% to 12%

Pathophysiology

Intrinsic Factors

- Proximal strength deficits at the scapula and glenohumeral joint
- Glenohumeral flexibility deficits such as loss of posterior shoulder flexibility
- Poor weightshifting during backhand, late backswing, and hitting with the front shoulder up
- Increased wrist extension at ball impact
- Poor general condition
- Poor upper-limb posture
- Inadequate rest and recovery
- Inadequate warmup

Extrinsic Factors

- Improper racquet grip size
- Racquet string tension too high
- Strings not resilient or soft enough
- Improper handle size of racquet or other sporting equipment that requires grip

Traumatic Factors

- Gradual increased load-related pain with increased activity
- Repetitive microtrauma
- Vascular compromise
- High eccentric and concentric stresses on the common extensor tendon (especially during the tennis backhand)

Classic Pathological Findings

- Angiofibroblastic hyperplasia, tendinosis
- Excessive vascular granulation
- Disorganized or degenerative collagen
- Degeneration, tendonopathy, tendinosis, and microtears of the extensor carpi radialis brevis (ECRB) and EDU tendon

Clinical Presentation

History

- Gradual onset of pain at the origin of the common extensor tendon (Figure 9-1)

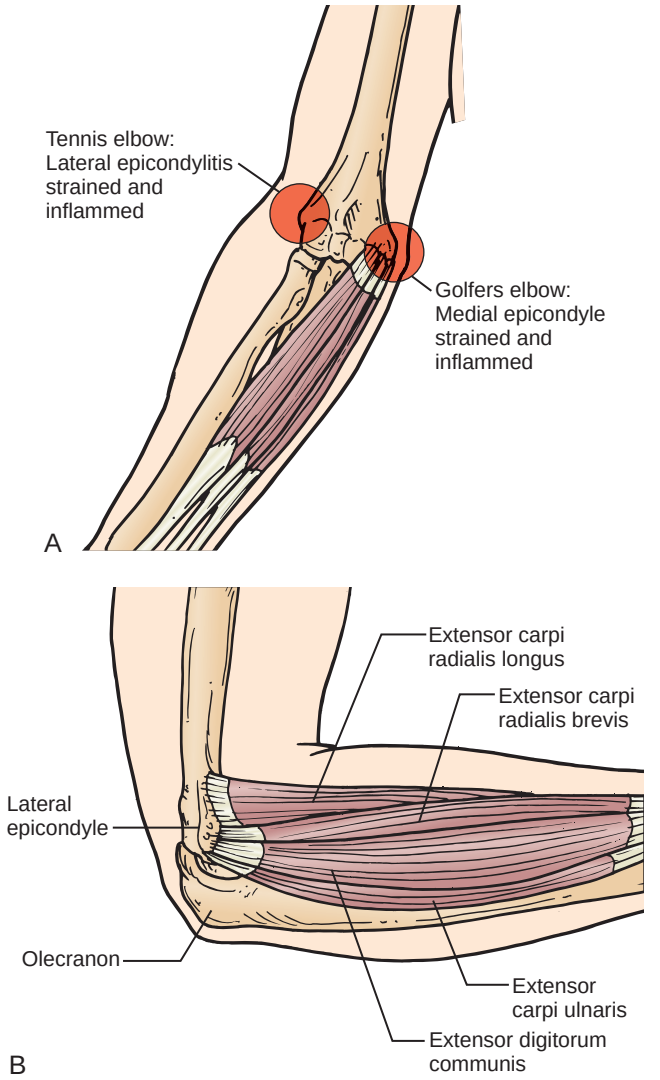

FIGURE 9-1. Lateral and medial epicondylitis. **A**, In lateral epicondylitis, or "tennis elbow," inflammation and pain occur in the outer side of the elbow, where muscles and tendons attach to the bone. The structures involved are the muscles or tendons of the forearm that bring the wrist back or extend the wrist, which is why this condition occurs not only in tennis players but also in anyone who performs repeated resisted motions of the wrist. In medial epicondylitis, or "golfer's elbow," inflammation and pain occur in the inner side of the elbow, where muscles and tendons attach to the bone. The structures involved are the muscles and tendons of the forearm that bring the wrist down and flex the wrist. This occurs not only in golfers but in anyone who performs repeated resisted motions of the wrist. **B,** Origin of the common extensor tendon.

- Often related to the backhand, especially in the novice and the recreational tennis player
- Other complaints may be related to repetitive labor activities, excessive computer work, or carrying bags with the elbow in extension.
- Symptoms often progress from pain after athletic or work-related activities to simple activities of daily living, such as shaking hands or holding an object with the elbow in extension.
- The elbow becomes painful at rest and disturbs sleep.

Physical Examination

Abnormal Findings

- Loss of wrist flexion range of motion
- Tenderness to palpation of the extensor origin at the lateral epicondyle (see Figure 9-1*B*)
- Localized edema, erythema
- Grip weakness
- Pain with passive wrist flexion
- Pain with resistive wrist and third-finger extension

Imaging

- Radiographs: tendinous calcific changes
- Magnetic resonance imaging (MRI): tears of the extensor tendon, abnormal tendinous tissue

Differential Diagnosis

- C6 to C7 nerve root compression: symptoms more radicular in nature
- Posterior interosseous nerve syndrome: may be differentiated by pain with wrist extension and radial deviation, weakness of finger extensors, and pain with thumb extension at the lateral epicondyle
- Lateral antebrachial cutaneous nerve irritation (the terminal sensory branch of the musculocutaneous nerve)

Treatment

Nonoperative Management

- Activity modification to avoid the aggravating behaviors
- Corticosteroid injections
- Nonsteroidal antiinflammatory drugs
- Counterforce bracing, wrist cockup splint
- Shock-wave therapy
- Physical therapy: strength, flexibility, conditioning, manipulation, and mobilization
  - Physical therapy modalities: cryotherapy, transcutaneous electrical nerve stimulation, iontophoresis, ultrasound, and low-level laser
- Improvement of sport mechanics
- Plasma-rich platelet injections

Guidelines for Choosing Nonoperative Treatments

- Diagnosis of tendinitis versus tendonopathy
- Severity and history of symptoms
- Clinical findings, such as strength, flexibility, postural, and conditioning deficits

Surgical Indications

- Failure of injections
- Associated intraarticular pathology
- Failure of conservative treatment for a minimum of 6 months

Aspects of History, Demographics, or Examination Findings that Affect Choice of Treatment

- Persistent pain that interferes with activities of daily living and disturbs sleep
- Pain that prevents return to sport such as tennis
- Persistent pain localized to the origins of the ECRB and extensor digitorum communis (EDC)
- Tear of the extensor demonstrated on MRI evaluation

Aspects of Clinical Decision-Making When Surgery Is Indicated

- Surgeon's experience and the efficiency of the procedure
- Other intraarticular pathology may dictate an arthroscopic procedure.
- Lateral epicondyle drilling can increase pain and potentially damage the EDC.
- Release techniques have potential for complications, such as damage to the lateral ligament complex, instability, and loss of grip strength.

Evidence

Barr S, Cerisola FL, Blanchard V: Effectiveness of corticosteroid injections compared with physiotherapeutic interventions for lateral epicondylitis: a systematic review. *Physiotherapy* 95:251–265, 2009.

This systematic review of randomized control trials compares corticosteroid injections with physiotherapeutic interventions. The authors indicate that injections are effective at short-term follow-up examinations and physiotherapeutic interventions are effective at intermediate and long-term follow-up examinations. (Level IIIA evidence).

Garg R, Adamson GJ, Dawson PA, et al: A prospective randomized study comparing a forearm strap brace versus a wrist splint for the treatment of lateral epicondylitis. *J Shoulder Elbow Surg* 19:508–512, 2010.

In this prospective, randomized study, 42 patients with lateral epicondylitis were given either a counterforce forearm strap or a wrist extension splint. Utilizing the Mayo Elbow Performance and ASES Assessment form, the researchers found that the wrist extension splint led to a greater degree of pain relief. (Level II evidence).

Nirschl RP, Rodin DM, Ochiai DH, et al: Iontophoretic administration of dexamethasone sodium phosphate for acute epicondylitis. *Am J Sports Med* 31:189–195, 2003.

In this randomized, double-blind, placebo-controlled trial, 199 patients with epicondylitis either were treated with iontophoresis with dexamethasone or received placebo treatment. More patients treated with dexamethasone scored moderate or better on the investigators' global improvement scale at 2 days, but the difference was not significant at 1 month. (Level IV evidence).

Oken O, Kahraman Y, Ayhan F, et al: The short-term efficacy of laser, brace and ultrasound treatment in lateral epicondylitis: a prospective, randomized, controlled trial. *J Hand Surg* 21:63–68, 2008.

In this prospective, randomized, controlled trial, three groups of patients with lateral epicondylitis were treated with braces and exercise, ultrasound and exercise, or low-level laser and exercise. Laser therapy was more effective than ultrasound or bracing in restoring grip strength. (Level IIIb evidence).

Peerbooms JC, Sluimer J, Bruijn DJ, et al: Positive effect of an autologous platelet concentrate in lateral epicondylitis in a double-blind randomized controlled trial: platelet-rich plasma versus corticosteroid injection with a 1-year follow-up. *Am J Sports Med* 38:255–262, 2010.

In this double-blind, randomized control trial, the researchers compared treatment of 100 patients with lateral epicondylitis, 51 treated with platelet-rich plasma (PRP), and 49 with corticosteroid injection. The results, based on the score on the visual analogue scale Disabilities of the Arm, Shoulder, and Hand Module, demonstrated that PRP reduces pain and increases function, exceeding the results of corticosteroid injection. (Level I evidence).

Multiple-Choice Questions

QUESTION 1. Which of the following is not an intrinsic factor that may predispose the patient to lateral epicondylitis while playing tennis?

A. Proximal strength or flexibility deficits
B. Increased wrist extension at ball impact
C. Increased wrist flexion at ball impact
D. Inadequate rest and recovery

QUESTION 2. Which of the following is not an extrinsic factor that contributes to lateral epicondylitis?

A. Improper racquet grip size
B. Racquet string tension that is too high
C. Improper footwear
D. Racquet string that is not resilient or soft enough

QUESTION 3. Which of the following conditions can easily be confused with, and needs to be differentiated from, lateral epicondylitis?

A. Posterolateral instability
B. Posterior interosseous nerve syndrome
C. Ulnar collateral ligament tear
D. C4 to C5 radiculopathy

QUESTION 4. Which of the following would not be a finding in a clinical examination for lateral epicondylitis?

A. Decreased grip strength
B. Loss of passive wrist extension
C. Pain with passive wrist and third-finger extension
D. Tenderness to palpation at the lateral epicondyle

QUESTION 5. Which of the following activities of daily living can exacerbate symptoms of lateral epicondylitis?

A. Handshaking
B. Excessive computer use
C. Carrying bags with the elbow in extension
D. All of the above

Answer Key

QUESTION 1. Correct answer: **C** (see Pathophysiology)

QUESTION 2. Correct answer: **C** (see Extrinsic Factors)

QUESTION 3. Correct answer: **B** (see Differential Diagnosis)

QUESTION 4. Correct answer: **D** (see Clinical Examination)

QUESTION 5. Correct answer: **D** (see Clinical Presentation)

NONOPERATIVE REHABILITATION OF LATERAL EPICONDYLITIS (TENNIS ELBOW)

Michael Levinson, PT, CSCS, and David Altchek, MD

GUIDING PRINCIPLES OF NONOPERATIVE REHABILITATION

- Understand the pathology: tendinitis versus tendonopathy
- Reduction of pain and inflammation and promotion of healing are the primary goals
- Control excessive loads to the injured area
- Pathologic tissue needs to be repaired and revitalized
- Reproduce the functional demands throughout the entire kinetic chain
- The patient's general fitness is critical to recovery and avoiding reinjury

Phase I (Guidelines are evaluation-based)

Protection

- Counterforce bracing or a wrist-cockup splint may be used for activities of daily living (Figure 9-2).
- Wrist splints should not be used during sleep, as they may cause shortening of the extensor tendons.
- Activity modification should be a significant factor in the treatment plan. The amount of incidental activities performed at home or at work (e.g., computer work, hand-shaking, carrying bags) should be taken into account.

Management of Pain and Swelling

- Modalities include cryotherapy, iontophoresis, ultrasound, TENS, and low-level laser.

Techniques for Progressive Increase in Range of Motion

Manual Therapy Techniques

- Joint mobilization may be used for pain control or if any capsular restrictions are present. Manipulations (Mill's manipulation) may also be utilized. Mill's manipulation is a small-amplitude, high-velocity thrust performed at the end of elbow extension while the wrist and hand are held flexed.

Soft-Tissue Techniques

- It is the authors' opinion that deep-tissue massage often exacerbates symptoms and has little therapeutic value.

Stretching and Flexibility Techniques for the Musculotendinous Unit

- Stretching of the wrist and finger extensors should be initiated in a pain-free range of motion (ROM) (Figure 9-3).

Other Therapeutic Exercises

- Multijoint, upper-extremity exercises should be initiated to restore total arm strength (TAS) and proximal stability. These should include scapula, deltoid, and rotator cuff strengthening.
- Often, the tennis player has a proximal muscle deficit.
- Biceps and triceps strengthening should be initiated in a pain-free ROM, avoiding full elbow extension.

FIGURE 9-2. Counterforce brace.

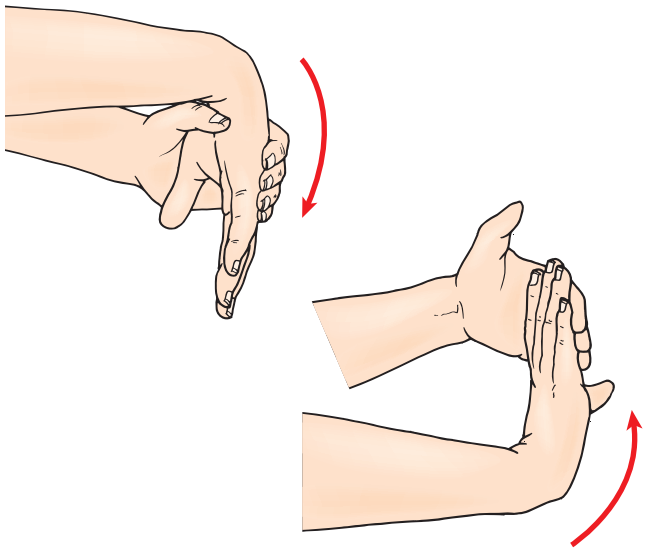

FIGURE 9-3. Stretching of the wrist and finger extensors.

- For the tennis player, core and lower-extremity strengthening may be initiated without holding weights in the hands.
- Upper-extremity posture should be addressed.

Open and Closed Kinetic Chain Exercises

- Closed kinetic chain exercises generally are performed with the wrist in extension and the elbow moving into full extension. This is contraindicated in Phase I.

Milestones for Progression to the Next Phase

- Reduction of symptoms (pain, edema, inflammation)
- Restoration of proximal stability (scapula function, rotator cuff strength)
- Normal wrist flexion ROM

Phase II (Guidelines are evaluation-based)

Protection

- Counterforce bracing or wrist-cockup splint as needed.

Management of Pain and Swelling

- Cryotherapy, iontophoresis, ultrasound, TENS, low-level laser as needed

Techniques for Progressive Increase in Range of Motion

Manual Therapy Techniques

- Joint mobilization and manipulation if any capsular restrictions are needed

Stretching and Flexibility Techniques for the Musculotendinous Unit

- Continue pain-free stretching of the wrist and finger extensors. Begin to address any shoulder flexibility deficits. For example, many tennis players have a loss of posterior shoulder flexibility.

Other Therapeutic Exercises

- Continue to progress general upper-extremity, multijoint exercises to normalize shoulder and scapula strength. For the tennis player, emphasize the scapula and posterior rotator cuff.
- Continue biceps- and triceps-strengthening to include concentric and eccentric activity.
- Initiate forearm-strengthening to include wrist flexion.
- Core and lower-extremity strengthening may be progressed, but the patient should still avoid holding heavy weights in the hands.

Activation of Primary Muscles Involved

- Initiate wrist extension and forearm pronation and supination. Exercises should be initiated with the elbow supported and in flexion to reduce the amount of bone-to-tendon contact at the origin of the common extensor tendon (Figure 9-4).

Techniques to Increase Muscle Strength, Power, and Endurance

- If proximal strength is adequate, the upper-body ergometer can be used to begin to restore power and endurance.

Neuromuscular Dynamic Stability Exercises

- Rhythmic stabilization should be initiated proximal to the elbow.

Functional Exercises

- Proprioceptive neuromuscular facilitation (PNF) patterns should be initiated.

Milestones for Progression to the Next Phase

- Normal upper-extremity flexibility
- Normal proximal upper-extremity strength
- Minimal pain with wrist extension exercises

Phase III (Guidelines are evaluation-based)

Management of Pain and Swelling

- Continue with prior modalities as needed as forearm-strengthening is progressed, symptoms may increase.

FIGURE 9-4. Forearm pronation (**A**) and supination (**B**) with the elbow in flexion.

Techniques for Progressive Increase in Range of Motion

Stretching and Flexibility Techniques for the Musculotendinous Unit

- A full upper-extremity flexibility program should be continued. Overstretching of the wrist and finger extensors should be avoided.

Other Therapeutic Exercises

- Continue to progress a full upper-extremity strengthening program, including overhead activities.
- Progress core and lower-extremity strengthening and flexibility program.
- Sport-specific general conditioning exercises

Activation of Primary Muscles Involved

- Eccentric wrist extension should be emphasized if tolerated. This should be initiated with the elbow in flexion and progressed to extension (Figure 9-5). All muscle groups of the forearm should be addressed to restore normal functional movement patterns.

Neuromuscular Dynamic Stability Exercises

- Rhythmic stabilization may be progressed to a longer-lever arm (distal to the elbow).

FIGURE 9-5. Resistive eccentric wrist extension.

- Exercises may be progressed to more challenging positions for the shoulder and elbow (Figure 9-6).
- The patient may then progress to the Bodyblade from a neutral position to positions throughout the tennis stroke.

Plyometrics

- A plyometric program should be initiated if the patient is asymptomatic and has a normal strength base and normal upper-extremity flexibility.

TIMELINE 9-1: **Nonoperative Rehabilitation of Lateral Epicondylitis (Tennis Elbow)**

PHASE I	PHASE II
• Physical therapy (PT) modalities • Pain-free wrist extensor stretching • Counterforce bracing/wrist-cockup splint • TBS/TAS/TLS activities as recommended and tolerated • Multijoint shoulder, scapula, and elbow strengthening • Mobilization and manipulation as needed	• PT modalities • Shoulder flexibility exercises • TBS/TAS/TLS activities as recommended and tolerated • Scapular exercises, shoulder exercises, and elbow exercises (including eccentrics) • Wrist flexion–extension, forearm pronation–supination (elbow in flexion) • Core and lower-extremity exercises • Rhythmic stabilization with proximal resistance • PNF patterns • Upper-body ergometer

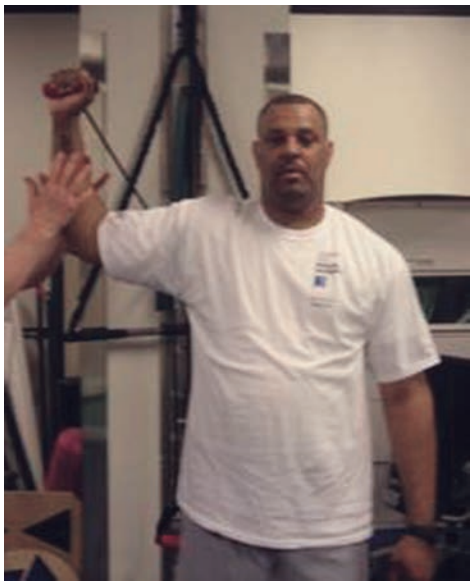

FIGURE 9-6. Rhythmic stabilization in the overhead position with distal resistance.

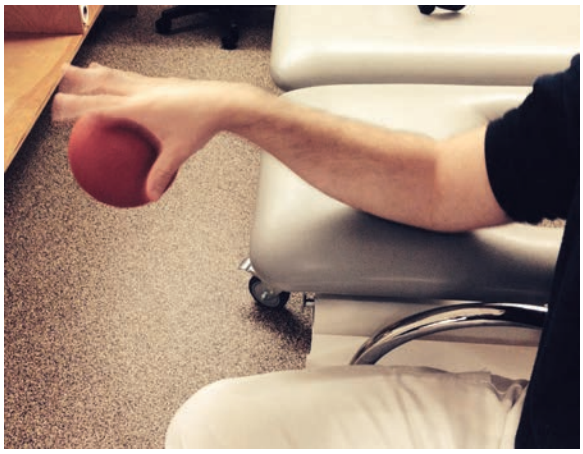

FIGURE 9-7. Wrist flips and snaps.

- A functional progression for a tennis player would follow: two-handed chest pass, side-to-side wood chops, overhead soccer pass, one-handed external rotation, one-handed backhand, one-handed 90° internal and 90° external position.
- Deceleration exercises by catching the plyo ball and slowing it down should be included.
- Wrist flexion flips and wrist flexion snaps may be incorporated (Figure 9-7).

Sport-Specific Exercises

- Resistive forehand and backhand exercises using elastic resistance or a cable system should be initiated.

Milestones for Progression to Advanced Sport-Specific Training and Conditioning

- Completion of a plyometric program without symptoms
- Full forearm strengthening without residual symptoms
- Upper-extremity strength and endurance that is equal or greater than the contralateral side

Phase IV (Guidelines are evaluation-based)

Management of Pain and Swelling

- Cryotherapy should be utilized throughout the return.

Techniques for Progressive Increase in Range of Motion

Stretching and Flexibility Techniques for the Musculotendinous Unit

- Continue full upper-extremity flexibility program.
- Avoid overstretching the extensor tendons.
- Stretching should always be pain-free.

Other Therapeutic Exercises

- Continue a full upper-extremity strengthening program to include the scapula, shoulder, elbow, forearm, and wrist.

TIMELINE 9-1: **Nonoperative Rehabilitation of Lateral Epicondylitis (Tennis Elbow)** (Continued)

PHASE III	PHASE IV
• PT modalities as needed • TBS/TAS/TLS activities as recommended and tolerated • Scapular exercises: PREs • TAS: Biceps/triceps PREs • Glenohumeral exercises: PREs • Rotator cuff exercises, including 90° internal and 90° external position PREs • Full forearm PREs • Eccentric wrist extension: PREs • PNF exercises • Rhythmic stabilization exercises with long lever arm; progress to Bodyblade • Core and lower-extremity exercises • Sport-specific plyometrics • Sport-specific PREs (forehand and backhand)	• PT modalities as needed • Full upper-extremity flexibility program • Wrist flexion–extension isokinetics • TBS/TAS/TLS activities as recommended and tolerated • Scapular exercises: PREs • TAS: biceps/triceps PREs • Glenohumeral exercises: PREs • Rotator cuff exercises: PREs • Forearm exercises • Core and lower extremity: PREs • PNF exercises • Open kinetic chain rhythmic stabilization exercises • Core and lower-extremity flexibility exercises • Interval tennis program

- Continue core stability with emphasis on trunk rotation and posture.
- Continue full lower-extremity strengthening program with emphasis on closed-chain activities, hip rotation, and unilateral activities. These may include leg press, squats, forward stepups, lunges, side lunges, back lunges, split squats, and lunges with trunk rotation.

Techniques to Increase Muscle Strength, Power, and Endurance

- Isokinetics for wrist flexion–extension and pronation–supination once a strength base has been established. This can be used to reproduce sport-specific speeds and train for endurance.

Plyometrics

- As an interval tennis program is initiated, plyometrics should be phased out.

Sport-Specific Exercises

- An interval tennis program should be initiated if criteria are met.
- The program should entail a progression of volume and intensity. The program should be progressed individually.
- Each phase should be completed without significant symptoms or fatigue prior to advancing to the next phase.

Criteria for Abandoning Nonoperative Treatment and Proceeding to Surgery or More Intensive Intervention

- Unable to perform sport-specific activities or return to preinjury activity level
- Continued pain with activities of daily living
- Failure to restore normal grip strength

Milestones for Progression to Sport-Specific Training and Conditioning

- Able to complete interval tennis program without symptoms
- Maintain normal upper-extremity strength and flexibility

Tips and Guidelines for Transitioning to Performance Enhancement

- When resuming tennis activities, the patient should not try to work through pain or fatigue.
- Use of low-compression tennis balls has been advocated when initiating an interval tennis program. These decrease the amount of stress on the elbow at ball impact.
- The patient's racquet should be evaluated for string tension and grip size. These can also be valuable in avoiding reinjury.
- Adequate rest and recovery are important to avoiding and minimizing fatigue and reducing the chances of reinjury.

Performance Enhancement and Beyond Rehabilitation: Training/Trainer and Optimization of Athletic Performance

- When returning to tennis activities, supervision by a professional to improve mechanics can enhance performance and prevent reinjury.
- Learning to weight-shift properly, use the core and lower extremities, and avoid hitting too late with the leading elbow posture can be very valuable.
- Upon returning to tennis, a program for full-body strength, flexibility, and endurance should be maintained. This will also reduce the risk of reinjury.

Specific Criteria for Return to Sports Participation: Tests and Measurements

- Normal grip strength on dynamometer
- Shoulder strength greater than contralateral side
- Normal upper-extremity flexibility
- Completion of full-interval tennis program

Evidence

Struijs PAA, Damen PJ, Bakker EWP, et al: Manipulation of the wrist for management of lateral epicondylitis: a randomized pilot study. *Phys Ther* 83:608–616, 2003.

In this randomized pilot study, two protocols were compared for patients with lateral epicondylitis. One was wrist manipulation, and the other consisted of ultrasound, friction massage, stretching, and strengthening. Follow-up was at 3 and 6 weeks. Manipulation of the wrist appeared to be more effective for the short-term.

Tanaka Y, Aoki M, Izumi T, et al: Effect of elbow and forearm position on contact pressure between the extensor origin and the lateral side of the capitellum. *J Hand Surg [Am]* 36:81–88, 2011.

In this cadaveric study, contact pressure between the origin of the common extensor tendons and the lateral side of capitellum was measured with a pressure sensor. Bone-to-tendon contacts is considered to be a cause of lateral epicondylitis with elbow extension, forearm pronation, and varus stress to the elbow.

Tyler TF, Thomas GC, Nicholas SJ, et al: Addition of isolated wrist extensor eccentric exercise to standard treatment for chronic lateral epicondylosis: A prospective randomized trial. *J Surg Shoulder Elbow* 19:917–922, 2010.

In this prospective randomized study, 21 patients with lateral epicondylosis were treated with eccentric strengthening for the wrist extensors using an inexpensive rubber bar. All outcome measures were found to have markedly improved with eccentric training on the basis of the Disabilities of the Arm, Shoulder, and Hand questionnaire; visual analogue scale measurement; and strength testing.

Vincenzino B, Smith D, Cleland J, et al: Development of a clinical prediction rule to identify initial responders to mobilisation with movement and exercise for lateral epicondylalgia. *Man Ther* 14:550–554, 2009.

In this post hoc analysis, 64 patients with lateral epicondylalgia were treated with standardized physical therapy. After

3 weeks, patients were categorized as improving or not improving. Factors with relationships to improvement were entered into a logistic regression model. Probability of improvement rose from 79% to 100% if all three factors were positive (Identify what the three factors were).

Wen DY, Schultz BJ, Schaal B, et al: Eccentric strengthening for chronic lateral epicondylosis: a prospective randomized study. *Sports Health* 3:500–503, 2011.

In this prospective randomized study, 28 patients with lateral epicondylosis were treated with eccentric strengthening or stretching. Pain scores rated with a visual analogue scale were used. Both groups had improved at 4 weeks, but there was no significant difference between groups at any follow-up time point.

Multiple-Choice Questions

QUESTION 1. Which cannot be utilized for protection and symptom reduction during the initial phase of nonoperative treatment?

A. Sling
B. Elbow counterforce brace
C. Activity modification
D. Wrist cockup splint

QUESTION 2. Which would not be considered a criterion for return to sport?

A. Normal shoulder forearm and shoulder flexibility
B. Completion of a sport-specific plyometric program
C. Interval tennis program with only minimal to moderate symptoms
D. Shoulder strength greater than contralateral side

QUESTION 3. Which position allows the most bone-to-tendon contact for the extensor tendons?

A. Elbow flexion and forearm supination
B. Elbow extension and forearm pronation
C. Elbow extension and forearm supination
D. Elbow flexion and forearm pronation

QUESTION 4. Which of the following should one do when returning to tennis activities?

A. Use tennis balls with high compression
B. Hit unsupervised
C. Play through fatigue to build endurance
D. Learn to weight-shift properly and avoid hitting too late with leading elbow

QUESTION 5. When should isolated strengthening of the wrist and finger extensors be initiated?

A. When a proximal strength base has been established
B. When forearm flexibility is restored
C. When the patient is asymptomatic
D. All of the above

Answer Key

QUESTION 1. Correct answer: **D** (see Phase I: Protection)

QUESTION 2. Correct answer: **C** (see Specific Criteria for Return to Sports Participation)

QUESTION 3. Correct answer: **B** (see Evidence)

QUESTION 4. Correct answer: **D** (see Performance Enhancement and Beyond)

QUESTION 5. Correct answer: **D** (see Phase II)

POSTOPERATIVE REHABILITATION AFTER OPEN OR ARTHROSCOPIC SURGERY FOR LATERAL EPICONDYLITIS

Michael Levinson, PT, CSCS, and David Altchek, MD

Indications for Surgical Treatment

- Failure of conservative treatment, which may include nonsteroidal antiinflammatory drugs, cortisone injections, splinting, and physical therapy and activity modification for a minimum of 6 months
- Persistent pain that interferes with activities of daily living
- Pain that prevents an athlete from returning to sport
- Clear localization of pain at the anatomic areas of the extensor carpi radialis brevis (ECRB) and extensor digitorum communis
- Tear of the extensor tendon diagnosed

Brief Summary of Surgical Treatment

Major Surgical Steps

- Supine position on the operating table
- Extensor carpi radialis longus (ECRL) is split longitudinally and retracted medially and laterally.
- The ECRB is exposed.
- Fibrinous material is debrided.
- Mini-Mitek suture anchor (De Puy Synthes, West Chester, Pennsylvania) is inserted into the lateral epicondyle.
- Two limbs of suture are passed through the ECRL and ECRB and reattached to the lateral epicondyle.
- Placed in posterior splint

Other Surgical Techniques and Options

- Major differences in other surgical techniques (if not covered in other sections)
- The ECRB can be debrided and released arthroscopically.
- The arthroscope is used to identify the location of the ECRB tendon and identify any other elbow joint pathologies, such as loose bodies.
- Any variance from rehabilitation guidelines would result from any postoperative joint effusion that might interfere with restoring range of motion (ROM) and strength.
- The clinician should be cognizant of any posterolateral instability that may result from this procedure.

Before Surgery: Overview of Goals, Milestones, and Guidelines[1]

GUIDING PRINCIPLES OF POSTOPERATIVE REHABILITATION

- Understand the surgical procedure performed and healing rates of the tissues involved
- Understand the positions and activities that stress the wrist and finger extensors and their attachment at the lateral epicondyle
- Minimize active wrist and finger extension during the early phases of rehabilitation
- Avoid painful ROM and strengthening
- Understand the criteria for returning to functional and athletic activities

Phase I: Immediate Postoperative Period (days 0 to 14)

Clinical Pearls

- Early range of motion is important. It should be performed actively or actively with assistance.
- Aggressive passive range motion should be avoided to allow optimal soft-tissue healing.
- A brace is generally not required. However, it may be indicated if patient activity modification is a concern.

Goals

- Patient education
- Activity modification to avoid stressing the repair
- Protect the surgical repair
- Minimize swelling, pain, and inflammation
- Avoid contracture

[1]*Prehabilitation, if appropriate, is described in the Nonoperative Rehabilitation section of this chapter.*

Protection

- A posterior splint is used for 1 week. As mentioned above, a brace is generally not indicated.

Management of Pain and Swelling

- Oral pain medications are prescribed.
- Cryotherapy is used for pain and inflammation.
- Activity modification to avoid pain is also critical. Minimizing activities that stress the wrist and finger extensors will help to reduce postoperative pain.
- For swelling, cryotherapy and activity modification

Techniques for Progressive Increase in Range of Motion

Stretching and Flexibility Techniques for the Musculotendinous Unit

- Codman exercises are used to increase blood flow into the entire upper extremity and maintain flexibility of the glenohumeral joint.
- Scapular retraction exercises are used to maintain posture and begin to restore proximal strength.
- Elbow active range of motion (AROM) and active assisted range of motion (AAROM) exercises are initiated. The therapist should not engage the patient with passive range of motion (PROM).

Other Therapeutic Exercises

- Once the sutures are removed, the patient may begin to use a stationary bicycle, but should avoid gripping the handle with the surgically treated hand.

Milestones for Progression to the Next Phase

- Minimal pain and swelling

Phase II (weeks 2 to 6)

Clinical Pearls

- The therapist should continue to avoid engaging the patient with aggressive PROM to allow optimal soft-tissue healing.
- Elbow extension should be restored by a low-intensity/long-duration stretch in supine.
- Patients should be advised to perform activities with their surgically treated arm with the elbow in flexion to reduce stress to the repair.

Goals

- Protect surgical repair
- Minimize pain, swelling, and inflammation
- Continue to modify activities of daily living (computer use, handshaking, carrying, and lifting)
- Avoid painful exercises.

Protection

- No protection is needed if the patient is compliant.

Management of Pain and Swelling

- Continue cryotherapy and oral pain medications as indicated.
- Continue cryotherapy and activity modification to control swelling.

Techniques for Progressive Increase in Range of Motion

Stretching and Flexibility Techniques for the Musculotendinous Unit

- Continue AROM and AAROM of the elbow.
- Low-intensity/long-duration stretch for elbow extension if needed; performed while supine with a towel roll under the humerus
- Gentle wrist ROM is initiated to avoid forearm stiffness and promote healing. This should be performed with the elbow in flexion.
- AROM of the shoulder is performed to maintain glenohumeral ROM and flexibility.

Other Therapeutic Exercises

- Continue stationary bicycle while avoiding gripping with the surgically treated hand.

Activation of Primary Muscles Involved in Injury Area or Surgical Structures

- Begin manual sidelying scapular stabilization exercise with resistance proximal to the elbow to continue to establish proximal strength (Figure 9-8).

Milestones for Progression to the Next Phase

- Minimal pain or swelling

FIGURE 9-8. Manual sidelying scapular stabilization exercises with proximal resistance.

Phase III (weeks 6 to 10)

Clinical Pearls

- When initiating isotonic exercises for the shoulder, scapula, and elbow, the patient should avoid end ranges of elbow extension. This will avoid excessive stress to the surgically repaired extensor tendon.
- Strengthening of the wrist and finger extensors should begin with the elbow supported and flexed. This will decrease bone-to-tendon contact pressure at the origin of the common extensor tendon at the lateral epicondyle.

Goals

- Continue to avoid excessive stress to the surgical repair.
- No pain with exercise or activities of daily living
- Full elbow ROM
- Begin to restore shoulder and scapular strength/flexibility.
- Begin to restore elbow and forearm strength.

Management of Pain and Swelling

- Cryotherapy is continued, and oral pain medication should be discontinued.

Techniques for Progressive Increase in Range of Motion

Manual Therapy Techniques

- In cases where extension is not full by 6 to 10 weeks, joint mobilization, such as joint distraction and posterior gliding of the ulna on the humerus, should be utilized.

Stretching and Flexibility Techniques for the Musculotendinous Unit

- If full extension has not been restored, a low-intensity/long-duration stretch should continue to be used. A weight or elastic resistance may be added.

Other Therapeutic Exercises

- Sport-specific core and lower-extremity strengthening may be introduced. However, holding heavy weights in the hands while performing these exercises should be avoided.
- Proximal strengthening should be introduced for the shoulder and scapula, including the rhomboids; serratus; upper, middle, and lower trapezius; and latissimus dorsi and rotator cuffs.
- All exercises should be performed while avoiding the end range of elbow extension (Figures 9-9 to 9-11).
- Begin biceps and triceps strengthening while avoiding the end stage of elbow extension.

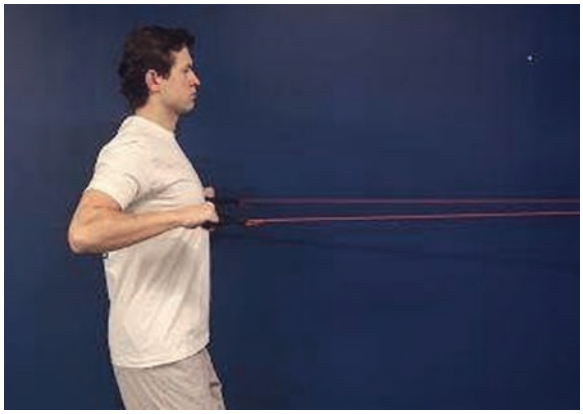

FIGURE 9-9. Scapula retraction with elastic resistance.

FIGURE 9-10. Serratus punch.

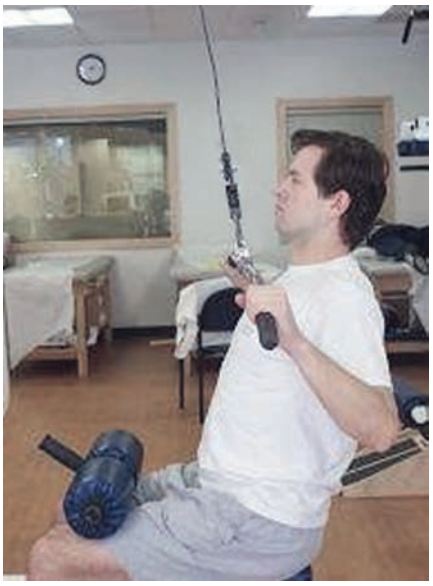

FIGURE 9-11. Latissimus dorsi pull-down.

Activation of Primary Muscles Involved in Injury Area or Surgical Structure

- Isotonic exercises for the wrist and finger extensors are initiated with the elbow supported and in flexion.

Open and Closed Kinetic Chain Exercises

- Most closed kinetic chain exercises put significant stress on the lateral epicondyle and common extensor tendon.

TIMELINE 9-2: **Postoperative Rehabilitation after Open or Arthroscopic Surgery for Lateral Epicondylitis**

PHASE I (weeks 1 to 2)	PHASE II (weeks 3 to 6)	PHASE III (weeks 6 to 10)
• Posterior splint for 1 week • Physical therapy (PT) modalities • Elbow AROM and AAROM • Codman's exercises	• PT modalities • Elbow AROM and AAROM • Low-intensity/long-duration stretch for extension (LILD) • Wrist AROM with elbow in flexion • Full elbow ROM • Manual sidelying scapular stabilization	• PT modalities as needed • Full AROM • Mobilization as needed • LILD as needed • Scapular exercises: progressive resistive exercises (PREs) • TAS: biceps and triceps PREs • Glenohumeral exercises: PREs • Rotator cuff exercises: PREs • Wrist flexor exercises • Wrist and finger extensor exercises with elbow in flexion • Rhythmic stabilization exercises proximal to the elbow • Closed kinetic chain exercises

FIGURE 9-12. Rhythmic stabilization with proximal resistance.

Neuromuscular Dynamic Stability Exercises

- Rhythmic stabilization exercises for the shoulder can be initiated with resistance proximal to the elbow (Figure 9-12).

Milestones for Progression to the Next Phase

- Full elbow ROM. Using standard goniometry, average elbow ROM is 0° internal and 140° external. However, it should be compared with the nonoperative side.
- Pain free with exercises and activities of daily living
- Good proximal strength base. All shoulder strength should be 5/5 using standard manual muscle testing. Scapulothoracic function should be within normal limits based on observation and comparison to the nonoperative side.
- Good shoulder flexibility determined using standard goniometry and compared with the nonoperative side. For shoulder internal rotation, vertebral level may be used.

Phase IV (weeks 10 to 14)

Clinical Pearls

- Elbow pathology in the athletic population is often associated with a selective loss of shoulder flexibility.
- In preparing for athletic activities, begin to restore proximal flexibility, especially in the posterior structures of the shoulder.
- The common extensor tendon often undergoes significant eccentric stresses. Eccentric training should begin to be incorporated into the program.

Goals

- Restore normal shoulder and scapular strength
- Restore normal shoulder flexibility
- Begin to restore forearm flexibility
- Progress to overhead activities

Management of Pain and Swelling

- Cryotherapy is continued to prevent any muscle soreness.
- Any significant pain in this phase indicates that the patient's activity level should be reduced.
- The surgeon should address any significant swelling in this phase.

TIMELINE 9-2: **Postoperative Rehabilitation after Open or Arthroscopic Surgery for Lateral Epicondylitis** (Continued)

PHASE IV (weeks 10 to 14)	PHASE V (weeks 14 to 24)	PHASE VI (weeks 24 to 52)
• PT modalities as needed • Full AROM • Mobilization as needed • Forearm stretching • Posterior shoulder stretching • TBS, TAS, and TLS activities as recommended and tolerated • Scapular exercises: PREs • TAS: biceps and triceps PREs • Glenohumeral exercises: PREs • Rotator cuff exercises: PRE progression to 90° internal and 90° external position • Eccentric wrist and finger extensor exercises • Proprioceptive neuromuscular facilitation (PNF) exercises • Rhythmic stabilization exercises distal to elbow and overhead position • Upper-body ergometry	• AROM: Maintain full motion • Mobilization as needed • Full upper-extremity flexibility exercises • Total body strengthening (TBS), total arm strengthening (TAS), and total leg strengthening (TLS) activities as recommended and tolerated • Scapular exercises: PREs • TAS: biceps and triceps PREs • Glenohumeral exercises: PREs • Rotator cuff exercises: PREs • Forearm exercises with elbow extension: PREs • Isokinetics if available • PNF exercises • Rhythmic stabilization exercises • Bodyblade when available • Deceleration exercises • Plyometrics: Two-arm progressing to one arm • Interval tennis or sport-specific program begins • Full lower-extremity and core strength and flexibility	• AROM: maintain full motion • Maintain full-body flexibility • TBS, TAS, and TLS activities as recommended and tolerated • Scapular exercises: PREs • TAS: biceps and triceps PREs • Glenohumeral exercises: PREs • Rotator cuff exercises: PREs • Internal rotation/external rotation exercises at 90° • Core and lower-extremity PREs • PNF exercises • Forearm exercises: PREs • Progress sport-specific program • Return to play

FIGURE 9-13. Posterior shoulder stretch.

Techniques for Progressive Increase in Range of Motion

Stretching and Flexibility Techniques for the Musculotendinous Unit

- Forearm stretching for both the lateral and medial side should be performed. Posterior shoulder flexibility exercises should be initiated (Figure 9-13).

Other Therapeutic Exercises

- Scapula, shoulder, and elbow strengthening should be progressed as tolerated.
- Rotator cuff strengthening should be progressed to the 90° internal and 90° external position (Figure 9-14).

Activation of Primary Muscles Involved in Injury Area or Surgical Structures

- Wrist and finger extension strengthening should begin to emphasize the eccentric activity of muscle contraction.

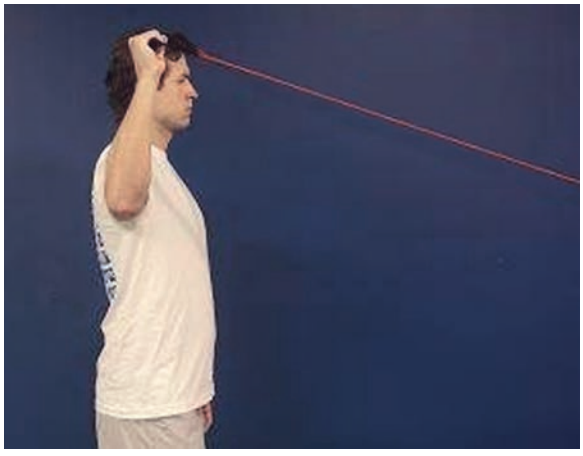

FIGURE 9-14. Rotator cuff strengthening in the 90° internal and 90° external position.

FIGURE 9-15. Upper-body ergometry

Sensorimotor Exercises

- Proprioceptive neuromuscular facilitation patterns are initiated.

Techniques to Increase Muscle Strength, Power, and Endurance

- Upper-body ergometry may be initiated to improve general upper-extremity endurance (Figure 9-15).

Neuromuscular Dynamic Stability Exercises

- Rhythmic stabilization exercise should be progressed to resistance distal to the elbow and to the overhead position.

Phase V (weeks 14 to 24)

Clinical Pearls

- Sport- or work-specific programs should be initiated only after the patient has demonstrated normal strength, flexibility, and endurance.
- The patient should have tolerated all neuromuscular drills, including plyometrics, prior to beginning a sport- or work-specific program.
- For the tennis player, problems are often initiated by strength and flexibility deficits at more proximal points in the chain, such as the trunk and hips.

Goals

- Restore normal neuromuscular function
- Begin sport- or work-specific activities without pain
- Restore full-body strength, ROM, flexibility, and endurance

Management of Pain and Swelling

- Cryotherapy

Techniques for Progressive Increase in Range of Motion

Stretching and Flexibility Techniques for the Musculotendinous Unit

- A full upper-extremity flexibility program should be continued for the shoulder, elbow, wrist, and forearm.

Other Therapeutic Exercises

- For the athlete, a full core and lower-extremity strengthening and flexibility program should be incorporated.
- For the tennis player, emphasis on hip and trunk flexibility and strength is critical.

Activation of Primary Muscles Involved in Injury Area or Surgical Structures

- Wrist and finger extensor strengthening should be performed with the elbow in extension if tolerated.
- Forearm pronation and supination exercises should be incorporated to improve total forearm function. Heavy resistance is not required and, in most cases, is contraindicated.

Techniques to Increase Muscle Strength, Power, and Endurance

- When available, isokinetics can be utilized to build endurance and simulate the speeds and loading rates of functional activities, such as tennis.

Neuromuscular Dynamic Stability Exercises

- Rhythmic stabilization may be progressed to all functional positions.
- The patient may be progressed to the Bodyblade if one is available.
- A functional progression should be followed from the patient's side to external rotation, then to the 90° internal and 90° external position, and then to follow-through (Figure 9-16).

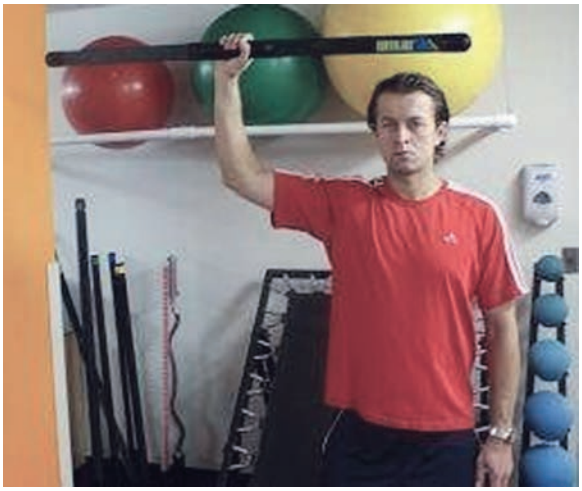

FIGURE 9-16. Bodyblade.

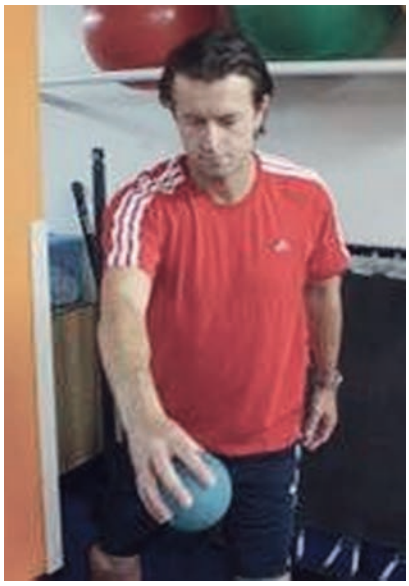

FIGURE 9-17. Deceleration exercises using a Plyoball.

Plyometrics

- When the patient is asymptomatic and with a normal strength base and upper-extremity flexibility within normal limits, a plyometric program should be initiated.
- Progression: Chest pass, side-to-side wood chops, overhead soccer pass, one-handed external rotation with arm at side, one-arm external rotation in 90° internal and 90° external position.

Functional Exercises

- Deceleration exercises are performed first in a kneeling position. Tossing a Plyoball over the shoulder and catching it and decelerating the arm.
- This should be progressed to a standing position where the patient trains the larger body parts to absorb stress from the upper extremity during a serve (Figure 9-17).

Sport-Specific Exercises

- For the tennis player, an interval tennis program should be initiated after completing several weeks of plyometrics without symptoms.
- Any sport-specific interval program should progress the intensity and volume of work.

Milestones for Progression to the Next Phase

- Normal grip strength
- Normal upper-extremity flexibility
- Normal upper-extremity strength, power, and endurance
- Completion of a sport-specific interval program.

Phase VI (weeks 24 to 52)

Goals

- Return to play
- Avoid reinjury
- Maintain strength and flexibility
- Maintain general fitness and improved posture

Management of Pain and Swelling

- Cryotherapy after activity or exercise

Techniques for Progressive Increase in Range of Motion

Stretching and Flexibility Techniques for the Musculotendinous Unit

- Maintain full upper-body, lower-body, and core flexibility program during play.

Other Therapeutic Exercises

- Continue full upper-body, lower-body, and core strengthening as they play.

Plyometrics

- Plyometrics should be phased out as the volume of play increases.

Sport-Specific Exercises

- Return to play.

Criteria for Return to Sport

General

- Pain free
- Normal grip strength with handheld dynamometer. Comparison with nonoperated side. There are also normative values for dominant and nondominant hands for various age groups.
- Normal rotator cuff ratio. Isokinetic dynamometer. External rotation/internal rotation is 66% in the normal population.
- Scapular symmetry. Observational comparison to the nonoperative side.
- Normal shoulder flexibility comparable to the contralateral side. Standard goniometry or vertebral level for shoulder internal rotation.

Sport-Specific

- See above.

After Return to Sport

Continuing Fitness or Rehabilitation Exercises

- Lower-extremity and core strengthening and flexibility training
- Full upper-extremity strengthening and flexibility training
- General conditioning

Exercises and Other Techniques for Prevention of Recurrent Injury

- Improve mechanics (emphasis on the backhand) to use the larger body parts more and improve weight shifting (for example, the trunk and lower extremities)
- Adjust racquet grip size
- Adjust racquet tension

Evidence

Baker CL, Jr, Baker CL, 3rd: Long-term follow-up of arthroscopic treatment of lateral epicondylitis. *Am J Sports Med* 36:254–260, 2008.

In this case series, 30 patients were located for follow-up after being treated for lateral epicondylitis with arthroscopic resection of pathologic tissue. A numeric pain scale and the Mayo Clinic Elbow Performance Index were used. The rate of success was maintained after a mean follow-up of 130 months. (Level IV evidence).

Dunn JH, Kim JJ, Davis L, et al: Ten- to 14-year follow up of the Nirschl surgical technique for lateral epicondylitis. *Am J Sports Med* 36:261–266, 2008.

Eighty-three patients with a mean follow-up of 12.6 years underwent the mini-open surgical technique for resection of tendinosis tissue. On the basis of the Numeric Pain Intensity Scale, the Nirschl and Verhaar tennis elbow scoring systems, and the American Shoulder and Elbow Surgeons elbow form, the surgery was successful. (Level IV evidence).

Rosenberg N, Henderson I: Surgical treatment of resistant lateral epicondylitis: follow-up study of 19 patients after excision, release and repair of proximal common extensor tendon origin. *Arch Orthop Trauma Surg* 122:514–517, 2002.

In this study, the researchers reported on 19 patients treated by excision, release, and repair of the common extensor tendon. Eighteen patients reported recovery from pain and a satisfactory regaining of forearm strength 3 to 4 months after surgery. (Level IIc evidence).

Szabo SJ, Savoie FH, Field LD, et al: Tendinosis of the extensor carpi radialis brevis: an evaluation of three methods of operative treatment. *J Shoulder Elbow Surg* 15:721–727, 2006.

In this retrospective review, outcomes were evaluated for 109 patients with lateral epicondylitis who had undergone open, arthroscopic, or percutaneous surgery. Outcomes were evaluated with the visual analogue scale and the Andrews-Carson score. At a mean follow-up of 47.8 months, there was no significant difference between the three procedures. All were considered effective. (Level IIb evidence).

Zingg PO, Schneeberger AJ: Debridement of extensors and drilling of the lateral epicondyle for tennis elbow: a retrospective follow-up study. *J Shoulder Elbow Surg* 15:347–350, 2006.

In this retrospective follow-up study, 21 patients treated for tennis elbow with extensor debridement without repair and with decortication drilling were reviewed after a mean follow-up of 15 months. Ninety-five felt they had improved; however, they reported that recovery was slow and painful. (Level IIb evidence).

Multiple-Choice Questions

QUESTION 1. When is AROM of wrist extension safe with the elbow in flexion?

A. 0 to 2 weeks
B. 3 weeks
C. 6 weeks
D. 8 weeks

QUESTION 2. In the initial postoperative phase, which of the following should be excluded?

A. Scapula retraction
B. Elbow AROM
C. Codman exercises
D. Elbow PROM

QUESTION 3. If there is difficulty in restoring elbow extension ROM, which of the following therapeutic techniques should be employed?

A. Aggressive PROM by the clinician
B. Manipulation
C. Low-intensity long-duration stretch and joint mobilization
D. Deep-tissue massage

QUESTION 4. When is it safe to initiate eccentric strengthening of the extensors?

A. 3 to 6 weeks
B. 6 to 10 weeks
C. 10 to 14 weeks
D. 14 to 24 weeks

QUESTION 5. Which of the following would not be an indication for surgical intervention for lateral epicondylitis?

A. Failure of at least 3 months of conservative treatment
B. Tear of the extensor tendon
C. Pain with activities of daily living
D. Unable to return to sport

Answer Key

QUESTION 1. Correct answer: **B** (see Phase II, 3 to 6 weeks)

QUESTION 2. Correct answer: **D** (see Phase I, 0 to 2 weeks)

QUESTION 3. Correct answer: **C** (see Phases II and III, 3 to 10 weeks)

QUESTION 4. Correct answer: **C** (see Phase IV, 10 to 14 weeks)

QUESTION 5. Correct answer: **A** (see Indications for Surgical Treatment)

BEYOND BASIC REHABILITATION: RETURN TO TENNIS AFTER TREATMENT FOR LATERAL EPICONDYLITIS

Jamie Osmark, CSCS, Michael Levinson, PT, CSCS, and David Altchek, MD

Introduction

- This injury is more common in the novice tennis player. It is not often seen in competitive tennis players.
- It is often related to poor mechanics in the tennis backhand, but it also can be related to trying to create topspin on a serve or forehand.
- Returning to tennis can be challenging. However, success can be correlated with becoming asymptomatic, restoring strength and flexibility and improving mechanics.

Aspects of Tennis that Require Special Attention in Rehabilitation

- Repetitive activities
- Rapid development of muscular activity, short bursts, and high intensity

- Strength, speed, power, flexibility, muscular endurance, and muscular balance
- Velocity, spin, and placement
- Number of strokes
- Anaerobic and aerobic activity

Phase I: Advanced Strength and Conditioning Programs

Periodization

- Linear
- Macrocycles
- Mesocycles
- Microcycles

Program Design/Performance Training Program

Sport-Specific Concepts of Integrated Training

- Training continuum
- Flexibility and joint mobility for joint stability
- Training with optimum posture
- Sensorimotor and balance training
- Core training
- Cardiorespiratory training
- Multiplanar training activities
- Training for optimum muscle balance
- Training for optimum muscle functional strength
- Training for optimum muscle functional power
- Neuromuscular dynamic stability exercises
- Training for speed, agility, and quickness (SAQ)
- Functional training

Olympic Lifts Used in the Training Program

- Clean and jerk
- Power clean

Training Principles Used in the Design of the Program

- Principle of progression
- Principle of overload
- Principle of variation
- Principle of individualization
- Principles of specificity: Specific adaptation to imposed demands (SAID)

Application of Acute Training Variables

- When returning to tennis, a linear periodized program consisting of endurance, hypertrophy, strength, and power phases should be implemented for a safe, strong return.
- Repetitions
  - Endurance phase: 12 to 20 repetitions
  - Hypertrophy phase: 7 to 12 repetitions
  - Strength phase: Four to six repetitions
  - Power phase: Two to five repetitions
- Sets
  - Endurance phase: Two or three sets
  - Hypertrophy phase: Three to six sets
  - Strength phase: Three to five sets
  - Power phase: Three five sets
- Rest interval
  - Endurance phase: 30 to 45 seconds
  - Hypertrophy phase: 45 to 60 seconds
  - Strength phase: 120 seconds
  - Power phase: 120+ seconds

TIMELINE 9-3: **Postoperative Rehabilitation After Open or Arthroscopic Posterior Shoulder Stabilization**

PHASE I (weeks 1 to 2)	PHASE II (weeks 3 to 6)	PHASE III (weeks 7 to 10)
• Sling • PT modalities • ROM: Scapular plane elevation to 90° • Active assisted Codman's exercises • TBS, TAS, and TLS activities as recommended and tolerated	• Sling • PT modalities • ROM during Wk 4: Scapular plane elevation to 120° • ROM during Wk 6: Scapular plane elevation to 160° • ROM during Wk 4: Start flexion to 90° • ROM during Wk 6: ER to 30° • ROM during Wk 6: Internal rotation (IR) to 0° • TBS, TAS, and TLS activities as recommended and tolerated • Scapular exercises • Wk 4: Active assisted range of motion exercises • Wk 4: Submaximal isometrics for glenohumeral joint muscles • Wk 4: Submaximal isometrics for external rotation (ER)	• DC sling • PT modalities as needed • PROM: Full • Mobilization as needed • TBS, TAS, and TLS activities as recommended and tolerated • Scapular exercises: Progressive resistive exercises (PREs) • TAS, biceps, and triceps PREs • Glenohumeral exercises: PREs • Rotator cuff exercises: PREs • Limit IR exercises to minimize strain to posterior capule • Proprioceptive neuromuscular facilitation (PNF) exercises • OKC rhythmic stabilization exercises • CKC exercises • Wk 10: Seated press-ups and increased weight-bearing through joint • CKC manual perturbation exercises

- Intensity
  - Endurance phase: <67% of 1RM
  - Hypertrophy phase: 67% to 85% of 1RM
  - Strength phase: >85% of 1RM
  - Power phase: 75% to 85% of 1 RM
- Repetition tempo
  - Endurance: 2/1/2
  - Hypertrophy: 2/0/2
  - Strength: 2/0/1
  - Power: 1/0/X
- Training frequency
  - 3 or 4 days
- Training duration
  - 60 minutes per session
  - 3 to 5 weeks per mesocycle
- Training volume
  - Endurance: 12 to 60 repetitions per exercise
  - Hypertrophy: 18 to 72 repetitions per exercise
  - Strength: 12 to 30 repetitions per exercise
  - Power: 6 to 25 repetitions per exercise
- Specific exercises used in the training
  - Clean and jerk
  - Clean
  - Squat
  - Dumbbell overhead press
  - Dead lift
  - Push press
  - Row
  - Lat pull-down
  - Pushup
  - Serratus punch
  - Chest fly
  - Prone Y's and T's
  - Plank
  - Side plank
  - Palloff press (Figure 9-18)
  - Stability chop and lift
  - Bridge
  - Dead bug (Figure 9-19)
  - Russian twist
  - Wrist extension and flexion
  - Wrist pronation and supination
  - Shoulder external rotation
  - Shoulder internal rotation
  - Quadruped thoracic rotation (Figure 9-20)
  - Hip airplane
  - Wall slide stretch
  - Sleeper stretch

FIGURE 9-18. Palloff press.

TIMELINE 9-3: **Postoperative Rehabilitation After Open or Arthroscopic Posterior Shoulder Stabilization** (Continued)

PHASE IV (weeks 11 to 14)	PHASE V (weeks 15 to 24)	PHASE VI (weeks 25 to 52)
• Physical therapy (PT) modalities as needed • PROM: Full • Mobilization as needed TBS, TAS, and TLS activities as recommended and tolerated • Scapular exercises: PREs • TAS, biceps, and triceps PREs • Glenohumeral exercises: PREs • Rotator cuff exercises: PREs • Thrower's Ten • Limit IR exercises to minimize strain to posterior capsule • PNF exercises • Open kinetic chain (OKC) rhythmic stabilization exercises • Closed kinetic chain (CKC) exercises • CKE manual perturbation exercises	• Passive range of motion (PROM): Maintain full motion • Mobilization as needed • TBS, TAS, and TLS activities as recommended and tolerated • Scapular exercises: PREs • TAS, biceps, and triceps PREs • Glenohumeral exercises: PREs • Rotator cuff exercises: PREs • Thrower's Ten progress intensity • PNF exercises • OKC rhythmic stabilization exercises • CKC exercises • CKC manual perturbation exercises • Plyometrics: Two- arm progressing to one-arm • Overhead strengthening exercises • Sport-specific exercises begin • Overhead throwing athletes can begin an easy interval throwing program • 20 wks: Begin full-windup throwing	• PROM: Maintain full motion • Mobilization as needed • Total body strengthening (TBS), total arm strengthening (TAS), and total leg strengthening (TLS) activities as recommended and tolerated • Scapular exercises: PREs • TAS, biceps, and triceps PREs • Glenohumeral exercises: PREs • Rotator cuff exercises: PREs • IR/ER exercises at 90° • Thrower's Ten progress intensity • PNF exercises • OKC rhythmic stabilization exercises • CKC exercises • CKC manual perturbation exercises • Plyometrics: Two-arm chest passes progressing to 90° internal and 90° external one-arm plyometrics • Overhead strengthening exercises • Sport-specific exercises progressed • Overhead throwing athletes progress through an interval throwing program

FIGURE 9-19. Dead bug.

Application of Chronic Training Variables

- The first phase, endurance, helps acclimate the player back to strength training by preparing the muscles, tendons, and overall joint stability for more volume and intensity. This phase also helps reestablish the neuromuscular connection to maximize muscular recruitment.
- The second phase, hypertrophy, is aimed to build muscular size.
- The third phase, strength, focuses on gaining maximal functional strength.
- The final phase, power, ties the prior phases together. Its focus is on the transfer and development of power through the legs, torso, and upper body.

Phase II: Performance Enhancement Training Techniques

Periodization

- Linear
- Macrocycles
- Mesocycles
- Microcycles

Program Design and Performance Training Program

Sport-Specific Concepts of Integrated Training

- Training continuum
- Flexibility and joint mobility for joint stability

FIGURE 9-20. Quadruped thoracic rotation.

- Training with optimum posture
- Sensorimotor and balance training
- Core training
- Cardiorespiratory training
- Multiplanar training activities
- Training for optimum muscle balance
- Training for optimum muscle functional strength
- Training for optimum muscle functional power
- Neuromuscular dynamic stability exercises
- Training for SAQ
- Plyometric training
- Functional training
- Sport-specific training
- Power training
- Speed agility training

Training Principles Used in the Design of the Program

- Principle of progression
- Principle of overload
- Principle of variation
- Principle of individualization
- Principles of specificity: SAID

Application of Acute Training Variables

- Repetitions
  - Plyometrics: 8 to 12 repetitions
  - Rotational power: 3 to 12 repetitions
  - Core strength: 1 to 12 repetitions
- Sets
  - Plyometrics: Two or three sets
  - Power: Three to five sets
  - Strength: One or two sets
- Rest interval
  - Plyometrics: 1 to 3 minutes
  - Rotational power: 3 to 5 minutes
  - Core strength: 1 to 2 minutes
- Intensity
  - Plyometrics: Body weight, medicine ball, dead ball, near-maximal effort (>90% of maximal effort)
  - Rotational power: 67% to 85% of 1RM
  - Strength: Body weight and weighted vest
- Repetition tempo
  - Plyometrics: Maximal effort
  - Rotational Power: Maximal effort
  - Strength: Controlled 3/1/2
- Training frequency
  - Two or three times per week
- Training duration
  - 60 minutes
  - 3 to 4 weeks
- Training volume
  - Plyometrics: 16 to 36 repetitions per exercise
  - Rotational power: 9 to 60 repetitions per exercise
  - Strength: 1 to 24 repetitions per exercise
- Specific exercises used in the training
  - Plyometrics
    - Bounding
    - 90°, 180° jumping exercise
    - Lateral bounding with resistance

FIGURE 9-21. Medicine ball rotational throw.

- Lateral bounding progression
- Box jumps
- Medicine ball squat thrust
- Medicine ball slam
- Medicine ball rotational throw (Figure 9-21)
- 90°/90° wall plyometrics
- Straight-arm ball dribbling on wall
- Medicine ball squat to rotational chest pass
- Medicine ball sit-up overhead throw
- Reaction/response training
- Rotational power
  - Squat to rotational press (Figure 9-22)
  - Rotational row (Figure 9-23)
  - Rotational push–pull
  - Rotational snatch
  - Explosive torso-and-hip rotation
  - Chop and lift
- Strength
  - Single-leg squat
  - Mini band lateral walk

FIGURE 9-22. Squat-to-rotational press.

FIGURE 9-23. Rotational throw.

- Single-leg Romanian dead lift
- Walking lunge with mini band rotation
- Triplanar lunge
- Pull-down
- Pushup
- Wrist extension and flexion
- Wrist pronation and supination
- Plank
- Side plank
- Quadruped thoracic rotation
- Hip airplane
- Wall slide stretch

Application of Chronic Training Variables

- During this phase of training, plyometrics are included in order to utilize the stretch-shortening cycle so that force production can be maximized. The typical focus in tennis is the development and transfer of lower-body power to upper-body rotational strength and stability. In this training phase, emphasis is placed on development of rotary power. The force delivered to the tennis ball from the tennis racket will be evenly distributed throughout the kinetic chain when rotational sequencing becomes more efficient. Additionally, stabilization exercises will complement the power movements and build the neuromuscular control required in tennis.

Phase III: Sport-Specific Training

Periodization

- Linear
- Macrocycles
- Mesocycles
- Microcycles

Program Design and Performance Training Program

Sport-Specific Concepts of Integrated Training

- Training continuum
- Flexibility and joint mobility for joint stability
- Training with optimum posture
- Sensorimotor and balance training
- Core training
- Cardiorespiratory training
- Multiplanar training activities
- Training for optimum muscle balance
- Training for optimum muscle functional strength
- Training for optimum muscle functional power
- Neuromuscular dynamic stability exercises
- Training for SAQ
- Plyometric training
- Functional training
- Sport-specific training

Training Principles Used in the Design of the Program

- Principle of progression
- Principle of overload
- Principle of variation
- Principle of individualization
- Principles of specificity: SAID

Application of Acute Training Variables

- Repetitions
  - Sport-specific agility: 8 to 20 repetitions
- Sets
  - Three or four sets
- Rest interval
  - 1:4 work-to-rest ratio
- Intensity
  - Maximal effort
- Training frequency
  - Two or three times per week
- Training duration
  - 60 to 90 minutes
  - 3 to 4 weeks
- Training volume
  - 24 to 80 repetitions per exercise
- Specific exercises used in the training
  - Medicine ball ground strokes
  - Lateral intervals
  - Linear intervals
  - Multidirectional intervals
  - Side shuffle
  - Crossover
  - Backpedal

Application of Chronic Training Variables

- In order to simulate the feeling of playing a match, sport-specific training will take place on the tennis court. Interval training should be implemented in order to exhaust the anaerobic system. As training progresses, rest time may be shortened to increase the conditioning

of the athlete. During this phase, the focus should be on improving response time, footwork, lateral speed, and overall conditioning.

Sports Performance Testing

General Information

- General history
- Subjective questionnaires
- Medical history
- Sports injury history
- Surgical history
- Chronic conditions and/or medications

Objective tests

- Physiological assessments
  - Lactate
    - Before, during, and after training
  - Heart rate
    - Throughout training
  - Rate of perceived exertion
    - Immediately after interval training
- Body composition tests: Body composition can be measured by using hydrostatic weighing, whole-body plethysmography (BOD POD), dual X-ray absorptiometry scan, or skin-fold measurements.
  - Preseason
  - End of preseason
  - Periodically through competition
- Static and dynamic postural assessments. Static posture can be assessed with the use of an AlignaBod (Dallas, TX) or a gridline, and dynamic posture can be observed on the tennis court by a coach.
  - Through preseason and competition
- Movement performance testing
  - Functional Movement Screen (FMS): The FMS is a great tool to use for looking at the athlete's overall movement strategy. It is a quick and easy way to screen the athlete for faulty movement patterns that potentially could lead to injury.
    - Periodically through preseason
  - Single-leg squat
    - Periodically through preseason
- Sport-specific testing: A tennis coach performs this type of testing by observing the overall form in real time or on two-dimensional videotape analysis.
  - Stroke analysis
    - Periodically through preseason and competition
  - Serve velocity
    - Periodically through preseason and competition
  - Ground stroke velocity
    - Periodically through preseason and competition

Specific Criteria for Progression to the Next Stage to Determine Readiness for Tennis

- The athlete is pain-free through all movements with symmetrical range of motion.
- Athlete has achieved increases in load, intensity, and volume and shows a strong adaptation to the current training phase.

Specific Criteria for Release to Unsupervised Complete Participation in Tennis

- There is no pain or tenderness in the affected area.
- The athlete presents symmetrical strength and range of motion through all strokes and can maintain adequate strength and symmetry as he or she fatigues.
- The athlete displays strong scapular and wrist stability and maintains proper form throughout a full match. Both can be observed and assessed by a skilled coach as the player transitions back to a full match.

Recommended Ongoing Exercises

- Wrist extension
- Wrist flexion
- Ball dribbling on wall
- Plank
- Side plank
- External rotation
- Internal rotation
- Prone T and Y
- Serratus punch

Evidence

Ellenbecker TS, Pluim B, Vivier SV, et al: Common injuries in tennis players: exercises to address muscular imbalances and reduce injury risk. *Strength Cond J*. 31:50–58, 2009.

This article explains common injuries presented in tennis and the muscle imbalances that may cause these injuries. Specific exercises are suggested to restore balance and improve performance and prevent injury.

Fernandez-Fernandez J, Sanz-Rivas D, Mendez-Villanueva A: A review of the activity profile and physiological demands of tennis match play. *Strength Cond J*. 31:15–26, 2009.

This review gives insight into the physical demands of a competitive tennis match. It also provides information that will help strength and conditioning coaches implement training protocols to improve performance.

Kovacs MS: Movement for tennis: the importance of lateral training. *Strength Cond J*. 31:77–85, 2009.

Tennis involves many different movement changes throughout a match with an emphasis on lateral movement. This article explains the importance of lateral movement training and offers exercises that train the lateral movements specific to tennis.

Kovacs MS: Tennis physiology: training the competitive athlete. *Sports Med* 37:189–198, 2007.

This article outlines the physiological changes that have occurred through the evolution of tennis. It illustrates how these physiological changes affect the way tennis performance and injury prevention programs are designed and implemented.

Lorenz DS, Reiman MP, Walker JC: Periodization: current review and suggested implementation for athletic rehabilitation. *Sports Health*. 2:509–518, 2010.

The authors review of 91 articles related to periodization, methods of periodization, and periodization program outcomes. They conclude that despite the evidence in the strength training literature supporting periodization programs, there is a considerable lack of data in the rehabilitation literature about program design and successful implementation of periodization in rehabilitation programs.

Roetart EP, Ellenbecker TS, Reid M: Biomechanics of the tennis serve: implications for strength training. *Strength Cond J*. 31: 35–40, 2009.

In this review, the authors discuss the biomechanics of the tennis serve and offer specific training exercises to optimize performance.

Roetart EP, Kovacs M, Knudson D, et al: Biomechanics of the tennis groundstrokes: implications for strength training. *Strength Cond J*. 31:41–49, 2009.

This article summarized recent research related to the biomechanics of tennis technique in groundstrokes and offers specific strength and conditioning exercises to improve performance and prevent injury.

Wakeham TR, Jacobs R: Preseason strength and conditioning for collegiate tennis players. *Strength Cond J*. 31:86–93, 2009.

In this article, the authors outline the requirements of tennis and how to achieve these outcomes by adhering to an annual plan consisting of different phases. The authors' objective is to review off-season strength and power training as well as preseason general and sport-specific conditioning.

Multiple-Choice Questions

QUESTION 1. Which of the following is the appropriate intensity for an athlete in the endurance phase of strength and conditioning program?

A. 60% to 67% of 1 RM
B. 85% to 95% of 1 RM
C. 75% to 85% of 1 RM
D. 10% of body weight

QUESTION 2. Which of the following is the result when rotational sequencing becomes more efficient?

A. Loss of energy transfer
B. Increase in upper-body dominance
C. Even force distribution through kinetic chain
D. Decrease in racket velocity

QUESTION 3. Which of the following is an example of a rotational power exercise?

A. Snatch
B. Chop and lift
C. Power clean
D. Side Plank

QUESTION 4. If an athlete continues to participate in tennis, which of the following exercises should he or she do indefinitely?

A. Pull-over
B. Ball-dribbling on wall
C. Snatch
D. Push press

QUESTION 5. In Phase I of strength and conditioning, which of the following is the correct order of mesocycles?

A. Sport-specific, endurance, power, strength
B. Strength, endurance, power, sport-specific
C. Endurance, hypertrophy, strength, power
D. Hypertrophy, endurance, strength, power

Answer Key

QUESTION 1. Correct answer: **A** (see Phase I)

QUESTION 2. Correct answer: **C** (see Phase II, Chronic training variables applied)

QUESTION 3. Correct answer: **B** (see Phase II, Specific exercises used)

QUESTION 4. Correct answer: **B** (see Phase III, Exercises to continue)

QUESTION 5. Correct answer: **C** (see Phase I, Training variables)

NONOPERATIVE REHABILITATION OF GOLFER'S ELBOW

Steven Michael Scher, MSPT, ATC, CSC, PES, TPI, Stacie Christine Graves, MS, PA-C, Beth E. Richardson, DPT, and Kyle Anderson, MD

GUIDING PRINCIPLES OF NONOPERATIVE REHABILITATION

- Minimize pain and edema
- Minimize formation of scar tissue
- Restore range of motion (ROM) and strength of both wrist and elbow
- Treat and correct areas of compensatory motions and restrictions and impairments above and below the elbow
- Increase strength to fair to good in wrist, elbow, and shoulder
- Full participation in sport without residual pain

Phase I (weeks 2 to 4)

Goals

- Reduce pain and edema
- Reduce the load and pull demands on the medial epicondyle
- Restore pain-free ROM to passive ROM (PROM) between 90° flexion and 80° extension of the wrist with cessation at comfortable stretch
- Minimize excessive loads and pull demands at the elbow by bracing at the wrist during the day and splinting at night
- Active rest

Protection

- Temporary cessation of the offending activity is often required, but immobilization or inactivity is not recommended because of the possibility of disuse atrophy or elbow stiffness.
- Icing for 20 minutes three to four times daily should be the first-line antiinflammatory treatment.
- Oral nonsteroidal antiinflammatory medications (NSAIDs) may be helpful for analgesia; however, because medial epicondylitis is a degenerative rather than an inflammatory process, the benefit of NSAIDs is debatable.
- Physical therapy modalities such as ultrasound, electrical stimulation, and iontophoresis can be useful for relieving pain due to medial epicondylitis.
- Counterforce bracing may be beneficial for pain in activities of daily living and also for return to sport.
- Compression neuropathies of the anterior interosseous nerve and posterior interosseous nerve have been reported with use of these braces; therefore, patients should be made aware of the risks, and instruction in proper application should be given.

Techniques for Progressive Increase in Range of Motion

Manual Therapy Techniques

- Functional massage to the involved wrist, forearm, and/or shoulder
- Astym (regenerative medicine therapy for the stimulation and regeneration of damaged tissues and resorption of fibrosis) to the affected upper extremity (UE), followed by soft-tissue mobilization/massage (STM) and manual stretches
- Grade II joint mobilization for pain or grade III joint mobilization at the wrist, carpals (improve wrist flexion/extension), and proximal or distal radial/ulnar joints (forearm pronation/supination) as restrictions are noted
- Mobilization with motion (MWM) for restrictions and/or pain during wrist flexion and/or extension as well as at the elbow.
- Because forces produced by the wrist flexor muscles affect the attachment point at the tendons, which have a small cross-sectional area, these muscles are vulnerable to injury if high and sustained forces are repetitively applied, such as during the golf swing.
- Given the decreased blood supply to the area of insertion, there is a slower healing time. This should be addressed during the rehabilitation process with any of the aforementioned manual and soft-tissue techniques as appropriate.
- The body regenerates connective tissue largely as a result of an inflammatory response consisting of three main phases (inflammation, proliferation, and remodeling), which begins with the release of inflammatory mediators and ends with remodeling of the repaired tissue.
- During maturation, the injured tissue is reshaped and strengthened by internal and external mechanical stress applied to the tissue. If left to immobilization secondary to pain, those tissues will rearrange in unorganized bundles oriented in various directions and not necessarily in the direction of the original, normally functioning tissue. Therefore, the body needs a stimulus for regeneration and also needs to be subjected to normal stresses using appropriate movement patterns for the given tissues, as with functional massage and a specific and individualized exercise program.
- Cross-friction massage (CFM) and other types of STM may assist in preventing adhesion formation and mobilize the cross-links between the collagen fibers, stimulating the regeneration phases at a localized region (wrist flexor origin)
  - Functional massage is a biomechanical soft-tissue technique that combines conventional massage and stretching. This is an appropriate technique to utilize following Astym or CFM followed by a specific and

FIGURE 9-24. Kinesiotaping for wrist flexor inhibition with fascial correction.

individualized exercise program for appropriate loading and tissue regeneration.
  - Neural mobilization: Median, ulnar, or radial as noted. Typically, however, ulnar nerve restriction and involvement occur due to the location in the ulnar groove, near the medial epicondyle.
  - Kinesiotaping (KT) for wrist flexor inhibition with fascial correction and/or space correction to decompress the tissues around the medial epicondyle (Figure 9-24)
- KT is a popular taping method that can gather and align the fascia into its desired position and lift the skin over areas of inflammation, pain, and edema, which then decreases the pressure over the lymphatic channels to provide a path for removal of exudates and provides a positional stimulus to the skin by activating mechanoreceptors to either stimulate or limit movement. Kinesiotape is an elastic tape that does not necessarily restrict muscular or blood flow movements as conventional athletic tape does.
- Modalities: Pulsed ultrasound (US), ice massage, or cold pack (Game Ready, a cold pack with compression; CoolSystems, Concord, California) to the tissues around the medial epicondyle, and H-wave therapy to increase blood flow, decrease muscle spasms, and/or decrease chronic intractable pain
  - H-wave utilizes electrodes around a specific area to activate muscles and can be used at a low frequency to promote local circulation around the medial epicondyle or at a high frequency for pain control.
- Interferential current for pain control

Stretching and Flexibility Techniques for the Musculotendinous Unit

Wrist flexor and other appropriate stretches
- Myofascial release (MFR): Mini foam self-rolling to affected forearm
- Trunk rotation stretches (Figures 9-25 and 9-26)
- Upper trapezius, pectoral, or hip stretches as limitations are noted, such as hip external and internal rotation, prone quadriceps length, and hip flexor ROM

Other Therapeutic Exercises

- Initiate HEP (home exercise program): Self-stretches as limitations are noted with gentle stretching of wrist flexors, active ROM (AROM), and closed kinetic chain (CKC) exercises

TIMELINE 9-4: **Rehabilitation Timeline for Medial Epicondylitis (Golfer's Elbow)**

PHASE I (weeks 1 to 4)
- Brace for wrist stabilization during day and positional night splinting
- PT modalities for pain and edema: H-wave, ultrasound, Hivolt, interferential current, ice 15 to 20 min
- Rest with complete cessation of wrist and elbow stress–related activities
- PROM and AROM of hand and wrist
- Joint and neural mobilization as appropriate
- Upper-body ergometer for ROM stimulus
- Soft-tissue techniques: Astym, functional massage, CFM
- Kinesiotaping for muscle inhibition and pain relief (space correction)
- Oral NSAIDs administered (10–14-d course)
- Consider local cortisone injection
- Stretching program including MFR mini-foam-rolling, trunk rotation stretches, upper trapezius, pectoral, or hip stretches as limitations are noted
- Sensorimotor and kinesthesia: Ball draw, supine alphabet for scapular stabilization
- Activation of wrist flexor and extensor mass, biceps and triceps, abdominal obliques, erector spinae muscles, gluteals
- Mobilization, submaximal isometrics for wrist
- Strengthening of shoulder and trunk
- Sensorimotor and kinesthesia
- Closed chain kinetics: Thera-Band wall two-point weight-bearing, straight-arm diagonals

PHASE II (weeks 4 to 6)
- Initiate pain-free wrist and elbow AROM
- Continue modalities for pain and inflammation control
- Astym and functional massage as appropriate
- Wrist isometrics: Increased resistance and repetitions
- Exercises performed in elbow flexion to minimize load on muscles
- D/C splint and bracing
- Gripping and pronation–supination exercises
- Shoulder program: IR, ER, low rows, and alternate rows, half-roll Thera-Band shoulder horizontal abduction, and PNF D2 pattern with the wrist in neutral
- Closed chain activities: Four-point BOSU rocks, fingertip pushups, walk out on Swiss ball with pushups with a plus, seated on Swiss ball, straight-arm trunk rotation with unilateral knee extension
- Plyometrics: Wrist flips with plyoball, wall dribble, IR rebounder eccentric loading

FIGURE 9-25. Sidelying trunk rotation, hips and knees 90° internal and 90° external.

FIGURE 9-26. Prayer stretch "thread the needle" arm reach-through.

- Wrist isometrics and progressive resisted exercises (PREs) as tolerated
- Power grip web
- Gripping and pronation–supination with power bar and/or towel roll
- Pronation–supination with weight
- Upper-body ergometer for upper-body ROM stimulus
- Shoulder isometrics: External rotation, internal rotation, extension, and abduction

Activation of Primary Muscles Involved

- Wrist flexor mass: The flexor carpi radialis and pronator teres at the insertion of the medial epicondyle are most likely to be involved, owing to the noted consistent burst of activity during the contact phase[1]
  - Occasionally, involvement of the flexor carpi ulnaris and flexor digitorum superficialis may be found. This may be due to the findings of a study on which electrode electromyography (EMG) recordings of the flexor muscles from symptomatic players are of greater magnitude during other phases of the golf swing, showing biomechanical differences between symptomatic and asymptomatic players.[1]
- Wrist extensor mass, because both wrist flexor and extensor muscles play a role in stabilization of the club during the contact phase
- Biceps and triceps

Activation of secondary muscle groups

- Abdominal obliques and erector spinae muscles show significant activity during the forward swing phase.[2]
- Shoulder ER/IR, scapula stabilizers, and abductors during backswing and follow-through

TIMELINE 9-4: **Rehabilitation Timeline for Medial Epicondylitis (Golfer's Elbow)** (Continued)

PHASE III (weeks 6 to 8)	PHASE IV (weeks 8 to 12)
• Full AROM restored • Continue modalities and soft-tissue techniques when necessary • Continue with scapular and core program: Half-roll alternating SASH series, upper-extremity step-ups, walk out on ball with fishtail • Neurodynamic stability, plyometrics and functional sport-specific exercises: Standing torso twists with partner, medicine ball pass, medicine ball tosses with release at deceleration/impact position, transverse plane lunges, single-leg balance, Thera-Band to golf swing impact position	• Goals: Return to sport using a functional exercise program and ensure independence with HEP • Continue with previous stretching, including thoracic rotation stretches • Sport-specific training: Single-leg reaches on half-foam roll and with one-arm row (woodpecker), single-leg PNF standing with 4- or 5-lb kettle ball, two-handed torso rotation kneeling on Swiss ball • Impact program for UE/elbow/wrist: Seated boat toss with medicine ball, four-point plank ball roll side to side • Address equipment issues to reduce stress on medial elbow

FIGURE 9-27. Standing ball draw (clockwise, counterclockwise, side to side, superior/inferior).

- Gluteals, especially the high activity of the gluteus maximus, is noted during the forward swing and initiation of power into the acceleration phase and hip abductors to stabilize the pelvis as that weight-shift occurs.[2]

Sensorimotor Exercises

- Ball draw: Straight arm, open palm: small superior/inferior and circles: clockwise/counterclockwise (CW/CCW) (Figure 9-27)
- Supine alphabet with or without weighted ball for scapular stabilization during UE activity

Closed Kinetic Chain Exercises

- Standing weight shifts on table and/or wall pushups
- Prone weight-shift/walk-out on therapeutic ball to tolerance
- Thera-Band (TB) around both arms and straight-arm star pattern reaches

Milestones for Progression to the Next Phase

- Full, pain-free AROM and PROM at the wrist
- Pain during palpation of the medial epicondyle reduced by 50%
- Elimination of edema: girth measurement compared to involved side

Phase II (weeks 4 to 8)

- Upon relief of symptoms, Phase II is initiated and a guided rehabilitation program is started.
- Stretches for the wrist and elbow are initiated, followed by progressive isometric exercises.
- Gradual progression to more resistive exercises and increasing duration results in resumption of sport.
- It is crucial to instruct the athlete to maintain a flexibility and strengthening program to reduce the possibility of reinjury.
- Injected corticosteroids have been shown to improve symptoms in the short term, but have not been proven efficacious in the long term. Stahl et al. reported significantly less pain at 6 weeks but no significant difference in pain scores compared with the placebo group at 3 months and 1 year follow-up examinations.[3] These may have a role in management between Phases I and II, but their use is controversial.

Goals

- Restore active assisted ROM and AROM
- Pain-free during palpation of the medial epicondyle and flexor muscle mass
- Improve strength
- Address and correct kinetic chain deficits to prevent future injury

Techniques for Progressive Increase in Range of Motion

Manual Therapy Techniques

- Functional massage per prior phase
- Joint mobilization and mobilization with motion

Soft-Tissue Techniques

- MFR skin-rolling
- MFR mini-roll as previously shown
- Continue with Astym as appropriate
- Modalities per Phase I

Other Therapeutic Exercises

2 sets, 10 repetitions each
- Anterior hip capsule and psoas stretching (3 × 30 seconds each)
- Wrist dumbbell series: 2 or 3 lb, 2 × 10 seconds each; increase weight as appropriate
  - Wrist flexion, extension, supination, pronation
- Wrist straight-arm TB: Straight-arm pull-downs/shoulder extension, rows, alternating rows, shoulder IR/ER
- Half-roll TB with shoulder in horizontal abduction, proprioceptive neuromuscular facilitation (PNF) D2 flexion with wrist in neutral (Figure 9-28)
- Four-way weighted-ball pass to partner (seated on Swiss ball): 2 × 10 in each direction
- For other components of kinematic chain, anterior hip capsule and psoas stretching: 3 × 30 seconds each

Open and Closed Kinetic Chain Exercises

2 sets, 10 repetitions each
- Four-point BOSU rocks (no side-to-side)
- Fingertip pushups
- Walk out on ball with pushup plus scapular protraction

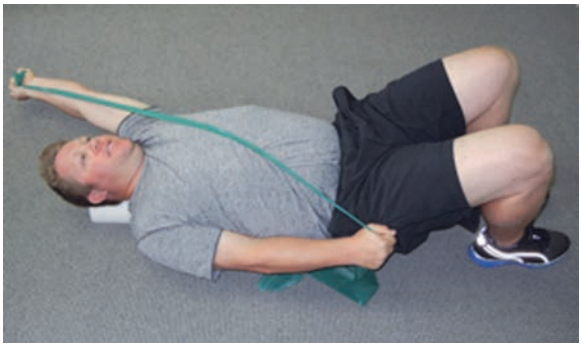

FIGURE 9-28. Half-roll supine Thera-Band shoulder PNF D2.

- Seated on Swiss ball, straight-arm trunk rotation with unilateral knee extension (Figure 9-29)

Plyometrics

2 sets, 10 repetitions each
- Wrist flips with plyoball (Figure 9-30)
- Wall dribble
- IR rebounder eccentric loading

Milestones for Progression to the Next Phase

- Full, pain-free AROM (especially gripping)
- Minimal to zero pain during palpation at the medial epicondyle
- Able to tolerate manual resistance testing of the wrist flexors
- Able to tolerate gripping objects and resisted supination/pronation

Phase III (weeks 6 to 8)

- Initial guidelines: ROM performed pain-free with zero pain at end-range wrist flexion and extension, zero tenderness over the medial epicondyle with stretching or resistance of the wrist flexor muscle group

FIGURE 9-29. Seated Swiss ball straight trunk rotation with unilateral knee extension.

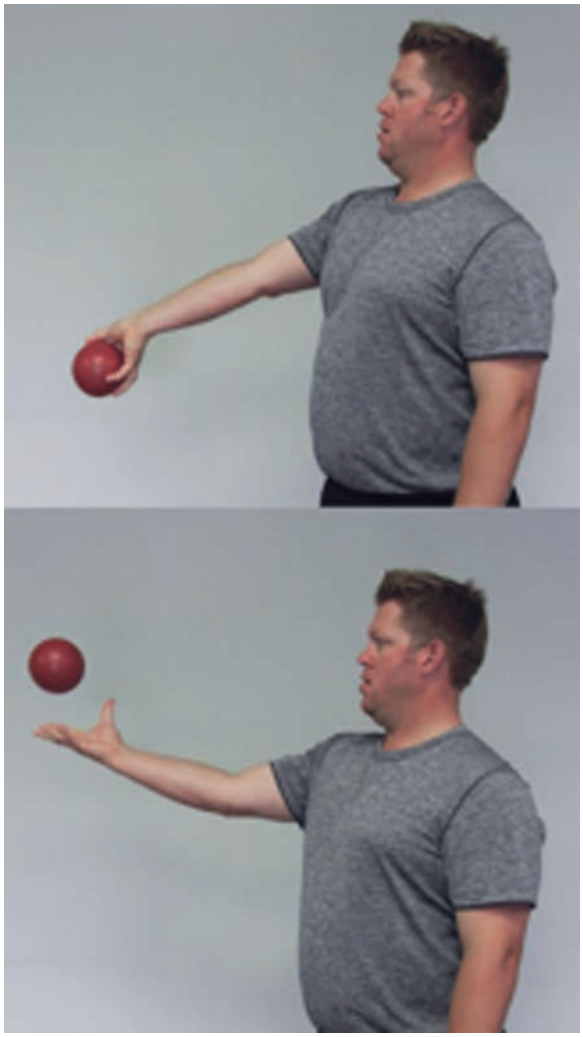

FIGURE 9-30. Wrist flips with plyoball.

Techniques for Progressive Increase in Range of Motion

Manual Therapy Techniques

- Functional massage and joint mobilization per prior phase as appropriate

Soft-Tissue Techniques

- Continue Astym as appropriate

Stretching and Flexibility Techniques for the Musculotendinous Unit

Backswing
- Hip ER walk 3×20 feet, side-stepping with feet outward
- Hamstring stretches, 3 × 30 seconds
- Hip swings ×30
- Latissimus dorsi stretch with hip ER 3 × 30 seconds (Figure 9-31)

Other Therapeutic Exercises

3 sets, 12 repetitions each
- Wrist pulses (fast twitches flexion and extension) with TB

FIGURE 9-31. Standing Latissimus dorsi and hip external rotation combination stretch.

- Wrist eccentrics: Start with 2 or 3 lb and increase 1 lb at a time as appropriate
- Bucket dig: 5-lb bucket filled with long grain rice, pronate/supinate to bottom of bucket ×10
- Pull the curtain (wrist flexion): TB wrist flexion
- Half-roll SASH, a/k/a PNF D1/D2 series, three-way (Figure 9-32)

Open and Closed Kinetic Chain Exercises

- UE step-ups
- Walk out on ball with fishtail (prone on ball bilateral lower extremities move side-to-side on ball)

FIGURE 9-32. Half-roll SASH series.

- Alternating rows with alternating staggered stance position

Techniques to Increase Muscle Strength, Power, and Endurance

- See "Other Therapeutic Exercises" in this phase

Neuromuscular Dynamic Stability Exercises

3 sets, 12 repetitions each
- Four-point foam wrist-rolling
- Bodyblade wrist flicks
- Bodyblade shoulder three-way: sagittal and frontal

Plyometrics

Three sets, 12 repetitions each
- Chest pass, over head, side-to-side
- Hay toss: Stride stance throwing a weighted ball from one side of the body to the other
- Standing torso twists with partner and medicine ball pass
- Medicine ball toss with release at deceleration/impact position (Figure 9-33)

Functional Exercises

- Transverse plane lunges with supination to pronation bar
- Single-leg balance Thera-Band to golf ball impact position (Figure 9-34)
- Single-leg balance TB pulses at golf ball impact position (Figure 9-35)

Milestones for Progression to the Next Phase

- Good overhead squat performed with zero or minimal heel raise; overhead squat shows overall functional strength
- Can hold single-leg stance with eyes closed for 10 seconds. Golf swing is needed with single-leg balance in both legs, from backswing to finish.
- 4/5 strength manual muscle testing: Wrist flexion/extension and elbow flexion/extension

FIGURE 9-33. Medicine ball tosses (release at golf ball impact position).

FIGURE 9-34. Single-leg balance Thera-Band to golf ball impact position.

Phase IV (weeks 8 to 12)

Goals

- Full AROM and end-range stretching of the wrist in all directions tolerated without pain
- Pain-free loading of wrist flexors during multiple repetitions
- Initiate eccentric loading and begin sport training

Techniques for Progressive Increase in Range of Motion

Stretching and Flexibility Techniques for the Musculotendinous Unit

Three times for 30 seconds each
- Thoracic rotation stretches: Prayer position reach through and sidelying with hips and knees at 90° IR and 90° ER
- Continue with previous stretches

FIGURE 9-35. Single-leg balance Thera-Band pulses (club or stick oscillation).

Other Therapeutic Exercises

CKC: 3 sets, 15 repetitions each
- Four-point plank pass of ball to each UE
- Single-leg balance: One-arm rebounder throw
- Stool prone wrist pulls and pushes
- Four-point plank ball roll side-to-side

Open and Closed Kinetic Chain Exercises

- Stool-walk, forward and backward propelled heel drives to move the stool, three times at 20 feet
- Bridge-walk over cones and hurdles, three times at 20 feet

Neuromuscular Dynamic Stability Exercises

- Single-leg reaches on a one-half foam roll: Multidirectional

Plyometrics

Three sets, 15 repetitions
- Seated boat position (seated long-sitting with B legs flexed off the ground) toss with medicine ball (Figure 9-36)

Functional Exercises

Three sets, 15 repetitions
- Single-leg PNF standing with 4- or 5-lb kettle ball

Sport-Specific Exercises

Three sets, 15 repetitions
- Pelvic tilts in golf posture on Bosu
- Two-handed torso rotation while kneeling on Swiss ball (Figure 9-37)

Milestones for Progression to Advanced Sport-Specific Training and Conditioning

- 4+/5 manual muscle test for strength of major muscle groups

FIGURE 9-36. Seated boat toss with medicine ball.

FIGURE 9-37. Kneeling on Swiss ball with two-handed torso rotation.

- Ability to load the elbow joint with wrist flexors activated, ability to lift 5 lb or more while keeping elbow flexed and extended.
- Absorbing impact position, the ability to swing a golf club and hit the ground or ball with no pain
- Ability to use the core to provide good energy transfer to the UE, complete planks series (prone plank, side plank, supine plank)

Criteria for Abandoning Nonoperative Treatment and Proceeding to Surgery or More Intensive Intervention

- Failed conservative management for a minimum of 3 to 6 months
- Poor progression in rehabilitation along with tendon avulsion or tear seen on magnetic resonance imaging scan in a high-demand athlete
- Continued or worsening objective changes, such as swelling, atrophy, and weakness
- Pain persisting past Phase III or interference with daily activities or sleep

Tips and Guidelines for Transitioning to Performance Enhancement

- Once rehabilitation is complete and the athlete is back to preinjury status, begin to evaluate the athlete's sport-specific demands
- Begin with a fitness examination with the goal of maximizing athletic potential. Prior medical history and injury history are ideal bases for developing a training program for the athlete.
- Posture and body mechanics are important to determining whether the athlete needs basic correction of alignment before performance training.
- The fitness examination or dynamic movement analysis allows determines if the athlete can move and perform according to the physical demands of the sport (Functional Movement Screen score of 14 or better).
- Correcting the athlete's imbalances will allow proper training and avoid injury. This means that the key is optimal body movement without weight before weight or resistance is added.
- Prevention of injuries and proper posture throughout movement-specific tasks allows the stage to be set for performance training.
- The goal is functional training—multiplanar movement involving acceleration, deceleration, and stabilization.

Performance Enhancement and Beyond Rehabilitation: Training/Trainer and Optimization of Athletic Performance

- Typically, the golf swing is described as a pendulum with the shoulders and arms taken as a single, rigid unit hinged to the golfer's body or trunk and the golf club hinged at the wrists and hands.
- It has been noted that the downswing motion can be initiated at the legs and hip muscles, followed by the upper-body muscles, and that the trunk is the body segment that connects the legs to the arms.[4] This supports the concept that trunk rotation, hip torque, and weight transfer provide the force and torque to the shoulders and arms.
- EMG-based studies have shown high levels of gluteus maximus and hip stabilizer activity as well as high erector spinae and abdominal oblique activity during certain phases of the golf swing.[2] Therefore, simple physics can connect the kinetic chain during a golf swing to address forces that the elbow sustains as a result of inadequacies or limitations (ROM, strength and/or neuromuscular control) at the hip, trunk, and shoulder. This is the rationale behind optimizing athletic performance and avoiding future injury during the rehabilitation process by addressing hip, trunk, shoulder, elbow, and wrist strength; AROM; and neuromuscular control.
- The stored power accumulated during the backswing is applied to the golf ball at impact in a specific and sequential order:
  - Uncocking of the left wrist at release, followed by straightening of the right arm, thus applying forces at the right arm
  - Rolling of the hands to maintain rhythm, followed by contact of the upper left arm, thus adding the force of the rotating trunk
- A good golf swing has been noted to apply almost no torque to the grip of the club. Furthermore, those with injuries have been shown to be clinically weaker and less mobile than asymptomatic golfers.[5] Therefore, appropriate wrist strength and control for stabilization during impact could prevent premature wrist flexor muscle activation, saving it for the flexor burst that typically occurs at ball impact to counter the energy transference (equal and opposite reaction), as seen in asymptomatic golfers.[1] This may assist in protecting

the tendon attachment site at the medial, and occasionally lateral, epicondyles.

Specific Criteria for Return to Sports Participation: Tests and Measurements

- Athlete is pain-free
- No swelling or edema
- Full active ROM compared to opposite side
- Athlete has within 80% strength (manual muscle-testing) compared to opposite side
- Perform proper movement patterns during sport specific activities
- The ability to load body weight through the upper extremities and complete pushup

Evidence

Cahalan TD, Cooney WP, 3rd, Tamai K, et al: Biomechanics of the golf swing in players with pathologic conditions of the forearm, wrist, and hand. *Am J Sports Med* 19:288–293, 1991.

Twenty subjects with a variety of upper-extremity disorders participated in the study to quantitate wrist motion and club head and ball impact force in a controlled environment. Although it was understandable that the involved group was clinically weaker, it was noted that they used more motion during their swings. This may have been due to the theory that the motion required for a full swing may stress the wrist beyond its limits, and, due to the weakness, they may not be able to resist the forces the wrist endures, allowing excessive motion. Therefore, good concentric and eccentric control, as well as mobility and strength, in not only the wrist but also the kinetic chain may be necessary to avoid injury. (Level II evidence).

Glazebrook MA, Curwin S, Islam MN, et al: Medial epicondylitis: an electromyographic analysis and an investigation of intervention strategies. *Am J Sports Med* 22:674–679, 1994.

An EMG study performed to compare the amount and/or timing of muscle activity in the common flexor and extensor muscles during the golf swing of symptomatic and asymptomatic subjects of low and high golf-scoring ability. Although the study did find biomechanical alterations when subjects used a club with an enlarged grip, it did show that both groups utilize significant amounts of flexor muscle activity during the contact phase, with higher amounts in the symptomatic group. This may indicate that more muscles of that group are utilized more often and therefore could cause damage to more muscles in the flexor group. (Level II evidence).

Gosheger G, Liem D, Ludwig K, et al: Injuries and overuse syndromes in golf. *Am J Sports Med* 31:438–443, 2003.

An epidemiologic study of 24 randomly selected golfers to uncover associations in age, sex, body mass index, warm-up routines, and playing-level data with occurrence of reported injuries. It was discovered that 82.6% of reported injuries involved overuse with typical injuries in the back, wrist, and shoulder, providing further support for the inclusion of hip, back, shoulder, and wrist in a good rehabilitation program. (Level III evidence).

Okuda I, Gribble P, Armstrong C: Trunk rotation and weight transfer patterns between skilled and low skilled golfers. *J Sports Sci Med* 9:127–133, 2010.

The full-shot golf swings of 13 skilled golfers and 17 low-skilled golfers were studied via three-dimensional videography and force plates to examine trunk rotational patterns and weight transfer patterns between skilled and low-skilled golfers. It was shown that skilled golfers had significantly less upper trunk horizontal rotation, which was explained with the notion that it may have been due to purposeful eccentric control earlier in the swing to transfer momentum to either the club or the distal body. This provides support for addressing trunk mobility, neuromuscular control, and strength of the hips, pelvis, and trunk during the rehabilitation process. (Level III evidence).

Stahl S, Kaufman T: The efficacy of an injection of steroids for medial epicondylitis: a prospective study of sixty elbows. *J Bone Joint Surg Am* 24:535–538, 1996.

A randomized, double-blind, prospective study in which the short-term and long-term effects of a local steroid injection to treat medial epicondylitis were analyzed. The investigators concluded that these injections offer only short-term relief of 6 weeks to 3 months. (Level II Evidence).

Watkins R, Uppal J, Pink M, et al: Dynamic electromyographic analysis of trunk musculature in professional golfers. *Am J Sports Med* 24:535–538, 1996.

A prospective study performed to uncover the high rate of back injury in golfers. Using EMG the muscle activity of bilateral abdominal obliques, gluteus maximus, erector spinae, and upper and lower rectus abdominal muscles was evaluated during various phases of the golf swing in 13 male professional golfers. The findings showed consistent patterns of trunk muscle activity throughout all phases of the golf swing, providing a basis for addressing deficits in those areas in a rehabilitation program. (Level III evidence).

Multiple-Choice Questions

QUESTION 1. Which one of the statements is correct about Phase I?

A. Protection of healing tissues
B. Rest
C. Pain-free PROM
D. All of the above

QUESTION 2. Which nerve is most involved and best for neural glides for treatment of golfers elbow?

A. Musculocutaneous
B. Axillary
C. Median
D. Ulnar

QUESTION 3. Which phase is best to start plyometrics?

A. Phase I
B. Phase II
C. Phase III
D. Phase IV

QUESTION 4. Which muscles are most appreciated in the diagnosis of medial elbow pain (golfer's elbow)? (Circle all that apply)

A. Flexor carpi ulnaris
B. Pronator teres
C. Flexor carpi radialis
D. Flexor digitorum

QUESTION 5. Please circle all that apply to the following statement: The manual techniques will help increase blood flow to the medial epicondyle.

A. Astym
B. Cross-friction massage
C. Functional massage
D. All of the above

Answer Key

QUESTION 1. Correct answer: **D** (Phase I)

QUESTION 2. Correct answer: **D** (Manual Therapy Techniques)

QUESTION 3. Correct answer: **C** (Phase III)

QUESTION 4. Correct answer: **A** and **B** (Phase I: Muscle Activation)

QUESTION 5. Correct answer: **D** (Manual Therapy Techniques)

BEYOND BASIC RECOVERY: RETURN TO GOLF AFTER TREATMENT FOR MEDIAL EPICONDYLITIS (GOLFER'S ELBOW)

Steven Michael Scher, MSPT, ATC, CSCS, PES, TPI, Stacie Christine Graves, MS, PA-C, Beth E. Richardson, DPT, and Kyle Anderson, MD

ASPECTS OF GOLF THAT REQUIRE SPECIAL ATTENTION IN REHABILITATION

- Although medial epicondylitis is termed "golfer's elbow," lateral epicondylitis is still more common in golfers.
- Golf club grip: Size of grips, position of hands, tension placed on club
- Proper swing mechanics: Medial elbow pain seen most often when golf club deviates from proper plane on the backswing, resulting in compensatory movements and injury
- Inflexibility or improper technique
- Even minor deviations in technique can be magnified with extreme overuse and practice regimens.

Phase I: Advanced Strength and Conditioning Programs (weeks 1 to 3)

- Preparation phase: correct movement pattern

Week 1

Flexibility/Warmup

- Arm circles
  - 50 big and 50 small
- Lunge walk to trunk rotation 3 × 30 ft
- High-step karaoke walk 3 × 30 ft
- Single-leg toe-touch reaches for hamstring ×10 each leg, hold stretch for 30 seconds each
- Stride lunge buddy latissimus dorsi stretch 3 × 30 seconds (Figure 9-38)

Joint Stability/Strength Program

- Rhythmic stabilization (RS)
  - Tubing shoulder horizontal adduction and abduction: Three times to fatigue
- Wall-draws on ball
  - Three times to fatigue (forward–back, side to side)
- Proprioceptive neuromuscular facilitation (PNF) chops seated on ball
  - 3 sets of 8
- Straight arm: Resisted Thera-Band (TB) one-handed supination to pronation (Figure 9-39)
  - TB/tubing: Three sets of eight

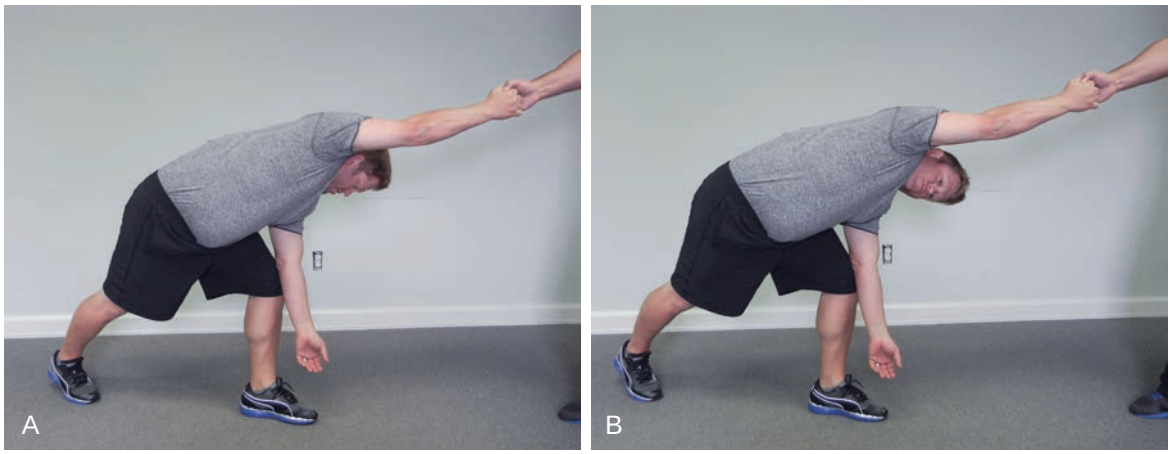

FIGURE 9-38. A, B, Stride lunge buddy latissimus dorsi stretch.

- Single-arm row (tubing/band/cable column)
  - Short arm, 3 sets of 10
  - Long arm, 3 sets of 10
- Prone Swiss ball (W, Y, and T): Lying flat, face down on ball, make W, Y, and T shapes with both arms. The exercise will start below body plane/top of ball, and each position will finish at body plane.
  - 3 × 10, arm weight
  - Proper upper- and lower-body form observed
- Body-weight squat: Overhead bar
  - Correct posture and form, 3 × 10
- Closed chain
  - BOSU rocks: Forward and back, side to side, three sets of eight
  - Pushup walk-up, 2-inch box, three sets of eight
- Trunk/core stabilization: Abdominal drawing-in maneuver (transverse abdominus)
  - Supine draw-in, three sets of eight (Figure 9-40)
  - Bridge draw-in, three sets of eight
  - Four-point/quadruped, three sets of eight
- Foam-rolling: Dynamic myofascial release/cool-down program
  - Hip external rotation (ER)/piriformis, gluteus (full pass on foam-roll from iliac crest to ischial tuberosity)
  - Iliotibial band (ITB) (Figure 9-41)
  - Rectus femoris
  - Hamstrings

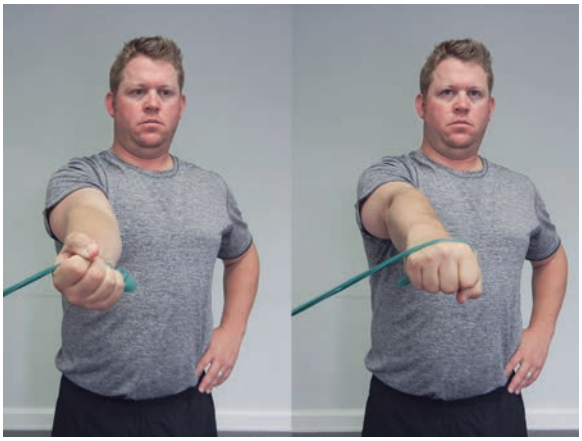

FIGURE 9-39. Straight-arm one-handed supination to pronation resisted Thera-Band.

Week 2

Flexibility/Warmup

- Arm circles
  - 50 big and 50 small
- Lunge walk to trunk rotation 3 × 30 ft

FIGURE 9-40. Supine draw-in (transverse abdominus muscle).

FIGURE 9-41. Iliotibial band foam-rolling (myofascial release).

- High-step karaoke walk 3 × 30 ft
- Latissimus dorsi stride-step buddy stretch, 3 × 30 seconds in stride step (reach and grasp hands of buddy (or golf cart)). To reference, the back leg is the same side of arm being stretched. Look under armpit of the stretched-out arm and simultaneously lean back.
- Single-leg toe-touch reaches for hamstring ×10 each leg, hold stretch for 30 seconds
- Foam-rolling: Dynamic myofascial release/cool-down program
  - Hip ER/piriformis, gluteus
  - Iliotibial band (ITB)

TIMELINE 9-5: **Rehabilitation of Medial Epicondylitis (Golfer's Elbow)**

PHASE I Preparation (weeks 1 to 3)

week 1

- Warmup: Arm circles, lunge walk to trunk rotation and high-step carioca 3 × 30 ft
- Flexibility/stretching and dynamic myofascial release
  - Stride lunge buddy latissimus dorsi stretch 3 × 30 s
  - Foam-rolling: Hip ER, piriformis, gluteal muscles, ITB, rectus femoris, hamstrings 3 × 30 s
- Joint stability and rhythmic stabilization: Wall-draws, PNF chops on ball, single-arm row, prone Swiss ball (W, T, Y), body weight squat: 3 sets of 10 repetitions

week 2

- Same warmup, flexibility, and foam-rolling as wk 1
- Joint stability and rhythmic stabilization: Wall-draws, tubing pulses with shoulder horizontal adduction and abduction six times to fatigue
- PNF chops on ball, single-arm row, prone Swiss ball (W, T, Y), body weight squat: 3 sets of 10 repetitions
- Hip rotation: Kneeling hip Thera-Band resisted rotation: IR and ER, 3 × 10
- Single-arm row: Short-arm and long-arm, 3 × 10 each
- Straight-arm supination to pronation, Thera-Band: 3 sets of 10
- Closed chain: BOSU rocks and pushup walk, 6-inch box, 3 sets of 10
- Trunk and core stabilization: Transverse abdominus draw-in, seated horizontal chops, standing single-leg chops/lawnmower: All for 3 sets of 10 repetitions

week 3

- Use prior warmup from wk 1 and 2 plus 15 upper body ergometer
- Foam-rolling, rhythmic stabilization, and wall-draws on ball
- Joint stability/strength: Tubing pulses, shoulder horizontal adduction and abduction, and wall-draws on ball: 8× to fatigue
- PNF chops seated on ball, add 3–5 lb, supination to pronation, single-arm row in opposite direction, single-leg balance short and long arm: 3 × 12
- Closed chain: BOSU rocks and pushup walk 6-in box: 3 × 12
- Trunk/core stabilization: Transverse abdominus, single-leg bridge draw-in, seated horizontal chops, standing single-leg chops/lawnmower, add 3–5 lb: All for 3 ×12
- Kneeling hip Thera-Band-resisted rotation, ER and IR: 3 × 12

PHASE II (weeks 4 to 6)

week 4

- Continue warmup and foam-rolling from preparation phase
- Dynamic trunk: Lunge walks, backward dive, supine-lying trunk twists, single-leg crossover latissimus stretches, hip flexor sleeper stretches
- Upper-extremity-specific: Dumbbell training with large grips performed in golf iron posture (supination and pronation, wrist extension and flexion, elbow flexion and extension): Three sets of eight repetitions with 5 lb
  - Bicep curl single-leg squats: 5–10 lb
  - X-outs with tubing, alternate arm, 3×8
  - Overload training with Bodyblade: Wrist 3× to fatigue
- Sensorimotor: Single-leg balance on foam pad with opposite Thera-Band hip abduction, 3 × 8
- Core training: Side plank series with windmill, ball bridge to alternate leg drop-off, both 3 × 8
- Torso rotations with lunge walk with 5-lb weighted ball, 3 × 8
- Plyometric: Trunk rotation development
  - Seated boat rotation, Russian twist, front twist throw, side throw, backward twist throw, all 3 × 8 with 5-lb weighted ball
- Multiplanar: Diagonal dumbbell press with squat and lunge, 3 × 8, 5-lb dumbbells
  - Transverse lunge with supination/pronation, 3 × 8 with 5-lb dumbbells

week 5

- Follow week 4, 3 × 10, increase weight by 3–5 lb per exercise

week 6

- Follow weeks 4 and 5, 3 × 10, increase weights by 3–5 lb per exercise

PHASE III (weeks 7 to 8)

week 7

- Two-handed powerball decelerations: Stop at impact position, start at impact position to follow-through, single-leg deadlift row, all 3 × 8
- Core resisted Thera-Band bird dog (quadruped): Opposite arm and leg, 3 × 8
- Eccentric backswing Thera-Band on BOSU, BOSU squat alternate trunk rotations, 3 × 8
- Single-leg balance golf stance Bodyblade, 3× to fatigue
- Squat weighted ball rotation raise: Double-leg, single-leg: 3 × 8, 20 lb
- Alternate dumbbell dynamic side plank, 3 × 8

week 8

- Warmup 15-minute jog
- Foam-rolling: Continued prior to and following training session
- Flexibility: Same as previous week with increase in repetitions to 3 × 10

- Rectus femoris
- Hamstrings

Joint Stability/Strength Program

- RS
  - Tubing shoulder horizontal adduction and abduction six times to fatigue
- Wall-draws on ball
  - Six times to fatigue (forward–back, side to side)
- PNF chops seated on ball
  - 3 sets of 10
- Straight arm: Two-handed supination to pronation
  - Thera-Band/tubing: 3 sets of 10
- Single-arm row
  - Short arm, 3 sets of 10
  - Long arm, 3 set of 10
- Prone Swiss ball (W, Y, and T)
  - 3 × 10, 3lbs
- Closed chain
  - Bosu rocks: Forward and back, side to side, 3 sets of 10
  - Pushup walk-up, 4-inch box, 3 sets of 10
- Trunk/core stabilization: Draw-in (transverse abdominus)
  - Single-leg bridge draw-in, 3 sets × 10
  - Seated horizontal chops, 3 ×10
  - Standing single-leg chops/lawnmower, 3 × 10 (Figure 9-42). This exercise replicates a pull of a lawnmower. By facilitating the hips to lead to upper-extremity (UE) movement. This allows contralateral hip to ipsilateral hip movement to the involved UE by performing diagonal pattern and ER of the glenohumeral joint.
- Hip rotation
  - Kneeling hip TB resisted rotation
    - ER and internal rotation (IR), 3 × 10

Week 3

- Use prior warmup from weeks 1 and 2, plus 15 upper-body ergometer

FIGURE 9-42. Standing single-leg chops/lawnmower.

- Foam-rolling: Dynamic myofascial release/cool-down program
  - Hip ER/piriformis, gluteus
  - ITB
  - Rectus femoris
  - Hamstrings

Joint Stability/Strength Program

- RS
  - Tubing pulses: Shoulder horizontal adduction and abduction
  - Eight times to fatigue (forward–back, side to side)
- Wall-draws on ball
  - Eight times to fatigue (forward–back, side to side)
- PNF chops seated on ball, add 3 to 5 lb
  - 3 sets of 12
- Straight arm: Two-handed supination to pronation
  - Thera-Band/tubing 3 sets of 12, increase resistance
- Single-arm row in opposite single-leg balance: Opposite side single-leg balance facilitates gluteus and core stabilization of the trunk, also activates the latissimus dorsi muscle. Perform a single-arm straight low row while standing on single leg of contralateral side.
  - Short arm, 3 sets of 12
  - Long arm, 3 sets of 12
- Prone Swiss ball (W, Y, and T)
  - 3 × 12 (5 lb)
- Closed chain
  - BOSU rocks: Forward and back, side to side, 3 sets of 12
  - Pushup walk 6-inch box, 3 sets of 12
- Trunk/core stabilization: Draw-in (transverse abdominus)
  - Single-leg bridge draw-in, 3 sets × 12
  - Seated Horizontal Chops, 3 x 12
  - Standing single-leg chops/lawnmower, 3 × 12, add 3 to 5 lb
- Hip rotation
  - Kneeling hip TB resisted rotation
    - ER and IR, 3 × 12

Phase II: Performance Enhancement Training Techniques (weeks 4 to 6)

- Continue warmup from preparation phase
- Foam-rolling from preparation phase

Week 4

Performance-Specific Flexibility Program: Anterior Hip/Psoas and Dynamic Trunk

- Lunge walks
- Backward dive (Figure 9-43)
- Supine trunk twists
- Latissimus dorsi buddy stretch
- Hip sleeper stretches while in sidelying with involved side down and hip and knee at 90°. Place a large towel or belt around foot, and pull foot, pulling hip, into IR. The increase stretch can be intensified by the pull or by

FIGURE 9-43. Backward dive (dynamic psoas stretch).

the body rolling toward the involved side being stretched.

Upper-Extremity-Specific

- Dumbbell training with large grips performed in golf iron posture:
  - Supination and pronation, 3 × 8, 5 lb
  - Wrist extension and flexion, 3 × 8, 5 lb
  - Elbow flexion and extension, 3 × 8, 5 lb
- Bicep curl single leg Squats, three sets of eight, 5 to 10 lb
- X-outs with tubing: Alternate arm, three sets of eight (Figure 9-44).
  - Position both hands inside tubing, so tubing is around both wrists.
  - Perform an X pattern with both arms, one arm at a time or at the same time.
- Overload training, Bodyblade (wrist): Three times to fatigue

FIGURE 9-44. X-outs with Thera-Band.

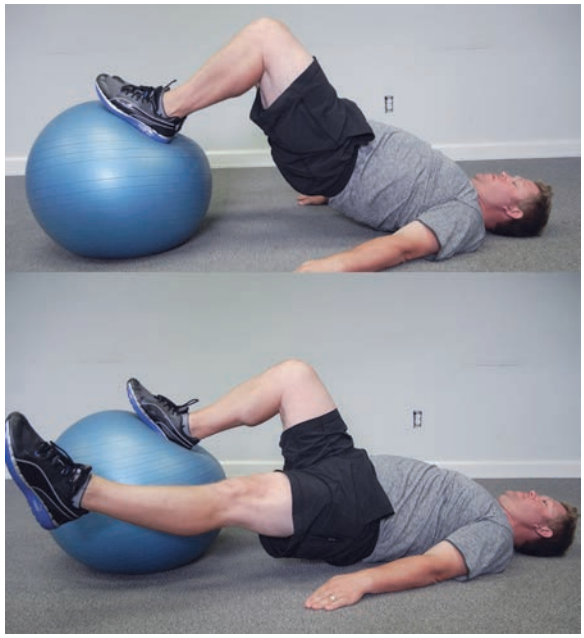

FIGURE 9-45. Ball bridge to alternate leg drop-off.

Sensorimotor

- Single-leg balance on foam pad with opposite TB: Hip abduction, three sets of eight

Core Training

- Side plank series with windmill, three sets of eight in side plank position reach with opposite arm to the ceiling, then switch to other side and repeat, making a windmill.
- Torso rotations with lunge walk, three sets of eight, weighted ball 5 pounds
- Ball bridge to alternate-leg drop-off, three sets of eight (Figure 9-45). Perform a bridge on stabilization ball (pelvis off ground), drop off one leg and lower slowly to the ground.

Plyometric: Trunk Rotation Development

- Seated boat rotation, three sets of eight, 5-lb weighted ball: Side to side in a "boat" or "V" position (low back or legs off ground). Take a weighted ball and rotate side to side of the abdomen.
- Russian twist, three sets of eight, 5-lb weighted ball (Figure 9-46)
- Front twist throw, three sets of eight, 5-lb weighted ball
- Side throw, three sets of eight, 5-lb weighted ball
- Backward twist throw, three sets of eight, 5-lb weighted ball

Multiplanar

- Diagonal dumbbell press, three sets of eight, 5-lb dumbbells
  - With squat
  - With lunge
- Transverse lunge with supination–pronation (elbow specific, three sets of eight, 5 lb)

FIGURE 9-46. Russian twist with weight ball.

Week 5

- Follow week 4, 3 sets of 10, increase weight 3 to 5 lb per exercise

Week 6

- Follow weeks 4 and 5, 3 sets of 10, increase weights 3 to 5 lb per exercise
- During performance enhancement phase, the weeks can be altered to focus more on endurance, strength, or power.
- For endurance, increase sets to four to six with rest 30 seconds between sets, low intensity, and high volume.
- For strength focus, sets of three to five, rest phase 30 to 60 seconds, intensity moderate with high volume.
- Last, power sets three to five, rest 120 to 240 seconds between sets, intensity high, and volume moderate to low.

Phase III: Sport-Specific Training (weeks 7 and 8)

- 15-minute warmup jog
- Foam-rolling: Continued, prior, and after training session
- Flexibility: Same as Phase II

Week 7

- Two-handed powerball decelerations with a powerball or weighted ball in both hands, throw down to waist height while stopping the ball before it gets to the waist.
  - Stop at impact position, three sets of eight
  - Start at impact to follow-through, three sets of eight
- Single-leg deadlift row (hamstring focus), three sets of eight
- Core-resisted TB bird dog (quadruped) (Figure 9-47) in a four-point position. Place TB around left foot and right hand. With the TB attached, lift the left foot and right hand to straight-arm position, applying resistance to the Thera-Band and controlling a two-point position.
  - Opposite arm and leg, three sets of eight, tubing/band
- Eccentric backswing TB on bosu, three sets of eight
- Single-leg balance golf stance bodyblade, three sets to fatigue
- Torso rotation: Single-leg, three sets of eight, TB resistance
- BOSU squat alternate trunk rotations, three sets of eight
- Squat weighted ball rotation raise, three sets of eight, 20 lb (Figure 9-48)
  - Double-leg
  - Single-leg
- Alternate dumbbell dynamic side plank, three sets of eight

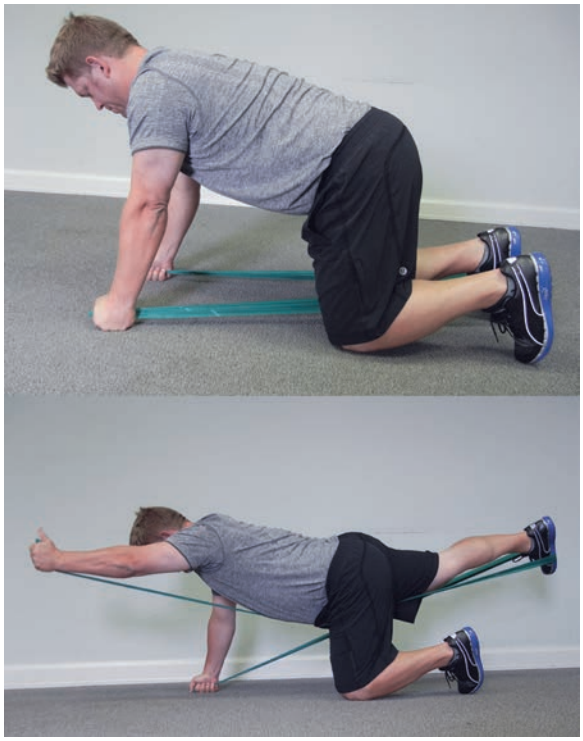

FIGURE 9-47. Thera-Band bird dog (quadruped opposite arm and leg).

FIGURE 9-48. Squatted medicine ball rotation raise.

Week 8

- Warmup 15-minute jog
- Foam-rolling: Continued, prior and after training session
- Flexibility: Same as prior phase
- Two-handed powerball decelerations
  - Stop at impact position, 3 × 10
  - Start at impact to follow-through, 3 × 10
- Single-leg deadlift row, 3 × 10
- Core-Resisted
  - TB Bird Dog (quadruped)
    - Opposite arm and leg, 3 × 10, tubing/band
- Eccentric backswing TB on BOSU, 3 × 10
- Single-leg balance golf stance Bodyblade, 3 x fatigue
- Torso rotation single-leg, 3 × 10, TB resistance
- BOSU squat alternate trunk rotations, 3 × 10
- Squat weighted ball rotation raise, 3 × 10, 20 lb
  - Double-leg
  - Single-leg
- Alternate dumbbell dynamic side plank, 3 × 10

Sports Performance Testing

History

- General history: Age, height, weight, prior injuries
- Medical history: Differential diagnosis, lateral epicondylitis, autoimmune diseases, diabetes, and circulation difficulties
- Surgical history: Prior capsular release of the medial or lateral elbow, shoulder or cervical disc pathology C5-C7
- Sports injury history: triangular fibrocartilage complex (TFCC) injury, back injury, lead shoulder problems, posterior shoulder hypermobility, anterior hip injury
- Chronic conditions/medications: Osteoarthritis, diabetes, total joint replacement

Sport-Specific Testing

- Golf posture: Two main posture types
  - S-posture: Excessive lumbar lordosis
  - C-posture: Excessive thoracic kyphosis
- Both of these common golf postures at address can cause major swing faults and lead to back and sport injury. In order to observe these faults, specific testing is needed to evaluate the body's capability to move, coordinate, and sequence a series of defined movements that make a golf swing.
- Refer to Table 9-1 for a list of the standard sport-specific tests for golf.

Specific Criteria for Progression from Advanced Strength Phase to Performance Enhancement

- Learn basic movement for each exercise, especially in preparation phase (observed with proper form and good posture).
- Body weight resistance first with good form and body mechanics
- Simple weight before complex/multidirectional movement patterns
- Resistance to fatigue completing third set of RS: Golfer can complete 3 sets of RSs, with each set lasting 20 to 30 seconds.
- Able to maintain golf/optimal posture throughout the advanced strength phase: Observe golf address and swing, looking for breakdown in posture (no C or S posture types).
- Improved flexibility from prescreen examination of hamstrings and hip rotation: Golfer passes the toe-touch test from golf screen.

Specific Criteria for Progression from Performance Enhancement to Readiness for Golf

- Increase flexibility noted by stretches or exercises completed with no loss of balance or lack of coordination: Completion of latissimus dorsi reach test, reach roll and lift test, and toe-touch test.
- All exercises performed in correct form, maintaining posture throughout all sets and repetitions
- Understand the feeling of separation between the trunk and hips to generate and release energy.
  - Completion of pelvic tilt, pelvic rotation, torso rotation, and lower-quarter rotation.
  - Completion of rolling. Rolling establishes coordination between upper and lower body. There are eight types of rolling exercises, four each in supine and prone positions: Initiate in left UE Z, right UE, left lower extremity (LE), and right LE. Repeat the same four in prone position. Observe the ability for the golfer to initiate with the extremity and complete the roll-over.

Table 9-1 Standard for Sport-Specific Testing for Golf: Titleist Performance Institute (TPI) Golf Screen: Identifying Limitations of the Golfer

Pelvic tilt test	Begin with player in stance, normal 5-iron posture (hip hinge as if the athlete is addressing a golf ball), with arms crossed over the chest. Observe standing posture and look for C and S posture. Ask the athlete to tilt the pelvis forward or anteriorly, and backward or posteriorly. Observe the amount of motion and the quality of the motion (a/k/a "shake and bake"). Observe for proper sequence from anterior tilt to posterior tilt. Observe the pelvic movement for quality (smooth or "shake and bake") and quantity of movement. In address positon, check whether the golfer is in neutral, excessive anterior tilt, or posterior tilt. As the golfer performs the tilt test, check for limitation in either anterior or posterior tilt.
Pelvic rotation test	Differentiates the ability of the lower body to rotate from the upper body. Begin in 5-iron posture with arms crossed over the chest. The golfer must keep the upper body still and rotate the lower body. Assess whether this issue is a mobility or stability problem. Observe quality of motion and amount between left and right. Hip rotation and thoracic and lumbar spine mobility can cause a limited pelvic rotation test. Smooth turn is observed without lateral movement or sway. Also, watch for the torso to be stationary during the test. Observe for good mobility: Both limited, limited left, limited right.
Torso rotation test	Assess the ability of the golfer to move the upper body independently of the lower body. In 5-iron posture, the athlete rotates the upper body with arms crossed against chest and keeps the lower body still. Observe the rotation motion side-to-side, assessing mobility and stability between the upper and lower body. Observe the upper body turning while the lower body is still. Observe good mobility: both limited, limited right, or limited left.
Overhead deep squat	A valuable assessment tool, it can be used to assess bilateral mobility and stability of the hips, knees, shoulders, and ankles. If a golfer cannot perform a deep squat, it is impossible for the golfer to maintain posture during the golf swing. Begin standing feet shoulder width apart and toes pointing forward, then grip a dowel rod or golf club overhead with elbows bent. With the shaft overhead and body in line, squat down as far as possible, keeping the club high above the head. Assess for pain, heels coming off the ground, loss of balance, and form. Observe the following criteria: Full deep-squat position, calf flexibility, weight distribution left and right, and limited in hip and knee mobility.
Toe-touch test	Assess for hamstring and low back mobility or flexibility. Look for good hip hinge and forward bend. Have player stand feet together and toes forward. Have them try and touch the tips of their fingers to their toes. Do not let them bend their knees. Unilateral toe touch can be offered for hip joint mobility. (Observe if the golfer can touch both toes (limited or not), and assess unilateral – right versus left. Test will allude to hamstring flexibility or hip mobility concerns.)
90°/90° shoulder test	Demonstrates the mobility of the glenohumeral joint and the stability in the scapulothoracic joint. The athlete can stand tall or in 5-iron posture, looking at the amount of glenohumeral external rotation (ER). The arm is abducted to 90° and elbow flexed at 90°, and the athlete rotates the arm back. This test is measured by less than spine angle, equal to spine angle, or more than spine angle. Limited rotation can lead to shoulder injuries. Measure full ER of the glenohumeral joint and observe if the forearm does not rotate externally past the angle of the spine (less than spine angle, equal to spine angle, or more than spine angle). Compare side to side.
Single leg balance test	Assess overall balance, but also core stability. The athlete stands tall with arms at side. Have one leg lifted until one thigh is parallel to the ground. Once stable, have the golfer close eyes and see how long he or she can maintain balance. Perform a single-leg balance for 25 seconds. If 25 seconds are completed with loss of balance, repositioning of the foot, or sway, the golfer has passed the test. The golfer must keep the opposite hip and knee flexed 90° during the test.
Latissimus dorsi length test	The flexibility of the latissimus dorsi muscle is important in the golf swing. The athlete performs a wall squat with back flat against wall. The back needs to stay flat at all times. The athlete lifts his or her arms up, elbows straight, and tries to touch the thumbs to the wall overhead. The golfer cannot bend the elbows, arch the back, or have pain. Observe whether the arm angle is below 120°, between 120° and 169°, or greater than 169°.
Seated trunk rotation test	The goal of this test is to get an appreciation for how much rotational mobility occurs at the lumbothoracic spine. Ask athlete to sit on a stool in upright position and arms crossed over the chest. Hold a bar/club across the shoulders. Use two clubs on the floor to create 45° degrees angles to assess rotation. The player should rotate as far as possible left and right to observe for quantity of motion keeping knees together and shoulder blade retracted. Observe for the athlete to move past the 45° club angle. Typical range of motion is 45° to 70°. Differences between sides do occur; observe for protraction or retraction of the scapula. Differences between sides are common.
Lower-quarter rotation	In tall stance, with one leg straight and the other up on the toe, rotate around the down leg. Keep hands on hips and hips square. The athlete rotates in ER and IR on the down leg. Assess both sides. Create two angles on the ground by using a 6 iron at approximately 60° to 62°. Many present with less than 40° hip ER and IR. PGA tour average is 60° in both directions. The golfer holds dowel rod or club across the posterior superior iliac spine, and then rotates as far as possible in each direction.
Bridge with leg extension test	Good dynamic movement assessment test for pelvis, lumbar spine, and core stability, specifically the gluteal muscle group. Golfer starts on the floor with knees bent and arms straight at shoulder height. The athlete bridges parallel to the floor, extending right leg from the knee. Hold this position for 10 seconds. Stability on the right side is questioned with left-side hip drop or left-leg shakes. Inhibition of the gluteal muscles can occur with cramping in hamstring or back. Repeat on both sides. Observe if there is cramping down (hamstring) in the leg indicating weakness in the gluteal muscles. Observe pelvic drop between one side and the other. The pelvis must stay level.
Reach, roll, and lift test	Scapular mobility and lower trapezius strength is important for the golf swing. The athlete needs to be in the prayer stretch position, resting backside on the heels and head on one fist. The other arm is reached out as straight as possible palm down, then palm turned up and arm lifted off the ground. Observe the ability of the golfer to keep arm straight and lift it. If the golfer cannot complete the test, evaluate glenohumeral joint mobility, latissimus dorsi flexibility, and upper thoracic kyphosis.

Courtesy of Greg Rose, Dave Phillips, and Lance Gill, Titleist Performance Institute, Oceanside, CA.

- The performance enhancement program must cover the training components of acceleration, deceleration, and change of direction.
- Ability to maintain posture for consistent ball address and posture throughout the swing (observe golf swing for C and S posture)

Specific Criteria for Release to Unsupervised Complete Participation in Golf

- Ability to shock-absorb club impact of the ground, sand, and rough multiple times: Golfer must be able to complete 80 to 100 shots on different surfaces before play without injury. Golfer must be able to complete four rounds before competition.
- Completed golf swings on a variety of different lies and turf conditions, typically three or four practice rounds
- Several pain-free range sessions, 80 to 100 balls hit per session
- No weakness or difficulty felt proximal or distal to the related joint injured. Complete manual muscle testing 4+/5 grade. Golf screen completed without pain.
- Understanding of medial and lateral elbow injuries in golfers and what can be done to help with injury prevention and treatment application. Golfer must understand that stopping the activity with recurrence. Learn stretching of the wrist flexor and extensor mass. Follow rest, ice, compression, and elevation protocol as needed. Learn about appropriate bracing for support.

Recommended Ongoing Exercises

- Squat rotation to overhead press
- Latissimus dorsi and hamstring flexibility
- Trunk rotation lunge walk
- Foam-rolling: ITB, quadriceps, hamstrings, piriformis, gluteal muscles

Evidence

Crossley K, Zhang W, Schache A, et al: Performance on the single-leg squat task indicates hip abductor muscle function. *Am J Sports Med* 39:866–873, 2011.

Panel of five experts rated 34 nonpathological participants performing a single-leg squat. Hip muscle electromyography activation along with compensation faults during the task were evaluated. The experts found that good performers had earlier onset of gluteus medius and greater abduction torque. They suggest that single-leg squat is a good predictor of hip muscle dysfunction. (Evidence for use of single leg tasks during Phases II and III).

Farber A, Smith J, Kvitne R, et al: Electromyographic analysis of forearm muscles in professional and amateur golfers. *Am J Sports Med* 37:396–401, 2009.

Twenty male professional and amateur golfers without history of elbow pathology underwent electromyography of the muscles in the forearm. Amateurs exhibited more pronator muscle activity in trailing arm, in contrast to the professionals, who had more in the lead arm. The authors suggested that, as a result, amateurs should perform stretching and strengthening of the pronator teres. (Evidence for pronator strength in Phase II, Performance enhancement phase).

Koa J, Pink M, Jobe F, et al: Electromyographic analysis of the scapular muscles during a golf swing. *Am J Sports Med* 23:19–23, 1995.

Fifteen competitive male golfers were studied for their scapular muscle involvement during the golf swing. The levator scapulae, trapezius, rhomboids, and serratus anterior were appreciated during the lead and trial arms during the golf swing. Scapular muscle work in synchrony throughout the golf swing and are important to strengthen to prevent injury and increase athletic performance. (Evidence for preparation and sport-specific phase strength foundation for scapular muscle groups).

Kraemer W, Ratamess N, Fry A, et al: Influence of resistance training volume and periodization on physiological and performance adaptations in collegiate women tennis players. *Am J Sports Med* 28:626–633, 2000.

Twenty-four collegiate tennis players were formed randomly into three groups: (1) No resistance training, (2) periodization resistance training, and (3) single-set circuit training program. They found that high-volume, periodized, multiple-set resistance training programs yielded greater results in muscle strength and power. They also suggested there were better long-term gains for the athletes in multiple-set, periodized programs with increases in performance enhancement. (Evidence for design of all three phases: Preparation, Performance, and Sport-Specific).

Vad VB, Bhat AL, Basrai D, et al: Low back pain in professional golfers the role of associated hip and low back range-of-motion deficits. *Am J Sports Med* 32:494–497, 2004.

Forty-two professional golf athletes were measured from hip and lumbar range of motion (ROM) and correlated this to recall of low back pain group and no low back pain group. ROM deficits in lead hip internal rotation and lumbar spine extension were correlated to history of low back pain in golfers. Proper hip lead internal rotation and lumbar spine flexibility is an important component in a return to golf program. (Preparation phase evidence for hip rotation strength).

Multiple-Choice Questions

QUESTION 1. In which training phase are form and correct movement patterns necessary for optimal gain?

A. Preparation
B. Sport-specific
C. Performance enhancement
D. All the above

QUESTION 2. Choose the best statement for increasing power in performance enhancement training:

A. Three to five sets, rest 30 to 60 seconds, intensity moderate, and volume high
B. Rest 30 seconds, intensity low, volume high, and four to six sets

C. Rest 2 minutes, intensity high, volume high, and three to five sets
D. Rest 2 to 4 minutes, three to five sets, intensity high, and volume moderate

QUESTION 3. Which of the following best describes performance enhancement?

A. Acceleration
B. Deceleration
C. Change of directions
D. All the above

QUESTION 4. Which of the following phase(s) is the most important free body squat?

A. Endurance strength phase
B. Preparation phase
C. Power phase
D. Acceleration phase
E. A and B

QUESTION 5. The single-leg deadlift row works on which primary muscle group?

A. Latissimus dorsi
B. Hamstring
C. Erector spinea
D. Piriformis

Answer Key

QUESTION 1. Correct answer: **A** (Preparation phase)

QUESTION 2. Correct answer: **D** (Performance enhancement phase)

QUESTION 3. Correct answer: **C** (Criteria to progress performance enhancement to sport-specific)

QUESTION 4. Correct answer: **B** (Preparation phase)

QUESTION 5. Correct answer: **B** (Phase III: Week 7)

Chapter 10

Epiphyseolysis and Osteochondritis

INTRODUCTION

Rob Hopkins, PT, SCS, and Champ L. Baker, Jr., MD

Epidemiology

- Elbow injuries common in young throwers
- 9 to 14 years old, predominantly male
- Primarily occurs in baseball; can also be seen in softball and volleyball
- Pitchers most often affected followed by catchers and position players

Pathophysiology

Intrinsic Factors

- Open physis at elbow (Figure 10-1)
- Inadequate hip mobility
- Weakness in hips/lower extremity
- Weakness in core

FIGURE 10-1. Open physis.

- Scapular dyskinesis/weakness
- Rotator cuff weakness
- Glenohumeral hypermobility
- Wrist flexor tightness/weakness

Extrinsic Factors

- Pitching too much/overuse
- Pitch selection, throwing curve ball or slider too soon
- Mound height
- Poor mechanics

Traumatic Factors

- Primarily an injury of overuse

Classic Pathological Findings

- Widening of physes on x-ray
- Loose body on x-ray (Figure 10-2)
- MRI demonstrating a nondisplaced osteochondritis dissecans fragment (Figure 10-3)

Clinical Presentation

- Intermittent elbow pain, possibly for years
- Loss of throwing velocity
- Loss of throwing control
- Loss of elbow extension (Figure 10-4)
- History of overparticipation in baseball activities: multiple leagues, travel teams, showcases, specialty coaches
- Pain with pitching or throwing only, hitting and position play do not reproduce pain

Abnormal Findings

- Weakness in core, scapular stabilizers, rotator cuff
- Loss of total arm motion (TAM) secondary to loss of internal rotation

FIGURE 10-2. Loose body on plain radiograph in a 14-year-old patient.

- Tenderness to palpation of medial epicondyle and pain on valgus stress test (Figure 10-5)
- General kyphosis with forward shoulder and head posture and protracted and tilted scapula (Figure 10-6)

Pertinent Normal Findings

- Normal sensation through upper extremity
- No pain at rest
- Full elbow flexion

Imaging Studies

- Plain radiographs
- MRI if patient does not respond to nonoperative management

FIGURE 10-3. Magnetic resonance image in a 14-year-old patient.

FIGURE 10-4. Loss of extension in a patient with Little League elbow.

Differential Diagnosis

- Medial epicondylitis
- Ulnar neuritis

Treatment

Nonsurgical

- Rest
- NSAIDs
- Activity/position modification
- Physical therapy
- Pitching mechanics evaluation
- Interval throwing program (ITP)

Guidelines

- Severity of symptoms
- Patients desire to play
- Time of year/time in season
- Other sports patient participates in

Surgical Indications

- Persistent pain over the medial epicondyle after prolonged rest and attempt to return to throwing
- X-ray/MRI evidence of persistent widening of the medial metaphysis specifically in comparison to contralateral side (Figure 10-7)
- Separation of medial epicondyle epiphysis if acute and retracted
- Persistent pain with activities of daily living even if not attempting sports
- Restricted sports

Aspects of History, Demographics, or Exam Findings That Affect Choice of Treatment

- Age of patient
- Desire to continue playing
- Other sports in which the patient participates
- Response to conservative measures

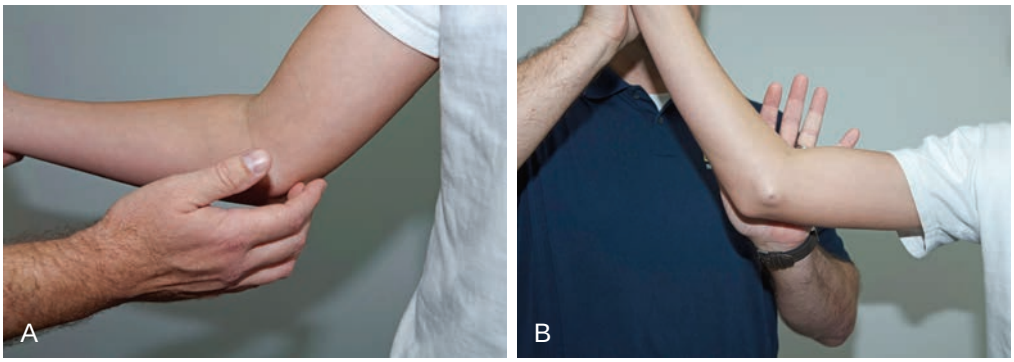

FIGURE 10-5. Physical findings include tenderness to palpation of the medial epicondyle (**A**) and pain on valgus stress (**B**).

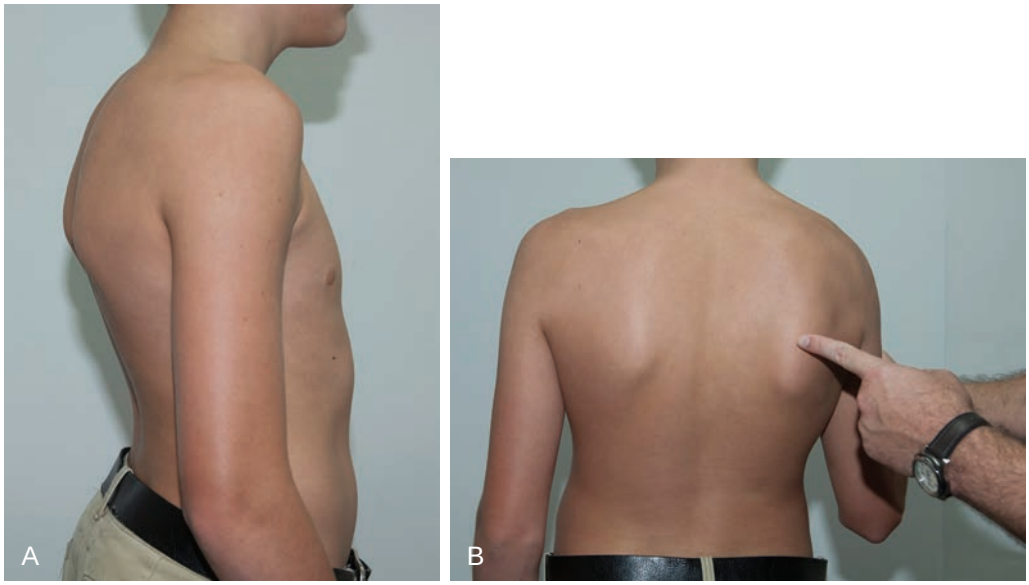

FIGURE 10-6. Patient's posture shows weak core and thoracic kyphosis (**A**) and malpositioned winging scapula (**B**).

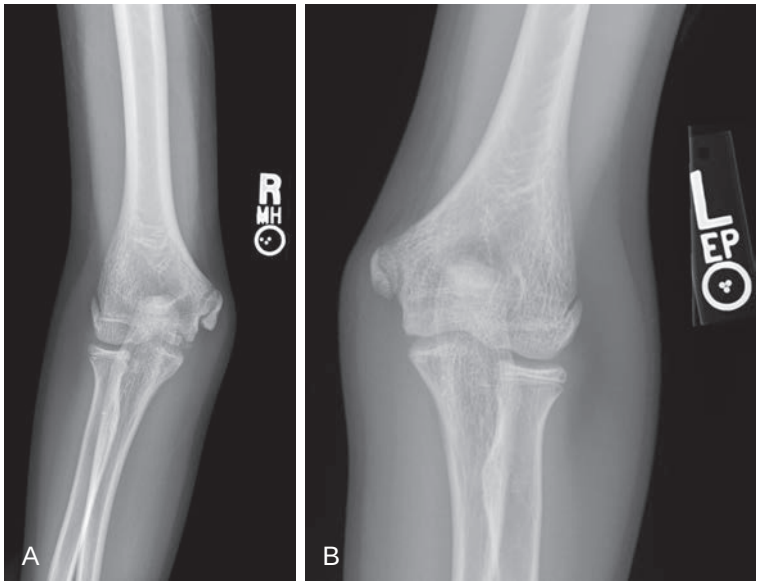

FIGURE 10-7. Plain radiograph of affected elbow (**A**) shows widening of medial metaphysis when compared with contralateral elbow (**B**).

Aspects of Clinical Decision Making When Surgery Is Indicated

- Age of the patient and desire to return to throwing sport are important.
- Skeletal maturity age should be determined by skeletal films of the hand.
- Radiographic comparison with the contralateral elbow should be made.
- Surgeon should be prepared to address ulnar nerve symptoms at the time of surgery.
- Patients must be advised that it can be as long as 3 months before bony closure is achieved and return to throwing is possible. Although it may require less time, it may be up to 6 months before full release to return to sports is possible.

Evidence

Axe MJ, Hurd W, Snyder-Mackler L: Data-based interval throwing programs for baseball players. *Sports Health* 1:145–152, 2009.

The authors developed data-driven programs based on the number, type, distance, and intensity of throws for baseball athletes at all levels of play. They recommend medical professionals use these programs for safe training, conditioning, and return to play. (Level of evidence NA)

Dines JS, Frank JB, Akerman M, et al: Glenohumeral internal rotation deficits in baseball players with ulnar collateral ligament insufficiency. *Am J Sports Med* 37:566–570, 2009.

In this case-control study of baseball players with and without ulnar collateral ligament insufficiency, investigators measured passive glenohumeral internal and external rotation, elbow flexion and extension, and forearm pronation and supination to determine the association between pathologic glenohumeral internal rotation deficit and elbow valgus instability. (Level III evidence)

Fleisig GS, Andrews JR, Cutter GR, et al: Risk of serious injury for young baseball pitchers: A 10-year prospective study. *Am J Sports Med* 39:253–257, 2011.

In this study, 481 youth pitchers were followed for 10 years to determine whether increased amount of pitching, throwing curveballs at a young age, and concomitantly playing catcher increased a young pitcher's risk of injury. (Level III evidence)

Marsh D: Little League elbow: Risk factors and prevention strategies. *Strength Cond J* 32:22–37, 2010.

The article discusses the risk factors and prevention strategies for Little League elbow in youth athletes. (Level of evidence NA)

Nissen CW, Westwell M, Ounpuu S, et al: A biomechanical comparison of the fastball and curveball in adolescent baseball pitchers. *Am J Sports Med* 37:1492–1498, 2009.

In this controlled laboratory study, 33 adolescent baseball pitchers with a minimum of 2 years of pitching experience underwent three-dimensional motion analysis using reflective markers aligned to bony landmarks. The authors looked for an association between pitch techniques and shoulder and elbow injuries. (Level of evidence NA)

Reinold MM, Escamilla RF, Wilk KE: Current concepts in the scientific and clinical rationale behind exercises for glenohumeral and scapulothoracic musculature. *J Orthop Sports Phys Ther* 39:105–117, 2009.

The authors of this paper provide the clinician with a thorough overview of the available literature relevant to develop safe, effective, and appropriate exercise programs for injury rehabilitation and prevention of the glenohumeral and scapulothoracic joints. (Level V evidence)

Multiple Choice Questions

QUESTION 1. What is the age range of most patients with Little League elbow?

A. 5 to 8 years
B. 9 to 14 years
C. 15 to 18 years
D. All ages are equal.

QUESTION 2. Which of the following is an extrinsic factor in the pathophysiology?

A. Overuse
B. Pitch selection
C. Pitching mechanics
D. All of the above

QUESTION 3. Which of the following is not in the normal clinical presentation?

A. Night pain
B. Loss of velocity
C. Loss of control
D. Loss of total arm motion
E. Night pain

QUESTION 4. The following are nonsurgical treatments except

A. change positions.
B. increase volume of throwing.
C. rest.
D. NSAIDs.

QUESTION 5. Which of the following findings will affect the choice of treatment?

A. Age
B. Desire to keep playing
C. Other sports played
D. Response to conservative management
E. All of the above

Answer Key

QUESTION 1. Correct answer: **B** (see Epidemiology)

QUESTION 2. Correct answer: **D** (see Extrinsic Factors)

QUESTION 3. Correct answer: **B** (see Clinical Presentation)

QUESTION 4. Correct answer: **A** (see Treatment)

QUESTION 5. Correct answer: **E** (see Findings That Affect Choice of Treatment)

NONOPERATIVE REHABILITATION OF EPIPHYSIOLYSIS OF THE MEDIAL EPICONDYLE (LITTLE LEAGUE ELBOW)

Rob Hopkins, PT, SCS, and Champ L. Baker, Jr., MD

Phase I (weeks 0 to 2)

Protection

- No sports activities
- A sling is rarely, if ever, needed. A sling may be used when necessary for elbow pain. Discontinue as soon as patient is pain free at rest.

Treatment for Pain/Swelling

- Ice, compression
- Over-the-counter pain medication/NSAIDs

Techniques for Progressive Increase in Range of Motion

Manual Therapy

- Joint mobilization of shoulder, primarily posterior capsule if glenohumeral internal rotation deficit (GIRD) is present

Soft Tissue Techniques

- Massage to facilitate edema reduction and release adhesions

Stretching/Flexibility Techniques

- Proprioceptive neuromuscular facilitation (PNF) muscle energy techniques and self-stretching to gain full elbow and shoulder range of motion (ROM)

Other Therapeutic Exercises

- Lower extremity strength and flexibility
- Core strength/stability
- Maintain cardiovascular endurance

Muscle Activation of Primary Muscles Involved

- Concentric activation of elbow flexors and extensors, wrist supination and pronation, wrist flexion and extension

Sensorimotor Exercises

- Manual joint replication activities at wrist and elbow

Open (OKC) and Closed (CKC) Kinetic Chain Exercises

- OKC exercises at this time

Techniques to Increase Muscle Strength, Power, and Endurance

- No activities for primary injury site
- Continue to maintain or increase lower body and core power and endurance.

Neuromuscular Dynamic Stability Exercises

- None at this time

Plyometrics

- None at this time

Functional Exercises

- Patient is encouraged to use upper extremity for all activities of daily living (ADLs). Patient is restricted from sports activities only at this time.

Sports-Specific Exercises

- None at this time

Milestones to Progress to Next Phase

- Pain free at rest
- Normal elbow ROM
- Nontender to palpation

TIMELINE 10-1: **Nonoperative Rehabilitation of Epiphysiolysis of the Medial Epicondyle (Little League Elbow)**

PHASE I (weeks 0 to 2)	PHASE II (weeks 2 to 6)
• Sling, if needed • Modalities to control pain and swelling • Restore full A/PROM to elbow • Evaluate throwing shoulder girdle (hyper/hypo mobility, scapular stability, etc.) • Core and lower-extremity strength and endurance training	• Elbow ROM WNL • Rotator cuff, deltoid, and scapular stabilization exercises, begin UBE • Proprioception exercises at shoulder and elbow • Continue core and lower-extremity strength and endurance training

Phase II (weeks 2 to 6)

Protection

- None

Treatment for Pain/Swelling

- Ice, compression, over-the-counter pain medication/NSAIDs

Initial Guidelines for Progressive Increase in ROM

Patient should have normal elbow ROM at this time.

Manual Therapy Techniques

- Joint mobilization of shoulder, primarily posterior capsule if GIRD is present

Soft Tissue Techniques

- Massage to facilitate edema reduction and release adhesions at elbow

Stretching/Flexibility Techniques for the Musculotendinous Unit

- PNF/muscle energy techniques and self-stretching to gain full shoulder ROM

Other Therapeutic Exercises

- Lower extremity strength and flexibility, focus on hips
- Core strength/stability
- Rotator cuff, deltoid, and scapular stabilization
- Maintain cardiovascular endurance

Muscle Activation of Primary Muscles Involved in Injury Area

- Concentric activation of elbow flexors and extensors, wrist supination and pronation, wrist flexion and extension progressing to eccentric as able

Sensorimotor Exercises

- Manual joint replication activities at wrist and elbow

Open (OKC) and Closed (CKC) Kinetic Chain Exercises

- OKC exercises for upper extremity
- CKC exercises for scapular stabilization and core

Increase Muscle Strength, Power, and Endurance

- Upper body exercises (UBE)
- Begin resisted activities for entire upper extremity, Thera-Band, free weights, etc
- Continue to maintain or increase lower body and core power and endurance

Neuromuscular Dynamic Stability Exercises

- None at this time

Plyometrics

- None at this time

Functional Exercises

- Patient should have no functional limitations. Patient is restricted form sports activities only at this time.

Sport-Specific Exercises

- None at this time

Milestones/Criterion-Based Rehabilitation Guidelines to Progress to Next Phase

- Pain free at rest
- Normal elbow ROM
- Nontender to palpation
- Complete Phase II exercises without increase in symptoms

Phase III (weeks 6 to 12)

Protection

- None

Treatment for Pain/Swelling

- Ice, compression
- Over-the-counter pain medication/NSAID

Techniques for Progressive Increase in ROM

Patient should have normal elbow ROM at this time.

Manual Therapy Techniques

- Joint mobilization of shoulder, primarily posterior capsule if GIRD is present

TIMELINE 10-1: **Nonoperative Rehabilitation of Epiphysiolysis of the Medial Epicondyle (Little League Elbow)** (Continued)

PHASE III (weeks 6 to 12)	PHASE IV (weeks 12+)
• Continue above exercises • Begin closed chain upper-extremity exercises • Begin PNF • Plyoball throws; two-hand progressing to one-hand • Return to hitting activity • Position play as indicated	• Continue to progress all above exercises • Pitching mechanics evaluation • Begin interval throwing program

FIGURE 10-8. Sleeper stretch for stretching posterior capsule is begun during Phase II.

Soft Tissue Techniques

- Massage to facilitate edema reduction and release adhesions at elbow

Stretching/Flexibility Techniques for the Musculotendinous Unit

- PNF/muscle energy techniques and self-stretching to gain full shoulder ROM (Figure 10-8)

Other Therapeutic Exercises

See Figure 10-9.
- Lower extremity strength and flexibility, focus on hips
- Core strength/stability
- Rotator cuff, deltoid and scapular stabilization
- Maintain cardiovascular endurance

FIGURE 10-9. Posterior shoulder stretching on BOSU Trainer for core, cuff, and scapula strengthening.

Muscle Activation of Primary Muscles Involved in Injury Area

- Concentric/eccentric activation of elbow flexors and extensors, wrist supination and pronation, wrist flexion and extension

Sensorimotor Exercises

- Manual joint replication activities at wrist, elbow, shoulder

Open (OKC) and Closed (CKC) Kinetic Chain Exercises

- OKC exercises for upper extremity at this time
- CKC exercises for lower extremity, scapular stabilization, core, upper extremity

Techniques to Increase Muscle Strength, Power, and Endurance

- Upper body exercises
- Begin resisted activities for entire upper extremity, Thera-Band, free weights, and so on.
- Continue to maintain or increase lower body and core power and endurance.

Neuromuscular Dynamic Stability Exercises

- Begin PNF patterns, concentric progressing to eccentric.

Plyometrics

- Begin two-handed Plyoball throws progressing to one.

Functional Exercises

- Patient should have no functional limitations at this time.

Sport-Specific Exercises

- Patient is allowed to hit off tee and progress to live batting. Patient may return to playing field position (noncatcher) if cleared by physician.

Milestones/Criterion-Based Rehabilitation Guidelines to Progress to the Next Phase

- Pain free at rest
- Normal elbow ROM
- Nontender to palpation
- Complete phase III exercises without increase in symptoms
- Able to hit without pain
- Pain free with all Plyoball exercises

Phase IV (weeks 12+)

Protection

None

Treatment for Pain/Swelling

- Ice, compression, over-the-counter pain medication/NSAID

Initial Guidelines and Guidelines for Progressive Increase in ROM

Patient should have normal elbow ROM at this time.

Manual Therapy Techniques

- Joint mobilization of shoulder, primarily posterior capsule if GIRD is present

Soft Tissue Techniques

- Massage to facilitate edema reduction and release adhesions at elbow

Stretching/Flexibility Techniques

- PNF/muscle energy techniques and self-stretching to gain full shoulder ROM

Other Therapeutic Exercises

- Lower extremity strength and flexibility exercises, focus on hips
- Core strength/stability
- Rotator cuff, deltoid and scapular stabilization
- Maintain cardiovascular endurance

Muscle Activation of Primary Muscles Involved in the Injury Area

- Concentric/eccentric activation of elbow flexors and extensors, wrist supination and pronation, wrist flexion and extension

Sensorimotor Exercises

- Manual joint replication activities at wrist, elbow, shoulder

Open (OKC) and Closed (CKC) Kinetic Chain Exercises

- OKC exercises for upper extremity
- CKC exercises for lower extremity, scapular stabilization, core, upper extremity

Techniques to Increase Muscle Strength, Power, and Endurance

- UBE
- Continue resisted activities for entire upper extremity, Thera-Band, free weights, etc.
- Continue to maintain or increase lower body and core power and endurance.

Neuromuscular Dynamic Stability Exercises

- PNF patterns, concentric progressing to eccentric

Plyometrics

- Two-handed and one-handed Plyoball throws

Functional Exercises

- Patient should have no functional limitations at this time.

Sport-Specific Exercises

- Continue hitting and playing field positions (non-catcher).
- Evaluate pitching mechanics.
- Begin interval throwing program (ITP).

Milestones/Criterion-Based Rehabilitation Guidelines to Progress to Next Phase

- Completion of ITP
- Faulty mechanics corrected
- Patient can return to pitching in 8 to 12 months pending physician clearance.

Criteria for Abandoning Nonoperative Treatment and Proceeding to Surgery

- Inability to return to pitching
- Pain with activities of daily living
- Loss of motion affecting performance

Milestones/Criterion-Based Rehabilitation Guidelines to Progress to Sport-Specific Training and Conditioning

- Completion of nonoperative rehabilitation
- No pain with ITP
- No pain with hitting
- Appropriate age to benefit from advanced training

Transition to Performance Enhancement: Tips and Guidelines

- Patients (and parents) need to be involved at young ages.
- Beware of compensatory movements after an injury.
- Patients have a tendency to overtrain after an injury.
- Patient must demonstrate correct form before increasing resistance.

Performance Enhancement and Beyond Rehab

- Performance enhancement improves an athlete's ability to succeed at his or her sport. It requires an understanding of the demands of the sport and the position being played by the athlete. This understanding must be coupled with the knowledge of human anatomy, physiology, psychology, and kinesiology. Putting these elements together gives the athlete the best opportunity to optimize his or her abilities and to perform at the highest level.

Criteria for Return to Sports Participation

- Completion of ITP
- Normal physical exam findings
- No pain with throwing

Evidence

Aguinaldo AL, Chambers H: Correlation of throwing mechanics with elbow valgus load in adult baseball pitchers. *Am J Sports Med* 37:2043–2048, 2009.

In this laboratory study, the authors analyzed the associations of 13 biomechanical variables with elbow valgus overload in 69 adult baseball pitchers. Their findings offer feedback for developing methods to minimize the effects of valgus load on elbow injuries. (Level of evidence NA. Descriptive laboratory study.)

Davis JT, Limpisvasti O, Fluhme D, et al: The effect of pitching biomechanics on the upper extremity in youth and adolescent baseball pitchers. *Am J Sports Med* 37:1484–1491, 2009.

Baseball pitchers aged 9 to 18 were studied in the laboratory while throwing fastballs to compare five pitching parameters with the pitcher's age, humeral internal rotation torque, elbow valgus load, and calculated pitching efficiency. The authors attempted to show how improper pitching mechanics adversely affected the upper extremity. (Level of evidence, NA. Descriptive laboratory study.)

Ogard WK: Proprioception in sports medicine and athletic conditioning. *Strength Cond J* 33:111–118, 2011.

This article discusses terminology and concepts of proprioceptive function and how it is addressed in the context of sports medicine and athletic conditioning. (Level of evidence NA)

Oliver JL, Lloyd RS, Meyers RW: Training elite child athletes: Promoting welfare and well-being. *Strength Cond J* 33:73–79, 2011.

The authors of this article identified risks to provide recommendations to help coaches promote the welfare and well-being of elite child athletes during training. (Level of evidence, NA)

Olsen SJ, 2nd, Fleisig GS, Dun S, et al: Risk factors for shoulder and elbow injuries in adolescent baseball pitchers. *Am J Sports Med* 34:905–912, 2006.

The authors make recommendations based on the results of this study comparing adolescent pitchers who had shoulder or elbow surgery with those who had never had a significant pitching-related injury. (Level III evidence)

Multiple Choice Questions

QUESTION 1. Which of the following is NOT a guiding principle of rehabilitation?

A. Patient and family education
B. Continue playing
C. Stopping stressful activity
D. Active rest

QUESTION 2. Which of the following should be examined on a pitcher with Little League elbow?

A. Elbow range of motion
B. Core strength
C. Shoulder mobility
D. All of the above

QUESTION 3. When should a patient expect to return to hitting?

A. 0 to 2 weeks
B. 2 to 6 weeks
C. 6 to 12 weeks
D. 12+ weeks

QUESTION 4. When should a patient expect to return to pitching?

A. 2 months
B. 4 months
C. 6 months
D. 8+ months

QUESTION 5. When transitioning from rehabilitation, a therapist/trainer should be aware of which of the following?

A. Overtraining
B. Overbearing parents
C. Substitution patterns/movements
D. All of the above

Answer Key

QUESTION 1. Correct answer: **B** (see Guiding Principles)

QUESTION 2. Correct answer: **D** (see Phase I)

QUESTION 3. Correct answer: **C** (see Phase III)

QUESTION 4. Correct answer: **D** (see Phase IV)

QUESTION 5. Correct answer: **D** (see Transition to Performance Enhancement)

POSTOPERATIVE REHABILITATION AFTER TREATMENT OF OSTEOCHONDRITIS DISSECANS OF THE CAPITULUM

Rob Hopkins, PT, SCS, and Champ L. Baker, Jr., MD

Indications for Surgical Treatment

- Displaced medial epicondylar fracture in acute injury as shown on plain radiographs (x-ray) and/or MRI
- Chronic pain with delayed closure of medial humeral epiphysis
- Nonoperative management is recommended for 3 to 6 months.

Brief Summary of Surgical Treatment

Major Surgical Steps

- Ensure adequate x-ray and/or fluoroscopic support.
- Create limited medial incision.
- Expose the medial epicondyle.
- Under fluoroscopic control, control insertion of cancellous screw fixation of the nondisplaced fragment (Figure 10-10). Countersink the screw to prevent postoperative discomfort.
- If the fragment is small, two parallel pins can be used instead of cancellous screw.
- Epiphysis does not need to be exposed.
- Nerve does not need to be exposed.

Factors That May Affect Details of Rehabilitation

- Surgery may be done using general anesthetic or nerve block, but choice should not affect rehabilitation.

Phase I: Immediate Postoperative Period (days 1 to 14)[1]

Goals

- Protect healing tissues.
- Decrease pain and inflammation.
- Decrease swelling.
- Increase range of motion (ROM) as tolerated at the elbow and wrist.

Clinical Pearl

Correct sling fit in the immediate postoperative phase is important in reducing the patient's pain. Slings that are the wrong size or applied incorrectly can generate pain, which will encourage the patient to remove the sling prematurely.

Protection

- Sling as needed for comfort for 2 to 6 weeks

Management of Pain and Swelling

- Pain medications
- Ice/cryotherapy
- Electrical stimulation

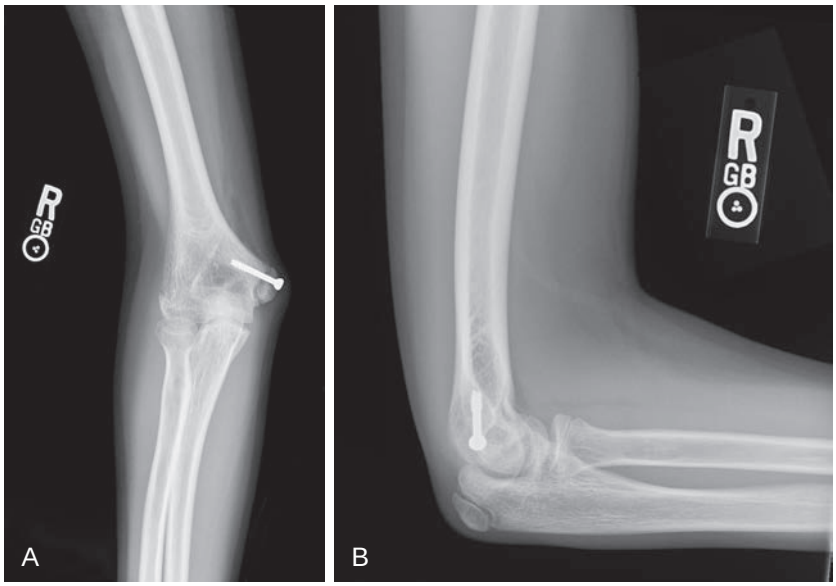

FIGURE 10-10. Anteroposterior (**A**) and lateral (**B**) radiographs show placement of cancellous screw used for fixation of fragment.

Techniques for Progressive Increase in Range of Motion

Manual Techniques

- Massage to reduce edema
- Scar massage

Stretching/Soft Tissue Techniques for the Musculotendinous Unit

- Avoid wrist flexion stretching.

Other Therapeutic Exercises

- Stationary bike or elliptical may be used to maintain cardiovascular endurance.

Activation of Primary Muscles Involved in Injury Area or Surgical Structures

- Encourage active movement of fingers, wrist, and elbow of involved arm, no resistance.
- Active ROM (AROM) of shoulder and scapula on involved side

Milestones for Progression to the Next Phase

- Incision healed, no signs/symptoms of infection

Phase II (weeks 2 to 6)

Goals

- No pain
- No swelling
- Full PROM

Protection

- Discontinue sling as able

Treatment for Pain and Swelling

- Pain medications
- Ice/cryotherapy
- Electrical stimulation

Techniques for Progressive Increase in Range of Motion

Manual Techniques

- Massage to reduce edema
- Joint mobilizations to facilitate full ROM
- Scar massage

Stretching/Soft Tissue Techniques for the Musculotendinous Unit

- Avoid wrist flexion stretching.

Other Therapeutic Exercises

- Stationary bike or elliptical may be used to maintain cardiovascular endurance

Activation of Primary Muscles Involved in Injury Area or Surgical Structures

- Encourage active movement of fingers, wrist, elbow of involved arm, no resistance.
- AROM of shoulder and scapula on involved side

Milestones for Progression to the Next Phase

- Pain free
- Full AROM
- No swelling

Phase III (weeks 6 to 10)

Goals

- Avoid overstressing repair.
- Maintain activity restrictions.
- Begin shoulder/scapula strengthening.

Treatment for Pain and Swelling

- Ice/cryotherapy post rehab

Therapeutic Exercises (Figure 10-11)

- Stationary bike or elliptical may be used to maintain cardiovascular endurance
- Shoulder and scapular strengthening exercises (Thrower's 10 program)
- Core strengthening

TIMELINE 10-2: **Postoperative Rehabilitation After Treatment of Osteochondritis Dissecans of the Capitulum***

PHASE I (weeks 0 to 2)	PHASE II (weeks 2 to 6)
• Sling as needed • Modalities as needed for pain • AROM elbow/wrist hand • Massage for edema	• Discontinue sling • Modalities as needed • Full P/A ROM at elbow • AROM scapula and glenohumeral joint exercises • Bike/elliptical for conditioning

*Prehabilitation, if appropriate, is described in the Nonoperative Rehabilitation section of this chapter.

FIGURE 10-11. Scaption on Swiss ball for rotator cuff, scapular, and core strengthening.

Activation of Primary Muscles Involved in Injury Area or Surgical Structures

- Begin upper body exercises
- Isotonic elbow, wrist, and hand strengthening

Sensorimotor Exercises

- Rhythmic stabilization for elbow, and shoulder in OKC (open kinetic chain) only

Open and Closed Kinetic Chain Exercises

- Thrower's 10 (OKC)

Neuromuscular Dynamic Stability Exercises

- Begin PNF patterns for the upper extremity

Milestones for Progression to the Next Phase

- Good proprioception in shoulder and elbow
- 70% strength in shoulder and elbow

Phase IV (weeks 10 to 14)

Goals

- No pain with weight bearing through upper extremity

Treatment for Pain and Swelling

- Ice/cryotherapy post rehab

FIGURE 10-12. Prone plank (**A**) and side plank (**B**) for core strengthening and scapular stabilization.

Therapeutic Exercises (Figure 10-12)

- Stationary bike, elliptical, or running may be used to maintain cardiovascular endurance
- Shoulder and scapular strengthening exercises (Thrower's 10 program)
- Core strengthening

Activation of Primary Muscles Involved in Injury Area or Surgical Structures

- UBE
- Isotonic elbow, wrist, and hand strengthening

Sensorimotor Exercises

- Rhythmic stabilization for elbow, and shoulder

Open (OKC) and Closed (CKC) Kinetic Chain Exercises

- Thrower's 10 (OKC)
- Begin closed chain stabilization exercises, stable surfaces, progressing to unstable surfaces (CKC)

Neuromuscular Dynamic Stability Exercises

- PNF patterns for the upper extremity

TIMELINE 10-2: Postoperative Rehabilitation After Treatment of Osteochondritis Dissecans of the Capitulum* (Continued)

PHASE III (weeks 6 to 10)	PHASE IV (weeks 10 to 14)	PHASE V	
		(weeks 14 to 24)	(weeks 24+)
• Begin UBE • Rhythmic stabilization exercises for upper extremity • Begin core strengthening • Throwers 10 for rotator cuff and scapula strengthening • Isotonic elbow/wrist/hand exercises	• Begin PNF • Progress throwers ten to include 90/90 exercises • Begin closed chain stabilization exercises • Begin upper extremity Plyoball exercises (two hand progressing to one hand)	• Continue above exercises • Begin interval throwing program	• Return to pitching when interval throwing program is completed

FIGURE 10-13. Patient progresses from two-handed Plyoball toss exercise (**A**) to one-handed wall dribble (**B**) and wrist flips (**C**).

Plyometrics

- Begin upper extremity Plyoball exercises using two hands, progressing to one hand (Figure 10-13).

Milestones for Progression to the Next Phase

- 80% shoulder and elbow strength

Phase V (weeks 14 to 24)

Goals

- Completion of interval throwing program

Treatment for Pain and Swelling

- Ice/cryotherapy post rehab

Therapeutic Exercises

- Stationary bike, elliptical, or running may be used to maintain cardiovascular endurance.
- Shoulder and scapular strengthening exercises (Thrower's 10 program)
- Core strengthening

Activation of Primary Muscles Involved in Injury Area or Surgical Structures

- UBE
- Isotonic elbow, wrist, and hand strengthening

Sensorimotor Exercises

- Rhythmic stabilization for elbow, and shoulder

Open (OKC) and Closed (CKC) Kinetic Chain Exercises

- Thrower's 10 (OKC)
- Closed chain stabilization exercises, stable surfaces, progressing to unstable surfaces (CKC)

Neuromuscular Dynamic Stability Exercises

- PNF patterns for the upper extremity

Plyometrics

- Upper extremity Plyoball exercises using two hands, progressing to one hand (see Figure 10-13).

Sport-Specific Exercises

- Interval throwing program

Criteria for Return to Play at 6 Months

- Normal upper extremity strength (90% of uninvolved side)
- Normal ROM
- Normal scapulothoracic mechanics
- Patient must have completed interval throwing program

After Return to Sport

- Athlete should maintain arm and body conditioning as described in the nonoperative section of this chapter.

Evidence

Cain EL, Dugas JR, Wolf RS, et al: Injuries in throwing athletes: A current concepts review. *Am J Sports Med* 27:621–635, 2003.

In this review of the diagnosis and treatment of overhead throwing injuries, the authors discuss anatomy and function of the elbow, biomechanics, mechanism of injury, and recent advances in surgical techniques used to treat the motivated athlete and return the athlete to competition. (Level V evidence)

Kibler WB: The role of the scapula in athletic shoulder function. *Am J Sports Med* 26:325–337, 1998.

Knowledge of the role and function of the scapula in shoulder function, injury, and rehabilitation helps the physician to provide more comprehensive care for the athlete. In this review, the author addresses those roles and functions. (Level V evidence)

Pabian PS, Kolber MJ, McCarthy JP: Post rehabilitation strength and conditioning of the shoulder: an interdisciplinary approach. *J Strength Cond Res* 33:42–54, 2011.

The authors' intent is to link the entire spectrum of the recovery process from common shoulder injuries for the understanding of the numerous professionals whom injured individuals will encounter. (Level of evidence NA)

Reinold MM, Escamilla RF, Wilk KE: Current concepts in the scientific and clinical rationale behind exercises for glenohumeral and scapulothoracic musculature. *J Orthop Sports Phys Ther* 39:105–117, 2009.

The authors of this paper provide the clinician with a thorough overview of the available literature relevant to develop safe, effective, and appropriate exercise programs for injury rehabilitation and prevention of the glenohumeral and scapulothoracic joints. (Level V evidence)

Wilk KE, Arrigo CA, Andrews JR: Current concepts: The stabilizing structures of the glenohumeral joint. *J Orthop Sports Ther* 25:364–379, 1997.

The authors of the review discuss concepts related to the anatomic stabilizing structures of the shoulder joint complex and their clinical relevance to shoulder instability. (Level V evidence)

Multiple Choice Questions

QUESTION 1. How long should a sling be worn postoperatively?

A. Never
B. 1 week
C. 2 to 6 weeks
D. 6 to 8 weeks

QUESTION 2. When should active range of motion of the hand begin?

A. 1 week
B. 2 weeks
C. 3 weeks
D. 4 weeks

QUESTION 3. When should the patient have full AROM of the involved elbow?

A. 2 weeks
B. 4 weeks
C. 6 weeks
D. 8 weeks

QUESTION 4. When should plyometrics be introduced into the rehab program?

A. Weeks 2 to 6
B. Never
C. Weeks 24+
D. Weeks 10 to 14

QUESTION 5. When should a patient be cleared to return to throwing?

A. Never
B. After completing the interval throwing program
C. 6 to 10 weeks
D. 10 to 14 weeks

Answer Key

QUESTION 1. Correct answer: **C** (see Phase II)

QUESTION 2. Correct answer: **A** (See Phase I)

QUESTION 3. Correct answer: **C** (See Phase II)

QUESTION 4. Correct answer: **D** (See Phase IV)

QUESTION 5. Correct answer: **B** (See Criteria for Return to Play at 6 Months)

BEYOND BASIC REHABILITATION: RETURN TO PITCHING AFTER OSTEOCHONDRITIS DISSECANS OF THE CAPITULUM

Rob Hopkins, PT, SC, and Champ L. Baker, Jr., MD

Introduction

KEY ASPECTS OF PITCHING THAT REQUIRE SPECIAL ATTENTION IN REHABILITATION

- Little League baseball has a high participation nationally.
- Overuse is the cause of most injuries.
- Pitching is a highly skilled activity and one of the most demanding of an individual's upper extremity.
- Pitching requires precise timing of multiple links in the kinetic chain.
- Pitching requires both upper and lower extremity flexibility, strength, and endurance.

Why Is Osteochondritis Dissecans of the Capitulum Being Reviewed?

- Elbow and shoulder injuries are common among young throwers.
- Many coaches and parents are ill informed as to the cause of injuries and the best techniques of injury prevention.
- Athletes are skeletally immature and are at a higher risk of injury than adults.
- There is often a desire to "play through the pain" among athletes, parents, and coaches.

Phase I: Advanced Strength and Conditioning Program[1]

Periodization

- Linear
- Undulating

Program Design/Performance Training Program

Sport-Specific Concepts of Integrated Training

- Training with optimum posture
- Sensorimotor and balance training
- Core training
- Cardiorespiratory training
- Multiplanar training activities
- Training for optimum muscle balance
- Training for optimum muscle functional strength
- Training for optimum muscle functional power
- Neuromuscular dynamic stability exercises

Olympic Lifts Used in the Training Program

- Squat
- Power clean

Training Principles Used in the Design of the Program

- Progression
- Overload
- Variation
- Individualization
- Specific adaptations to imposed demands (SAID)

Application of Acute Training Variables

- Repetitions: rotate between 5-10-15 reps
- Sets: two to four
- Rest: 30 sec to 2 min
- Intensity: low to high
- Repetition tempo: slow to fast
- Frequency: two to four times per week
- Duration: 45 to 60 min
- Volume: varies with intensity
- Specific exercises: body weight exercises focusing on form, rotator cuff strengthening, plank exercises for core

Application of Chronic Training Variables

- Sets, repetitions, and rest time are changed at each training session. This also changes volume and intensity and prevents chronic adaptations.

Phase II: Performance Enhancement Training Techniques

Periodization

- Linear
- Undulating

Program Design/Performance Training Program

Sport-Specific Concepts of Integrated Training

- Training with optimum posture
- Sensorimotor and balance training
- Core training
- Cardiorespiratory training
- Multiplanar training activities

- Training for optimum muscle balance
- Training for optimum muscle functional strength
- Training for optimum muscle functional power
- Neuromuscular dynamic stability
- Training for speed agility and quickness
- Plyometrics training
- Sport-specific training
- Single leg lunges
- BOSU and Swiss ball used when able
- Plyoball for upper extremity plyometrics

Olympic Lifts Used in the Training Program

- Squat
- Power clean

Training Principles Used in the Design of the Program

- Progression
- Overload
- Variation
- Individualization
- Specific adaptations to imposed demands

Application of Acute Training Variables

- Repetitions: rotate between 5-10-15 reps
- Sets: two to four
- Rest: 30 sec to 2 min
- Intensity: low to high
- Repetition tempo: slow to fast
- Frequency: two to four times week
- Duration: 45 to 60 min
- Volume: varies with intensity
- Specific exercises: single leg activities, use of BOSU and Core Board for standing upper extremity exercises, Swiss ball for seated exercises

Application of Chronic Training Variables

- Sets, repetitions, and rest time are changed at each training session. This also changes volume and intensity and prevents chronic adaptations.

Phase III: Sport-Specific Training

Periodization

- Linear
- Undulating

Program Design/Performance Training Program

Sport-Specific Concepts of Integrated Training

- Training with optimum posture
- Sensorimotor and balance training
- Core training
- Cardiorespiratory training
- Multiplanar training
- Training for optimum muscle balance
- Training for optimum muscle functional strength
- Training for optimum muscle functional power
- Neuromuscular dynamic stability
- Training for speed agility and quickness
- Plyometrics training
- Sport-specific training
- Single leg exercises versus double
- BOSU and Core Board used for standing exercises, Swiss ball used for seated and prone exercises
- Plyoball for upper extremity plyometrics

Olympic Lifts Used in the Training Program

- None

Training Principles Used in the Design of the Program

- Progression
- Overload
- Variation
- Individualization
- Specific adaptations to imposed demands

Application of Acute Training Variables

- Repetitions: rotate between 5-10-15 reps
- Sets: two to four
- Rest: 30 sec to 2 min
- Intensity: low to high
- Repetition tempo: slow to fast
- Frequency: two to four times week
- Duration: 45 to 60 min
- Volume: varies with intensity
- Specific exercises: Interval throwing program/long toss program. Pitching mechanics evaluation

Application of Chronic Training Variables

- Sets, repetitions, and rest time are changed at each training session. This also changes volume and intensity and prevents chronic adaptations.

Sports Performance Testing

General Information

- Medical history
- Injury history
- Throwing history (number of pitches per outing, season, year and what types of pitches thrown)

Specific Tests for Determining Readiness to Pitch

- Functional movement screen
- Hand held dynamometer for strength
- Physiological assessments
- Pitching mechanics evaluation (video)

Specific Criteria for Determining Readiness to Pitch

- Able to complete exercises with correct form/no substitution
- Pain free with all activities/exercises
- Athlete beginning to plateau with current program

Specific Criteria for Release to Unsupervised Complete Participation in Pitching

- Normal physical exam
- Completed interval throwing program
- Cleared by MD

Recommended Ongoing Exercises

- Posterior capsule stretching (sleeper stretch/cross-body stretch)
- Throwers 10 cuff program

Evidence

Axe MJ, Hurd W, Snyder-Mackler L: Data-based interval throwing programs for baseball players. *Sports Health* 1:145–152, 2009.

The authors developed data-driven programs based on the number, type, distance, and intensity of throws for baseball athletes at all levels of play. They recommend medical professionals use these programs for safe training, conditioning, and return to play. (Level of evidence NA.)

Fleisig GS, Andrews JR, Cutter GR, et al: Risk of serious injury for young baseball pitchers: A 10-year prospective study. *Am J Sports Med* 39:253–257, 2011.

In this study, 481 youth pitchers were followed for 10 years to determine whether increased amount of pitching, throwing curveballs at a young age, and concomitantly playing catcher increased a young pitcher's risk of injury. (Level III evidence)

Granacher U, Muehlbauer T, Maestrini L, et al: Can balance training promote balance and strength in prepubertal children. *J Strength Cond Res* 25(6):1759–1766, 2011.

The authors investigated the impact of balance training followed by detraining on postural control, plantar flexor strength, and jumping height in 30 prepubertal children. (Level of evidence NA.)

Marsh D: Little League elbow: Risk factors and prevention strategies. *Strength Cond J* 32:22–37, 2010.

The article discusses the risk factors and prevention strategies for Little League elbow in youth. (Level of evidence NA.)

Oliver JL, Lloyd RS, Meyers RW: Training elite child athletes: Promoting welfare and well-being. *Strength Cond J* 33:73–79, 2011.

Elite child athletes can be exposed to potentially large volumes of specialized training and early competition at a time when they are still maturing, thus exposing them to a variety of risks. This article identifies risks and provides recommendations to help coaches promote the welfare and well-being of elite child athletes during training. (Level of evidence NA.)

Multiple Choice Questions

QUESTION 1. Which one of the following is not an Olympic lift?

A. Deadlift
B. Snatch
C. Curl
D. Squat

QUESTION 2. Which of the following is not a reason returning an athlete to pitching is difficult?

A. Pitching is a highly skilled activity and one of the most demanding you can do with your upper extremity.
B. Pitching requires precise timing of multiple links in the kinetic chain.
C. Good pitchers only use their arms.
D. Most pitchers tend to throw too much.

QUESTION 3. Why is this topic being reviewed?

A. Most coaches are ill informed as to the causes of elbow injuries.
B. Young throwers are at a higher risk of injury.
C. Most young athletes want to play through the pain.
D. All of the above

QUESTION 4. Which of the following is an acute training variable?

A. Sets
B. Music playing
C. Temperature
D. Time of day

QUESTION 5. Which of the following is not a sports performance test used in sports-specific training?

A. Functional movement screen
B. 40-yard dash
C. Physiological assessments
D. Pitching mechanics evaluation (video)

Answer Key

QUESTION 1. Correct answer: **C** (see Phase I, Advanced Strength and Conditioning)

QUESTION 2. Correct answer: **C** (see Introduction)

QUESTION 3. Correct answer: **D** (see Introduction)

QUESTION 4. Correct answer: **A** (see Phase II: Performance Enhancement Training Techniques)

QUESTION 5. Correct answer: **B** (see Sports Performance Testing)

Chapter 11

Ulnar Collateral Ligament Injuries

INTRODUCTION

E. Lyle Cain, Jr., MD

Epidemiology

- Most common in young amateur or professional athletes, ages 15 to 40 years
- Most common in males, with 9:1 ratio male:female
- Most common in baseball, with occasional occurrence in other overhead sports (football, javelin throwing, softball, tennis, wrestling, soccer, gymnastics, cheerleading, and pole vaulting)
- Baseball pitchers make up 89%, followed by catchers
- Incidence evenly distributed among high school, collegiate, and professional levels
- Incidence of UCL injury requiring surgery in high school and adolescent athletes has risen dramatically in the past 5 years.

Pathophysiology

Intrinsic, Extrinsic, and Traumatic Factors

- Injury generally occurs during the acceleration phase of the throwing motion (Figure 11-1).
- Biomechanical factors resulting in poor power transfer from the trunk to the arm may predispose the athlete to UCL injury.
- Based on cadaveric testing, UCL tensile failure is approached with every throw, especially in high-velocity throwers.
- Overuse-type throwing habits result in repeated microtrauma to the static restraints of the throwing elbow, without adequate time for healing.

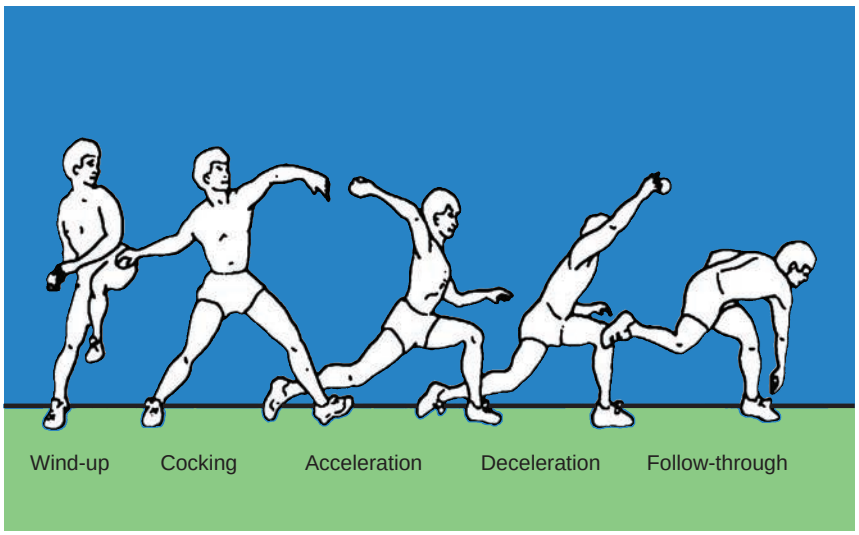

FIGURE 11-1. Phases of the overhead throwing motion.

- Accumulation of elbow microtrauma causes the UCL to become weakened and prone to catastrophic failure.
- The failure process is exacerbated by high pitch velocity, the throwing of breaking pitches, and inadequate warm-ups.

Classic Pathological Findings

- Anterior bundle of the ulnar collateral ligament (UCL) is the primary restraint to valgus stress at the elbow during functional range of motion between 20° and 120° of flexion.
- Dr. Frank Jobe pioneered surgical reconstruction of the UCL in 1974, often referred to as "Tommy John Surgery" in reference to the first recipient of the reconstruction procedure.

Clinical Presentation and Examination

- All patients report elbow pain while athletically active (throwing, tennis).
- Baseball players primarily (96%) complained of pain during the late cocking and acceleration phase of throwing.
- Half report an acute onset of pain at the medial elbow, whereas half cannot identify a single inciting event.
- For those athletes who can identify the onset of symptoms, three out of four report that the onset occurred during a game, 10% during practice, 10% during the preseason, 4% during the off-season, and 1% while playing recreationally.
- Decreased velocity and/or loss of control is a common complaint.

Abnormal Findings

- The primary exam finding is tenderness to palpation of the anterior band of the UCL.
- Pain with valgus stress (milking maneuver) and active valgus stress are common.
- Preoperatively one in four athletes has neurological symptoms, most commonly intermittent paresthesias in the ulnar nerve distribution (ring and small fingers) during throwing.

Pertinent Normal Findings

- Elbow range of motion is generally full, although many overhead athletes have a flexion contracture of about 5°.
- Only one in four patients demonstrates valgus instability to manual testing at 30° elbow flexion.

Imaging Studies

- Radiographic examination is normal in half, whereas half have assorted radiographic abnormalities, most commonly olecranon osteophyte formation and ectopic calcification within the UCL substance.
- Magnetic resonance arthrography (MRA) with intraarticular contrast is the gold standard diagnostic test.
- MRA may show complete tearing or a partial undersurface tear of the anterior band of the UCL.
- CT arthrogram is useful in patients who cannot undergo MRA
- Ultrasound may be useful in diagnosis and may be helpful to allow some level of reparative process of the ligament with nonsurgical treatment.

Differential Diagnosis

- Flexor pronator tendinitis: tenderness anterior to the UCL along the medial epicondyle, pain with resisted wrist pronation
- Ulnar neuritis: sensory disturbance to the ring and small fingers, positive Tinel's at the cubital tunnel, normal imaging
- Olecranon osteophyte/valgus extension overload: posterior medial pain along the olecranon tip with extension, pain during ball release or follow-through, osteophyte on radiographs

Treatment

Nonsurgical Options

- Rest: cessation from throwing or any valgus producing stress to the elbow
- NSAIDs
- Physical therapy to maintain elbow motion, decrease pain, strengthen both the shoulder and elbow musculature
- Injection of corticosteroids or platelet rich plasma: *controversial*

Guidelines for Choosing among the Nonsurgical Treatment Options

- Level of play: Higher level of play (major league) is more likely to have successful outcomes than lower level (high school, recreational).
- Degree of injury (partial vs. complete): Complete tears are more likely to lead to chronic symptoms.
- Timing of season: Return to play generally takes approximately 1 year.
- Position (pitcher vs. fielder): Pitcher and catcher require more elbow endurance, and may take longer to return after surgery.
- Acute versus chronic injury: Chronic ligament insufficiency is less likely to respond favorably to nonsurgical treatment.
- Symptom magnitude: Some athletes can participate at various levels (i.e., fielding but not pitching) despite ligament damage.

Surgical Indications

- Absolute: complete tear in pitcher who has failed nonoperative treatment and is unable to participate at the desired level of play

- Relative: any degree of tear in any sport or position that is unable to return to the desired level of competition after appropriate nonsurgical treatment, and is willing to participate in a minimum 1 year rehabilitation period
- Most UCL injuries in nonoverhead athletes (e.g., football, gymnastics, soccer) do not require surgery for continued participation.

Aspects of History, Demographics, or Exam Findings That Affect Choice of Treatment

- Age
- Level of play
- Degree of injury (partial vs. complete)
- Timing of season
- Position (pitcher vs. fielder)
- Acute versus chronic injury
- Symptom magnitude

Aspects of Clinical Decision Making When Surgery Is Indicated

- Graft choice: palmaris longus versus gracilis tendon (autografts)
- Additional procedures as indicated: ulnar nerve transposition, olecranon osteophyte excision, loose body removal
- Muscle-splitting versus modified Jobe (muscle elevation)
- Graft fixation: suture fixation versus interference screw versus docking

Evidence

Azar FM, Andrews JR, Wilk KE, et al: Operative treatment of ulnar collateral ligament injuries of the elbow in athletes. *Am J Sports Med* 28:16–23, 2000.

The authors evaluated the first large series of ulnar collateral ligament reconstructions (78) or repairs (13) by one surgeon (JRA). Thirty-seven patients (41%) were professional baseball players, 41 (45%) were collegiate baseball players, and 7 (7.7%) were high school or recreational players. Subcutaneous ulnar nerve transposition with stabilization of the nerve with fascial slings of the flexor pronator mass was performed in all patients. Reconstruction of the ulnar collateral ligament was found to be effective in correcting medial instability of the elbow and allowed most athletes (79%) to return to previous levels of play in less than 1 year. (Level IV evidence)

Cain EL, Andrews JR, Dugas JR, et al: Outcome of ulnar collateral ligament reconstruction of the elbow in 1281 athletes: Results in 743 athletes with minimum 2-year follow-up. *Am J Sports Med* 38:2426–2434, 2010.

The authors report follow-up data on a large case series of ulnar collateral reconstruction (1266) or repair (15) performed in 1281 patients over a 19-year period using a modification of the Jobe technique. Seven hundred forty-three patients (79%) were contacted for follow-up evaluation and/or completed a questionnaire at an average of 37 months postoperatively. Six hundred seventeen patients (83%) returned to the previous level of competition or higher. The average time from surgery to the initiation of throwing was 4.4 months and the average time to full competition was 11.6 months after reconstruction. Complications occurred in 148 patients (20%), including 16% considered minor and 4% considered major. (Level IV evidence)

Conway JE, Jobe FW, Glousman RE, et al: Medial instability of the elbow in throwing athletes. Treatment by repair or reconstruction of the ulnar collateral ligament. *J Bone Joint Surg Am* 74:67–83, 1992.

The authors report longer-term follow-up of the original Jobe cohort of UCL reconstruction. Seventy patients were reported at an average of 6.3 years post surgery. Seven of fourteen repairs (50%) and 38 of 56 (68%) reconstructions returned to the same level of competition or higher. Twelve of sixteen major league players were able to return to the major leagues after reconstruction. Ulnar neuropathy occurred postoperatively in 15 patients, with nine requiring subsequent surgery for the neuropathy. Patients with previous surgery on the elbow had a significantly lower chance of return to the same level of competition. (Level IV evidence)

Jobe FW, Stark H, Lombardo SJ: Reconstruction of the ulnar collateral ligament in athletes. *J Bone Joint Surg Am* 68:1158–1163, 1986.

The is the landmark article reported by Jobe on reconstruction of the ulnar collateral ligament using a free tendon graft on 16 athletes in sports that involved throwing (mostly professional baseball). Jobe describes his surgical technique and rehabilitation program. Ten of the sixteen patients returned to their previous level of participation in sports, one returned to a lower level of participation, and five retired from professional athletics. There was a high incidence of complications related to the ulnar nerve. Two patients had postoperative ulnar neuropathy that required a secondary operation, but they eventually recovered completely, and three others reported some transient postoperative hypoesthesia that resolved after a few weeks or months. (Level IV evidence)

Petty DH, Andrews JR, Fleisig GS, et al: Ulnar collateral ligament reconstruction in high school baseball players: Clinical results and injury risk factors. *Am J Sports Med* 32:1158–1164, 2004.

The authors report the outcome of ulnar collateral ligament reconstruction and evaluated potential risk factors for injury at the high school level. Follow-up physical examination and questionnaire data were collected at an average of 35 months after ulnar collateral ligament reconstruction from 27 former high school baseball players. Six potential risk factors were evaluated: year-round throwing, seasonal overuse, event overuse, throwing velocity more than 80 mph, throwing breaking pitches before age 14, and inadequate warm-ups. Overall, 74% returned to baseball at the same or higher level. Patients averaged three potential risk factors, and 85% demonstrated at least one overuse category. Of the pitchers, the average self-reported fastball velocity was 83 mph, and 67% threw breaking pitches before age 14. The success rate of ulnar collateral ligament reconstruction in high school baseball players is nearly equal to that in more mature groups of throwers. Overuse of the throwing arm and throwing breaking pitches at an early age may be related to their injuries. Special attention should be paid to elite-level teenage pitchers who throw with high velocity. (Level IV evidence)

Smith GR, Altchek DW, Pagnani MJ, et al: A muscle-splitting approach to the ulnar collateral ligament of the elbow. Neuroanatomy and operative technique. *Am J Sports Med* 24:575–580, 1996.

The authors describe the relevant anatomy of a novel surgical approach to the UCL by a muscle-splitting approach, rather than the traditional muscle detachment (Jobe) or elevation (Andrews).

Thompson WHJF, Yocum LA: Ulnar collateral ligament reconstruction in throwing athletes: Muscle-splitting approach without transposition of the ulnar nerve [abstract]. *J Shoulder Elbow Surg* 7:175, 1998.

The authors report the outcome of UCL reconstruction with a muscle-splitting approach without transposition of the ulnar nerve in 83 athletes with medial elbow instability. Thirty-three were available for minimum 2-year follow-up. Postoperatively, 5% of this group had transient ulnar nerve symptoms, all of which resolved with nonoperative management. There were no reoperations for nerve dysfunction and no permanent nerve problems. Ninety-three percent of the highly competitive athletes who had not had a prior surgical procedure had an excellent result. All athletes, regardless of whether they had a prior procedure, were able to return to their sport. The authors felt these surgical modifications yielded a decreased postoperative complication rate and improved outcomes compared with the results of prior procedures. (Level IV evidence)

Multiple Choice Questions

QUESTION 1. During which phase of the throwing motion do symptoms most commonly occur with UCL injury?

A. Wind-up
B. Acceleration
C. Ball release
D. Follow-through

QUESTION 2. What position in baseball most commonly injures the UCL?

A. Catcher
B. Infield
C. Outfield
D. Pitcher

QUESTION 3. What is the most common physical exam finding with UCL injury?

A. Pain with resisted pronation
B. Positive Tinel's at the cubital tunnel
C. Pain with valgus stress
D. Loss of motion

QUESTION 4. What percentage of athletes is expected to return to the same level or higher competition after UCL reconstruction?

A. Less than 25%
B. 25% to 50%
C. 50% to 75%
D. Greater than 75%

QUESTION 5. What is the gold standard diagnostic test for UCL injury?

A. Plain radiographs
B. CT scan
C. Ultrasound
D. Arthrogram MRI

Answer Key

QUESTION 1. *Correct answer:* **B** (see Clinical Presentation)

QUESTION 2. *Correct answer:* **D** (see Epidemiology)

QUESTION 3. *Correct answer:* **C** (see Clinical Presentation)

QUESTION 4. *Correct answer:* **D** (see Evidence)

QUESTION 5. *Correct answer:* **D** (see Imaging Studies)

NONOPERATIVE REHABILITATION OF ULNAR COLLATERAL LIGAMENT INJURIES

E. Lyle Cain, Jr., MD, Kevin E. Wilk, PT, DPT,
and Todd R. Hooks, PT, OCS, SCS, ATC, MOMT, MTC, CSCS, FAAOMPT

GUIDING PRINCIPLES OF REHABILITATION

- Restrict elbow range of motion and valgus forces during the early phases of treatment to minimize stresses upon healing structures.
- Conduct a proper assessment and institute a proper rehabilitation of the entire kinetic chain to reduce the valgus stresses imparted upon the elbow during overhead athletics.
- Ensure an appropriate functional interval return to play program is implemented to allow for a controlled progression into sporting activities.
- Proper communication between coach, player, physician, and clinician to determine appropriate return to play guidelines based upon sport of the athlete.

Phase I (Immediately following injury through week 2)

Protection

- A hinged elbow brace is used to restrict motion and prevent valgus strain.
- The athlete is allowed to perform personal care ADLs while wearing brace.

Management of Pain and Swelling

- Analgesic and antiinflammatory medications may be used as needed to decrease pain and swelling.
- The athlete is instructed to perform cryotherapy for 20 minutes every hour throughout the acute phase or until swelling subsides.
- Therapeutic modalities (IFC, Hi-Volt, TENS, and low level laser therapy [cold laser]) can be used to decrease pain and inflammation and augment the healing process.
- A compression wrap can be worn to decrease swelling.

Techniques for Progressive Increase in Range of Motion

Manual Therapy Techniques

- The rehabilitation specialist can perform manual PROM of the elbow within 20° to 90° to neuromodulate pain and aid in collagen alignment of the healing ligamentous tissue.

Soft Tissue Techniques

- The clinician may begin edema massage from distal to proximal to assist in swelling reduction.
- Soft tissue mobilizations to decrease muscle guarding and tone can be performed by the clinician.

Stretching and Flexibility Techniques for the Musculotendinous Unit

- Light pain-free stretching activities can be prescribed for the wrist and forearm musculature within the prescribed elbow range of motion limitations.
- Shoulder PROM can be conducted to maintain capsular and shoulder mobility.

Other Therapeutic Exercises

- The athlete can perform stationary biking activities while wearing a hinged elbow brace to maintain cardiovascular fitness.
- Core strengthening exercises that do not task the upper extremity, such as crunches, can be implemented.
- Lower extremity strengthening and stretching exercises may be initiated to retard muscle atrophy and maintain flexibility.

Activation of Primary Muscles Involved

- Week 1: gripping exercises, wrist, elbow, and shoulder isometrics
- Week 2: rotator cuff (ER/IR tubing at 0° abduction, full can, and abduction) and scapular (prone row, prone horizontal abduction) exercises can be performed.

Sensorimotor Exercises (Balance Proprioception, Kinesthesia)

Rhythmic stabilization drills for the scapula (Figure 11-2), shoulder, and elbow joint can be performed as well as passive/active joint repositioning for sensorimotor stimulus (Figure 11-3).

Open and Closed Kinetic Chain Exercises

- Week 1: OKC exercises for the throwing arm are performed to minimize any undue stresses at the elbow.
- Week 2: CKC exercises can be initiated such as wall wipes (Figure 11-4) and table slides.

FIGURE 11-2. Sitting rhythmic stabilization drills performed to develop proximal stability for the upper extremity during throwing.

FIGURE 11-3. Passive/Active reproduction of the elbow can be performed as the clinician will impart a passive motion upon the elbow as the athlete's eyes are closed. The athlete actively reproduces this joint angle to provide proprioceptive input.

Techniques to Increase Muscle Strength, Power, and Endurance

- The patient will perform low resistance, high repetition exercises for the involved upper extremity to improve vascularity, endurance, and diminish atrophy.

Neuromuscular Dynamic Stability Exercises

- The athlete may perform sitting or side-lying scapular PNF (Figure 11-5) and neuromuscular drills.
- The clinician can give tactile and verbal cueing to the patient to assist in proper muscle recruitment and correct movement patterns during the exercises.

Milestones for Progression to the Next Phase

- Minimal joint effusion
- Elbow ROM 20° to 90°
- Pain free special tests and minimum to no increased laxity with valgus stress testing
- No pain to palpation at medial elbow

Phase II (weeks 2 to 10)

Protection

A hinged elbow brace should continue to be used and will be gradually opened 10° per week.

Management of Pain and Swelling

- The patient can continue with NSAID treatment as prescribed by MD.
- The clinician can initiate rehabilitation with moist hot pack to increase local blood flow and prepare tissues for treatment by increasing tissue extensibility.

TIMELINE 11-1: **Nonoperative Rehabilitation Following Ulnar Collateral Ligament Sprains of the Elbow in Throwers**

PHASE I (weeks 0 to 2)	PHASE II (weeks 3 to 10)

• Goals:
  • Increase range of motion
  • Promote healing of ulnar collateral ligament
  • Retard muscular atrophy
  • Decrease pain and inflammation
• Absolute control of valgus forces for __ weeks (physician discussion)
• ROM:
  • Brace (optional) nonpainful ROM [20°-90°]
  • AAROM, PROM elbow, and wrist (nonpainful range)
  • Shoulder ROM, especially internal rotation and horizontal adduction
• Exercises:
  • Isometrics wrist and elbow musculature
  • Shoulder strengthening (Throwers' Ten Program)
  • Initiate rhythmic stabilization of elbow
• Ice and compression
	• Goals:
	  • Increase range of motion
	  • Improve strength/endurance
	  • Decrease pain and inflammation
	  • Promote stability
	• ROM: Gradually increase motion 0° to 135° (increase 10° per week)
	• Exercises:
	  • Continue Throwers' Ten Program
	  • Initiate manual resistance of elbow/wrist flexor/pronator
	  • Emphasize wrist flexor/pronator strengthening
	  • Initiate rhythmic stabilization drills for elbow
	• Ice and compression
	• No throwing motion or valgus stress

FIGURE 11-4. Closed kinetic chain exercises can be initiated with exercises such as wall wipes. The athlete can emphasize the rotator cuff by performing circular movements and target the scapular musculature with horizontal abduction/adduction motions.

FIGURE 11-5. Side-lying scapula PNF. The clinician will give tactile input to the superior, medial, inferior border of the scapula, and at the elbow to provide resistance as the athlete performs scapula elevation, retraction, depression, and protraction.

- Laser treatment can also be performed to assist in soft tissue healing.
- Following the rehabilitation treatment, the clinician can mitigate any exercise induced inflammation and/or soreness with the use of ice, compression, and electrical stimulation treatment.

Techniques for Progressive Increase in Range of Motion

Manual Therapy Techniques

- The clinician can progress with passive range of motion to the elbow to allow full elbow range of motion by week 4.

Soft Tissue Techniques

- The clinician should assess for any increase muscle guarding, tone, and/or trigger points.
- The clinician can perform soft tissue mobilization techniques to restore normal muscle extensibility and hemodynamics to the forearm musculature.

Stretching and Flexibility Techniques for the Musculotendinous Unit

- The athlete can continue to progress with a flexibility program for the forearm and glenohumeral musculature.
- The clinician should assure full mobility and flexibility of the scapula, trunk, and lower extremity to allow for the transfer and absorption of kinetic chain energy to optimize performance and decrease potential strains incurred during overhead athletics.

TIMELINE 11-1: **Nonoperative Rehabilitation Following Ulnar Collateral Ligament Sprains of the Elbow in Throwers** (Continued)

PHASE III (weeks 10 to 14)

- Criteria to progress:
  - Full range of motion
  - No pain or tenderness
  - No increase in laxity
  - Strength 4/5 of elbow flexor/extensor
- Goals:
  - Increase strength, power, and endurance
  - Improve neuromuscular control
  - Initiate high speed exercise drills
- Exercises:
  - Initiate isotonic strengthening
  - Thrower's Ten Program
  - Biceps/triceps program
  - Supination/pronation wrist
  - Extension/flexion
  - Plyometrics throwing drills
- Two- hand drills at week 10 to 12
- Single arm plyos at week 12 to 14

PHASE IV (weeks 14 to 18)

- Criteria to progress to return to throwing:
  - Full nonpainful ROM
  - No Increase in laxity
  - Isokinetic test fulfills criteria
  - Satisfactory clinical exam
  - No pain on valgus stress test
- Exercises:
  - Initiate interval throwing—monitor signs and symptoms
  - Continue Thrower's Ten Program
  - Continue plyometrics
  - Continue rhythmic stabilization drills

Other Therapeutic Exercises

- Lower extremity exercises can be progressed including elliptical and machine-based LE strengthening exercises.
- The athlete can perform well-armed strengthening exercises such as lateral raises, shoulder rows, and shoulder press to maintain strength and promote the neuromuscular crossover effect for the involved upper extremity.
- Core strengthening and stabilization exercises can be performed including planks, and stabilization exercises on unstable surface (physio ball) (Figure 11-6).

Activation of Primary Muscles Involved

- Wrist strengthening exercises are progressed, with emphasis upon wrist flexion and pronation strengthening.
- Biceps and triceps exercises can be implemented as tolerated.
- Scaption, abduction, side-lying ER, prone row, prone extension, prone horizontal abduction, prone scaption, and prone row into ER are progressed as tolerated.

Sensorimotor Exercises (Balance Proprioception, Kinesthesia)

- Lower extremity proprioception and coordination drills can be performed for hip/core stabilization, including: tilt board squats, single leg activities, and perturbation training drills.

Open and Closed Kinetic Chain Exercises

- CKC exercises can be integrated into rehabilitation program, including stabilization exercises on a ball (Figure 11-7), push-up plus, and upper extremity machine-based weight training. The athlete is instructed to perform these exercises in a pain-free range and perform the exercise with the elbows maintained close to the trunk to minimize strain upon the UCL.

FIGURE 11-6. Trunk and scapula stabilizations performed on a BOSU ball as the clinician incorporates perturbations upon the athlete's trunk and upper extremity.

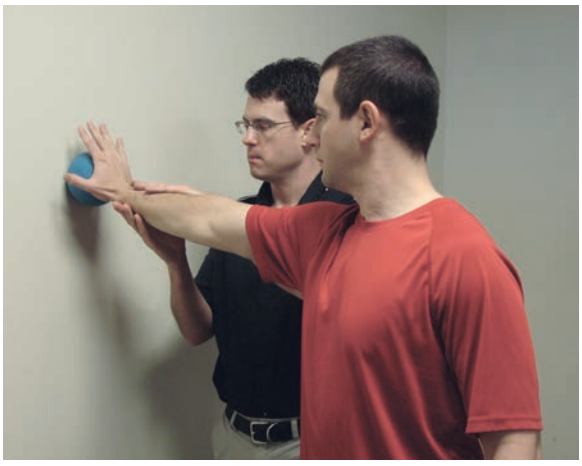

FIGURE 11-7. Ball on wall stabilization drills. The athlete places an open palm onto a ball and maintains a static position while keeping the elbow extended as the clinician performs rhythmic stabilizations. These stabilization can begin proximally upon the upper arm and progress distally upon the wrist.

Techniques to Increase Muscle Strength, Power, and Endurance

- The athlete can be progressed with strengthening exercises by decreasing repetitions and increasing weight to allow for progression training of the forearm, glenohumeral, and scapulothoracic musculature.

Neuromuscular Dynamic Stability Exercises

- Manual PNF resistance exercises for the distal arm can by performed by alternating resistance of the elbow, wrist, and finger flexion and forearm supination followed by elbow, wrist, and finger extension and forearm pronation (Figure 11-8).
- Manual resistance exercises can also be performed for external rotation. Because of the high EMG activity in

FIGURE 11-8. Manual PNF resistance of the elbow/wrist performed as the clinician concomitantly resists elbow, wrist, and finger flexion and supination followed by elbow, wrist, and finger extension and pronation.

the follow-through phase of throwing, eccentric manual resistance exercises can be implemented for the scapula, rotator cuff, and forearm musculature.

Functional Exercises

- The athlete should perform total body strengthening exercises to allow for synchronization of hips/core/shoulder movement patterns. This can also include performing single leg and split stance exercises, as well as PNF patterns involving the trunk and lower extremities.
- Agility exercises for the lower extremity such as cone and agility ladder exercises can be incorporated into the athlete's program.

Sport-Specific Exercises

- Athletes involved in contact sports and those suffering from injury on the nondominant extremity may be released to return to competitive sports following clearance from MD.
- In addition, quarterbacks have been shown to return to competition sooner than baseball pitchers. Dodson et al. (2010) reported a mean return to play following nonoperative management of an acute UCL injury to be 26.4 days; therefore proper communication is needed to determine appropriate return to play expectations.

Milestones for Progression to the Next Phase

- Full, pain-free elbow range of motion
- MMT 5/5 for involved upper extremity
- Satisfactory clinical examination with negative valgus laxity and provocation testing.

Phase III (weeks 10 to 14)

Protection

- The hinged elbow brace can be discharged during this phase.

Management of Pain and Swelling

- Cryotherapy can be used following treatment as needed to avoid post-rehabilitation soreness and inflammation.

Techniques for Progressive Increase in Range of Motion

Manual Therapy Techniques

- Ensure the athlete maintains full elbow and shoulder range of motion throughout treatment and avoiding the potential loss of motion with the addition of plyometric and the integration of sporting activities.

Soft Tissue Techniques

- The clinician should continue to evaluate the entire upper extremity and scapular musculature to assess for pliability of the soft tissue. Soft tissue restrictions, trigger points, and decreased flexibility could cause movement impairments for the athlete.
- The clinician can perform soft tissue mobilization treatments and in addition instruct the athlete in soft mobilization techniques as part of the activity warm-up and cool down program.

Stretching and Flexibility Techniques for the Musculotendinous Unit

- The clinician should continue to monitor the flexibility and pliability of the soft tissue of the entire upper extremity to ensure the athlete does not develop any diminished flexibility as the result of delayed onset muscle soreness (DOMS).

Other Therapeutic Exercises

- Lower extremity strength training should continue to be progressed for quadriceps, hamstrings, and hip musculature. These exercises can be progressed to include functional exercises such as multidirectional lunges, and step up drills.
- Core stabilization and strengthening exercises should be progressed to include stable and unstable surfaces and resistive core training.
- Upper extremity weight training can be progressed with rows, lat pull downs, shoulder presses, and bench press as tolerated.

Activation of Primary Muscles Involved

- The athlete should continue with Thrower's Ten exercise progression (see Figure 11-3).

Sensorimotor Exercises (Balance Proprioception, Kinesthesia)

- The athlete can perform PNF training exercises on unstable surface in both seated and standing position to allow integration of core and lower extremity stabilization.

Open and Closed Kinetic Chain Exercises

- The athlete can progress with upper extremity CKC exercises including front and side planks, push ups, and weight bearing stabilization drills on unstable surfaces as deemed necessary based upon sporting participation.

Techniques to Increase Muscle Strength, Power, and Endurance

- Lower extremity and core strengthening and stabilization exercises can be performed in a kneeling, double and single leg stance to allow for functional training of the athlete.
- Upper extremity strengthening exercises are progressed with machine and free weight training with bench press, rows, latissimus dorsi pull downs, and triceps extension exercises are incorporated.

Neuromuscular Dynamic Stability Exercises

- Dynamic rhythmic stabilization and upper extremity strengthening exercises can be performed with the arm

FIGURE 11-9. Stabilization drills performed at 90/90 position as the athlete performs external plyometric wall dribbles.

in an overhead position to increase strength and stability with the arm in a functional position (Figure 11-9).

Plyometrics

- Two-hand plyometric exercises are initiated at week 10. The athlete will begin with hands close to the trunk with chest and side throws, and progress to side-to-side throws and soccer style throw.
- The athlete will perform two hand plyometric exercises for approximately 2 weeks and upon successful completion will progress to one-hand plyometric drills.

Functional Exercises

- A swimming program can be implemented to include an aquatic shoulder therapeutic program that can be performed as an adjunct to the rehabilitation program.

Sport-Specific Exercises

- Stabilization exercises and manual resistance training drills are performed in an overhead position. The athlete can perform plyometric exercises and drills that incorporate the trunk and lower extremity with weighted medicine balls (Figure 11-10).

Milestones for Progression to the Next Phase

- Full pain-free elbow ROM
- Satisfactory clinical examination, including valgus and provocation testing
- Satisfactory completion of two-hand plyometric drills
- MMT 5/5 strength all muscle groups

Phase IV (weeks 14 to 18)

Protection

- Functional elbow brace if prescribed by MD if athlete is involved in a contact sport

Management of Pain and Swelling

- Cryotherapy as needed to mitigate postexercise-induced soreness.

Techniques for Progressive Increase in Range of Motion

Manual Therapy Techniques

- PROM to maintain full wrist, elbow, and shoulder ROM

Soft Tissue Techniques

- The clinician can continue with soft tissue mobilization techniques to address facial or musculature restrictions as well and any tone or trigger points that may occur as part of an increase in workload activities.

Stretching and Flexibility Techniques for the Musculotendinous Unit

- Flexibility exercises for the wrist, elbow, and shoulder musculature are encouraged throughout the rehabilitation program pre- and posttreatment to minimize postexercise soreness.

Other Therapeutic Exercises

- Lower extremity strengthening exercises are progressed with free and machine-based strengthening exercises.
- The athlete can progress with dynamic movement drills to replicate throwing motion. Core stabilization exercises drills can be performed in quadruped, kneeling, and standing position to progress with core training.

Activation of Primary Muscles Involved

- Advanced Thrower's Ten exercise program is continued and can be performed on stability ball to integrate core stabilization with upper extremity exercises.

Sensorimotor Exercises (Balance Proprioception, Kinesthesia)

- PNF patterns to include the trunk and upper extremity using medicine balls, cables, or kettle bells (Figure 11-11).

FIGURE 11-10. Forward lunge with overhead plyometric toss to incorporate trunk synchronization with upper extremity movement patterns.

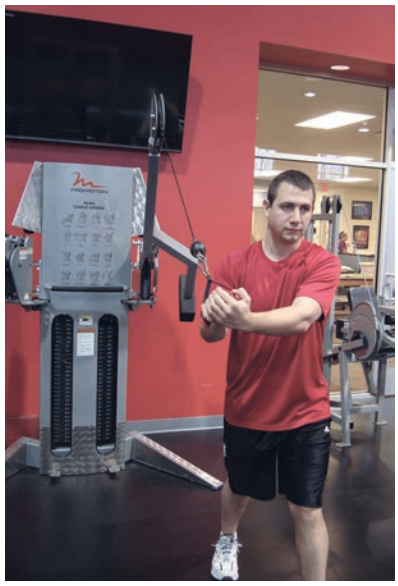

FIGURE 11-11. Cable chops performed in a split stance position.

Open and Closed Kinetic Chain Exercises

- Upper extremity CKC exercises on both stable and unstable support to facilitate proprioception input. These exercises and drills can be performed with and without manual stabilizations.

Techniques to Increase Muscle Strength, Power, and Endurance

- The athlete can perform high-speed coordination and neuromuscular training exercises for the involved upper extremity including the rotator cuff and biceps musculature. Training at high speeds prepares the athlete for sporting activity to eccentrically control and dissipate the forces that are imparted upon the elbow during overhead activities such as throwing.

Neuromuscular Dynamic Stability Exercises

- Dynamic training exercises on unstable surfaces, trunk perturbations, and single leg activities are performed to mimic the throwing motion.

Plyometrics

- One-hand plyometric drills are initiated at week 12. These exercises are begun with internal and external rotation throws at 0° of abduction and wall dribbles. These exercises can be progressed to 90/90 throws and simulated throwing motion.

Functional Exercises

- Lower extremity agility and sport-specific running program to increase overall cardiovascular function and preparation for athletic competition.

Sport-Specific Exercises

- Initiate interval throwing program (Phase I) can be implemented during this phase and progressed to throwing off the mound (Phase II) upon successful completion.

Table 11-1 Isokinetic Testing of Elbow Flexion/Extension

Bilateral Comparison		
Velocity	**Elbow (Flex)**	**Elbow (Ext)**
180°/sec	110% to 120%	105% to 115%
300°/sec	0.5% to 115%	100% to 110%
Unilateral Muscle Ratios		
Velocity	**Elbow (Flex/Ext)**	
180°/sec	70% to 80%	
300°/sec	63% to 69%	

Milestones for Progression to the Next Phase

- Pain that limits athlete at sporting activity
- Inability to complete sport specific program
- Unsatisfactory clinical examination including valgus testing
- Inability to return to competition following 3+ months of conservative management

Milestones for Progression to Advanced Sport-Specific Training and Conditioning

- Full elbow ROM
- Completion of sport-specific training program
- Isokinetic testing of bilateral elbow flexion and extension reveals: elbow flexion 10% to 20% stronger and 5% to 15% stronger in extensors as compared with the noninvolved arm
- Satisfactory isokinetic testing (Table 11-1).

Tips and Guidelines for Transitioning to Performance Enhancement

- The clinician should make certain the athlete maintains full shoulder and elbow ROM throughout the rehabilitation and return to sports program in order to minimize any stresses imparted upon the elbow with throwing activity.
- Total arm including scapular muscle strength should be emphasized during treatment to increase performance and minimize injury potential.
- The clinician should ensure a systematic program is used, including strength training, proprioception drills, flexibility, and proprioception, performed before the initiation of a throwing program.

Performance Enhancement and Beyond Rehab: Training/Trainer, and Optimization of Athletic Performance

- Continued maintenance program for the throwing athlete during the season that is usually performed every other day

- Endurance and cardiovascular fitness to decrease injuries related to fatigue
- Core strengthening and stabilization exercises to allow for efficient transfer and dissipation of energy throughout the kinetic chain.

Specific Criteria for Return to Sports Participation: Tests and Measurements

- Satisfactory clinical examination
- Clearance by MD
- Successful completion of an interval sporting program
- Pain and symptom free with sports participation
- MMT 5/5 strength for all muscle groups
- Satisfactory isokinetic testing (see Table 11-1)

Evidence

Dodson CC, Slenker N, Cohen SB, et al: Ulnar collateral ligament injuries of the elbow in professional football quarterbacks. *J Shoulder Elbow Surg* 19:1276–1280, 2010.

This retrospective study examined the outcome of 10 reported cases of UCL injuries in NFL quarterbacks from 1994 to 2008. Nine cases were treated nonoperatively and were able to return to play at a mean of 26.4 days. (Level III evidence)

Elliott B, Fleisig G, Nicholls R, et al: Technique effects on upper limb loading in the tennis serve. *J Sci Med Sport* 6:76–87, 2003.

This controlled laboratory study analyzed the kinematics and kinetics during a tennis serve of 20 male and female Olympic athletes. The authors noted athletes who demonstrated less knee flexion of the front leg during the backswing of the serve (7.6 degrees vs. 14.7 degrees) had an increased valgus load of 21% at the elbow.

Fleisig GS, Bolt B, Fortenbaugh D, et al: Biomechanical comparison of baseball pitching and long-toss: Implications for training and rehabilitation. *J Orthop Sports Phys Ther* 41:296–303, 2011.

This controlled laboratory study examined the kinematic and kinetic differences between pitching from a mound and a long-toss in 17 healthy college pitchers. Analysis was performed during mound pitching, horizontal throws at 37 and 55 m, and maximum distance throws with no restraint upon arc of trajectory. Results indicate that horizontal, flat throws produce biomechanical patterns similar to pitching, whereas maximum distance throws had increased torques (including an elbow varus torque) as compared to mound pitching.

Rettig AC, Sherrill C, Snead DS, et al: Nonoperative treatment of ulnar collateral ligament injuries in throwing athletes. *Am J Sports Med* 29:15–17, 2001.

This retrospective study examined the outcome of 31 throwing athletes following ulnar collateral ligament injury and determined which factors would predict return to competition nonoperatively. Thirteen (42%) athletes were able to return the previous level of competition at an average of 24.5 weeks. No findings obtained through history or physical examination were noted to predict successful outcome. (Level III evidence)

Multiple Choice Questions

QUESTION 1. Once adequate strength, range of motion, and tissue healing has occurred, when is it safe to begin a plyometric program?

A. Week 2
B. Week 6
C. Week 10
D. Week 16

QUESTION 2. Based upon anatomical approximation to the UCL, these muscle groups are emphasized during rehabilitation to provide dynamic stability to the medial aspect of the elbow with overhead athletics.

A. Wrist extensors and forearm pronators
B. Wrist extensors and forearm supinators
C. Wrist flexors and forearm pronators
D. Wrist flexors and forearm supinators

QUESTION 3. A hinged elbow brace is frequently prescribed during the acute phase to minimize stress upon the UCL and diminish inflammation. What range of motion guidelines are generally used for elbow motion?

A. 0° to 90° for 1 week, full elbow motion by week 2
B. 20° to 90° for 2 weeks, full elbow motion by week 4
C. 40° to 100° for 4 weeks, full elbow motion by week 6
D. Full elbow ROM allowed immediately within brace

QUESTION 4. Which statement is NOT true in regard to Phase II (weeks 3 to 10)?

A. An interval throwing program can be initiated during this phase.
B. Elbow range of motion is gradually restored to full range.
C. Thrower's Ten Program is progressed for elbow, glenohumeral, and scapulothoracic strengthening.
D. Hinged elbow brace may be discharged during this phase.

QUESTION 5. Which of the following criteria would warrant failure of nonoperative treatment and consideration of surgical repair of UCL?

A. Unable to complete sport-specific program
B. Failure to return to competition following 3+ months of conservative management
C. Pain that limits sporting activity
D. All of the above

Answer Key

QUESTION 1. Correct answer: **C** (see Phase III)

QUESTION 2. Correct answer: **C** (see Phase II)

QUESTION 3. Correct answer: **B** (see Phases I and II)

QUESTION 4. Correct answer: **A** (see Phase II)

QUESTION 5. Correct answer: **D** (see Phase IV)

POSTOPERATIVE REHABILITATION AFTER ULNAR COLLATERAL LIGAMENT RECONSTRUCTION

E. Lyle Cain, Jr., MD, Kevin E. Wilk, PT, DPT,
and Todd R. Hooks, PT, OCS, SCS, ATC, MOMT, MTC, CSCS, FAAOMPT

Indications for Surgical Treatment

- Physical examination demonstrating excessive valgus instability
- Imaging studies (i.e., MRI) confirming UCL injury (Figure 11-12)
- Persistent pain with inability to perform at desired level of sports/activities
- Failure of nonoperative rehabilitation program
- Surgery may be recommended without undergoing nonoperative rehabilitation in the overhead athlete depending on history and seasonal timing issues.

Brief Summary of Surgical Treatment

Major Surgical Steps

- Our current surgical approach is a modification of the original technique described by Jobe et al.
- The modifications include elevation of the flexor-pronator muscle mass without detachment and subcutaneous rather than submuscular ulnar nerve transposition.
- An anterolateral arthroscopic portal is established for evaluation of the anterior compartment articular surfaces and synovium and to perform the arthroscopic valgus stress test at 70° of flexion with the arm pronated.
- A medial opening of greater than 1 to 2 mm suggests ulnar collateral ligament insufficiency.
- The open procedure begins with a medial incision centered over the medial epicondyle.
- The medial antebrachial cutaneous nerve is initially identified and protected.
- The ulnar nerve is carefully dissected free from the cubital tunnel and protected with a vessel loop. Ulnar nerve release must continue proximally to the arcade of Struthers and distally into the flexor carpi ulnaris muscle mass.
- A portion of the medial intermuscular septum is removed to prevent tenting of the ulnar nerve after transposition.
- The anterior band of the ulnar collateral ligament is exposed by elevation of the flexor muscles from the ulnar collateral ligament distal attachment at the sublime tubercle of the ulna.
- The ligament is inspected for attenuation or tearing and is incised longitudinally to permit visualization of the deep portion of the ligament if a complete tear is not present.
- If concomitant valgus extension overload with olecranon osteophytes is suspected, a vertical posterior capsulotomy is placed proximal to the fibers of the posterior band of the ulnar collateral ligament to expose the olecranon tip. Posteromedial olecranon osteophytes are removed with a small osteotome and high-speed burr.
- Graft harvest is then performed. Ipsilateral palmaris longus tendon is our current graft choice, followed by contralateral palmaris longus or contralateral gracilis (autografts).
- The median nerve lies deep to the palmaris longus tendon and should be protected during harvest by avoiding deep dissection.
- Tunnels are then placed in the ulna and medial epicondyle with a 3.2-mm drill bit. A single ulnar tunnel is made by placing two ulnar drill holes 3 to 4 mm distal to the articular surface of the coronoid process, separated by approximately 1 cm at the native attachment site of the ulnar collateral ligament.
- Two medial epicondylar tunnels are placed along the proximal portion of the epicondyle and converge at the origin of the native ulnar collateral ligament.
- The graft is then passed in a figure-eight fashion.
- The elbow is placed at 30° of flexion and varus stress is applied while the graft is secured side-to-side with multiple nonabsorbable sutures.

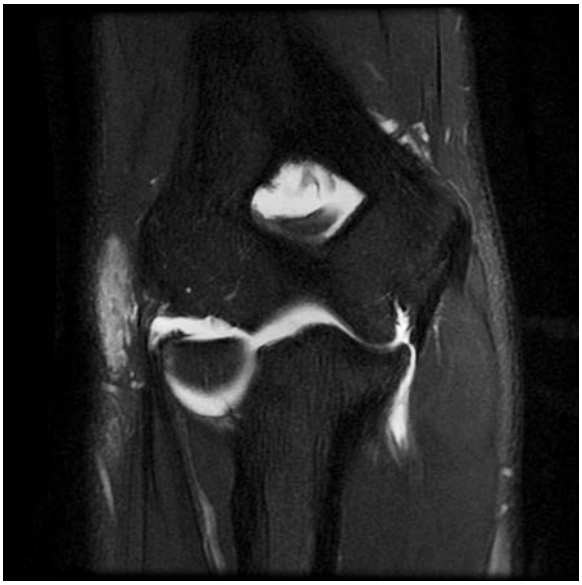

FIGURE 11-12. MRI of a full-thickness UCL tear.

- The ulnar nerve is then transposed subcutaneously and held in place with a single fascial sling from the flexor pronator muscle fascia. The sling is tensioned loosely to prevent any compression of the ulnar nerve.
- The skin is closed with subcuticular suture and the elbow is splinted at 90° of flexion for the first week after surgery to allow soft tissue healing.

Factors That May Affect Rehabilitation

- Graft choice, graft fixation, additional procedures (osteophyte excision, ulnar nerve transposition)

Other Surgical Techniques and Options

- Other techniques use a flexor muscle splitting approach, often without ulnar nerve transposition.
- Graft fixation using interference screws or a "docking technique" may also alter the rehab program.

Before Surgery: Overview of Goals and Guidelines[1]

- Educate patient about postoperative rehabilitation and expectations.
- Normalize elbow range of motion and document preoperative elbow motion.
- Diminish pain and swelling.
- Perform wrist, elbow, glenohumeral, and scapula strengthening exercises.
- Normalize shoulder ROM and scapular posture.

GUIDING PRINCIPLES OF POSTOPERATIVE REHABILITATION

- Understand the surgical technique, including graft selection and whether a concomitant ulnar nerve transposition was performed.
- Appreciate the biomechanical stresses that occur with exercises and activities during the rehabilitation program.
- Utilization of elbow hinged brace for 4 to 6 weeks to minimize stress.
- Respect ROM progression and proper end feel assessment to determine the appropriate manual therapy and exercise techniques to restore motion.
- Proper rehabilitation progression to allow for return to sports for the overhead athlete, including plyometric exercises and completion of an interval throwing program.
- Protection of the repair during postoperative therapy.

[1]*The pre-habilitation outline is included in the nonoperative treatment section of this chapter.*

Phase I (first days 14): Immediate Postoperative Period

- Decrease pain and swelling through cryotherapy, compression, PROM, and electrotherapeutic modalities.
- Minimize the effects of immobilization.
- Protect the reconstructed UCL and associated surgeries.
- Elbow PROM 25° to 100°.

Clinical Pearl

During this phase the clinician should assess for any postoperative complications involving the ulnar nerve. The patient should perform isometric and ROM exercises to diminish the effects of inactivity. The patient should avoid exercises on the involved leg for 1 week if a gracilis graft was used. Initiate wrist and hand ROM, gripping exercises to prevent Complex regional pain syndrome (CRPS).

Protection

- The patient will wear posterior splint with compression dressing locked at 90° flexion for 1 week and then day 8 the patient will be placed into a hinged brace set at 25° to 100°.
- The patient will wear this brace at all times, including during sleep.
- If a gracilis graft is used for reconstruction, the patient may use one crutch the first week as needed.

Management of Pain and Swelling

- Analgesics and antiinflammatory medicines.
- The patient is instructed in cryotherapy for 20 minutes every hour for the first 2 weeks based on pain and swelling.
- A vasopneumatic compression device may be used for simultaneous swelling and pain control.
- Therapeutic modalities for pain and inflammation, including IFC, Hi-Volt, TENS, and therapeutic laser.
- A compression sleeve or wrap may be used to reduce swelling.

Techniques for Progressive Increase in Range of Motion

Manual Therapy Techniques

- The rehabilitation specialist may begin manual PROM of the elbow to neuromodulate pain and aid in collagen alignment of the healing ligamentous tissue.
- PROM for the first 2 weeks is limited to 20° to 100°.

Soft Tissue Techniques

- Light scar mobilization along distal incision can be performed once sutures have been removed and adequate tissue healing has occurred. Scar mobilization to graft location (wrist or knee).

Stretching and Flexibility Techniques for the Musculotendinous Unit

- Shoulder ROM to maintain capsular mobility and shoulder motion. Stretching exercises for wrist, elbow (calf/knee, if gracilis graft is used) not performed to allow for soft tissue healing and transposed ulnar nerve to embed in fascial sling.

Other Therapeutic Exercises

- Patient can perform stationary biking activities while wearing the elbow brace for low intensity cardiovascular conditioning.
- Patient can perform selected and specific core, hip, and LE exercises.

Activation of Primary Muscles Involved in Injury Area or Surgical Structures

- Gripping activities and active wrist ROM exercises.
- Shoulder isometrics all planes except external rotation (to minimize possible valgus torque at the elbow).
- Biceps and triceps isometrics.

Sensorimotor Exercises

- Passive/active joint reposition exercises and drills.
- Rhythmic stabilization drills for the shoulder and elbow joint.

Open and Closed Kinetic Chain Exercises

- The patient should only perform OKC exercises during the immediate postoperative phase.
- Week 2: The patient is able to perform WB exercises against the wall or onto a table.

Techniques to Increase Muscle Strength, Power, and Endurance

- The patient performs light muscle activation exercises for the intrinsics, wrist, elbow, and shoulder during this phase.

Neuromuscular Dynamic Stability Exercises

- Scapular neuromuscular control drills seated and side-lying position
- Rhythmic stabilization drills for the shoulder, elbow, and wrist

Milestones for Progression to the Next Phase

- Minimal effusion in elbow and distal upper extremity.
- Elbow PROM 30° to 100°
- No marked pain at medial elbow or signs of infection.
- No distal (hand) neurologic symptoms.
- Incision is healed.

Phase II (weeks 2 to 6 postop)

- Protect repaired soft tissues.
- Minimize the effects of immobilization.
- Discharge hinged elbow at 5 weeks postoperative.
- Obtain full elbow PROM at 6 weeks postoperative.
- Progress with scapular strengthening and Thrower's Ten Program (Figure 11-13).

Clinical Pearl

The rehabilitation specialist will gradually progress the patient to full elbow ROM during the first 6 weeks following surgery while ensuring no deleterious stresses are imparted upon the healing structures. Because of the adaptive changes that frequently occur in the overhead athlete, the clinician should understand the patient's preinjury elbow ROM in order to establish appropriate ROM expectations following surgery. Be sure to correct or normalize shoulder ROM (esp. IR) and normalize scapular position. Base elbow ROM on end feel assessment, especially when improving elbow extension.

Protection

- Elbow hinged brace will be unlocked at week 2 and set at varying degrees to allow for gradual restoration of motion:
  - Week 2: 20° to 100°
  - Week 3: 10° to 110°
  - Week 4: 0° to 120°
  - Week 5: 0° to 130°
  - Week 6: Discontinue use of elbow brace

Management of Pain and Swelling

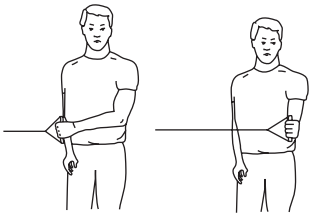
- The patient has discontinued the use of oral pain medications and is taking a nonsteroidal antiinflammatory medication (NSAID).
- The rehabilitation specialist can use moist heat, laser, cryotherapy, vasopneumatic devices, and electrical stimulation (ESTIM) for pain and for preparatory rehabilitation.
- The patient can be prescribed NSAIDs as needed for swelling. The clinician can use vasopneutic devices, and ESTIM, and apply compressionette tubing for swelling reduction.

CSM CHAMPION SPORTS MEDICINE

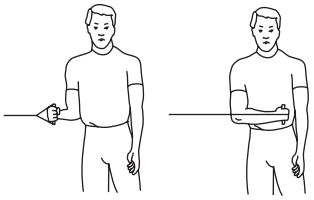
"Throwers Ten + 2" Exercise Program

The Thrower's Ten Program is designed to exercise the major muscles necessary for throwing. The Program's goal is to be an organized and concise exercise program. In addition, all exercises included are specific to the thrower and are designed to improve strength, power and endurance of the shoulder complex musculature.

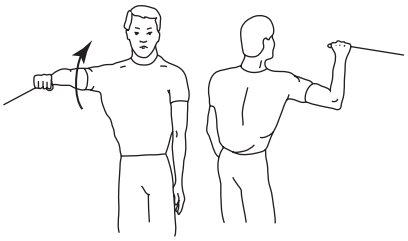
1A. **External Rotation at 0° Abduction:** Stand with involved elbow fixed at side, elbow at 90° and involved arm across front of body. Grip tubing handle while the other end of tubing is fixed. Pull out arm, keeping elbow at side. Return tubing slowly and controlled. Perform _____ sets of _____ repetitions _____ times daily.



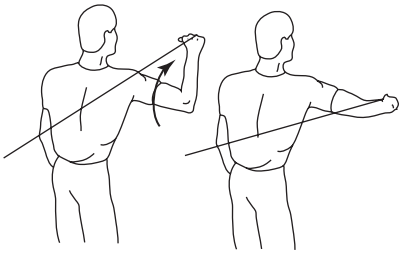
2A. **Internal Rotation at 0° Abduction:** Standing with elbow at side fixed at 90° and shoulder rotated out. Grip tubing handle while other end of tubing is fixed. Pull arm across body keeping elbow at side. Return tubing slowly and controlled. Perform _____ sets of _____repetitions _____ times daily.



1B. (Optional) **External Rotation at 90° Abduction:** Stand with shoulder abducted 90°. Grip tubing handle while the other end is fixed straight ahead, slightly lower than the shoulder. Keeping shoulder abducted, rotate shoulder back keeping elbow at 90°. Return tubing and hand to start position.
I. Slow Speed Sets: (Slow and Controlled) Perform _____ sets of _____ repetitions _____ times daily.
II. Fast Speed Sets: Perform _____ sets of _____ repetitions _____ times daily.



2B. (Optional) **Internal Rotation at 90° Abduction:** Stand with shoulder abducted to 90°, externally rotated 90° and elbow bent to 90°. Keeping shoulder abducted, rotate shoulder forward, keeping elbow bent at 90°. Return tubing and hand to start position.
I. Slow Speed Sets: (Slow and Controlled) Perform _____ sets of _____ repetitions _____ times daily.
II. Fast Speed Sets: Perform _____ sets of _____ repetitions _____ times daily.



4. **Scaption, ER "Full Can":** Stand with elbow straight and thumb up. Raise arm to shoulder level at 30° angle in front of body. Do not go above shoulder height. Hold 2 seconds and lower slowly. Perform _____ sets of _____ repetitions _____ times daily.

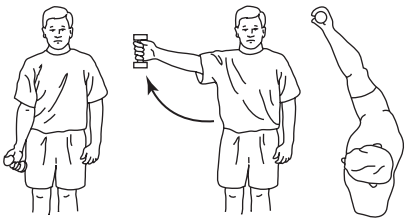


FIGURE 11-13. Thrower's Ten Exercise Program.

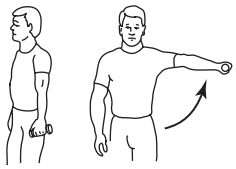
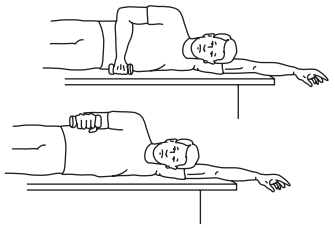
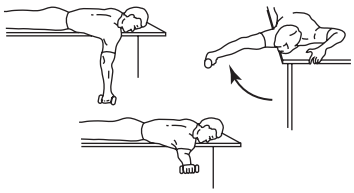
3. **Shoulder Abduction to 90°:** Stand with arm at side, elbow straight, and palm against side. Raise arm to the side, palm down, until arm reaches 90° (shoulder level). Perform _____ sets of _____ repetitions _____ times daily.



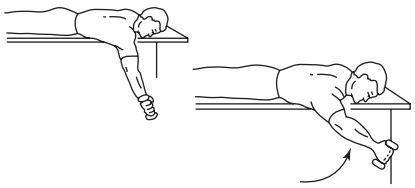
5. **Sidelying External Rotation:** Lie on uninvolved side, with involved arm at side of body and elbow bent to 90°. Keeping the elbow of involved arm fixed to side, raise arm. Hold seconds and lower slowly. Perform _____ sets of _____ repetitions _____ times daily.



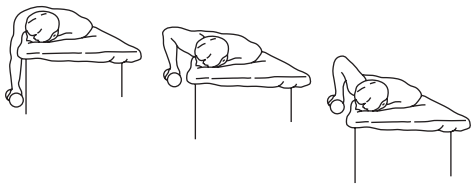
6A. **Prone Horizontal Abduction (Neutral):** Lie on table, face down, with involved arm hanging straight to the floor, and palm facing down. Raise arm out to the side, parallel to the floor. Hold 2 seconds and lower slowly. Perform _____ sets of _____ repetitions _____ times daily.



6B. **Prone Horizontal Abduction (Full ER, 100° ABD):** Lie on table face down, with involved arm hanging straight to the floor, and thumb rotated up (hitchhiker). Raise arm out to the side with arm slightly in front of shoulder, parallel to the floor. Hold 2 seconds and lower slowly. Perform _____ sets of _____ repetitions _____ times daily.



6C. **Prone Rowing:** Lying on your stomach with your involved arm hanging over the side of the table, dumbbell in hand and elbow straight. Slowly raise arm, bending elbow, and bring dumbbell as high as possible. Hold at the top for 2 seconds, then slowly lower. Perform _____ sets of _____ repetitions _____ times daily.



6D. **Prone Rowing into External Rotation:** Lying on your stomach with your involved arm hanging over the side of the table, dumbbell in hand and elbow straight. Slowly raise arm, bending elbow, up to the level of the table. Pause one second. Then rotate shoulder upward until dumbbell is even with the table, keeping elbow at 90°. Hold at the top for 2 seconds, then slowly lower taking 2 – 3 seconds. Perform _____ sets of _____ repetitions _____ times daily.

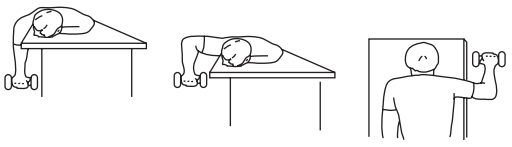


FIGURE 11-13, cont'd

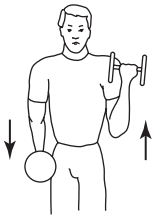
8. **Rows into ER at 90° Abduction, seated on stability ball:** Seated on Stability Ball, with both arms straight ahead, grasping tubing. Keeping arms at shoulder height bend elbows and pull tubing towards the body until elbows are at shoulder level and directly out to both sides (90° Abduction). Hold for a second then rotate shoulder upward until arm is at 90° of ER and Abduction. Hold at top for 2 seconds then return slowly to starting position. Perform _____ sets of _____ repetitions _____ times daily.

8B. **Lower trap, Seated on stability ball:** Seated on Stability Ball, with both arms fixed at side and elbows bent to 90°, thumbs facing upwards. Grasp tubing with both hands and rotate both shoulders outward (External Rotation), rotating thumbs until parallel with floor. Hold for 2 seconds then return to starting position.
Perform ____ sets of ____ repetitions ____ times daily.

9A. **Elbow Flexion:** Standing with arm against side and palm facing inward, bend elbow upward turning palm up as you progress. Hold 2 seconds and lower slowly. Perform _____ sets of _____ repetitions _____ times daily.



9B. **Elbow Extension, Tricep Pushdowns (Optional):** Standing with arms against side, elbows bent to 90°, facing cable column machine. Grasp handles of short bar and "pull down" until elbows straighten. Hold at bottom for 2 seconds then slowly return to starting position. Perform _____ sets of _____ repetitions _____ times daily.

10A. **Wrist Extension:** Supporting the forearm and with palm facing downward, raise weight in hand as far as possible. Hold 2 seconds and lower slowly. Perform _____ sets of _____ repetitions _____ times daily.

FIGURE 11-13, cont'd

Techniques for Progressive Increase in Range of Motion

Manual Therapy Techniques

- Manual passive range of motion to restore full elbow motion by week 5.

Soft Tissue Techniques

- Soft tissue mobilization to decrease muscle guarding and tone, and to reduce edema. Scar mobilization to prevent adhesions along surgical incisions

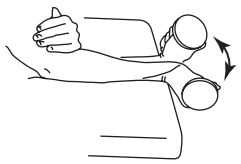
Stretching and Flexibility Techniques for the Musculotendinous Unit

- Initiation of light stretching activity at week 3 for wrist (palmaris graft) and hamstring (gracilis graft)

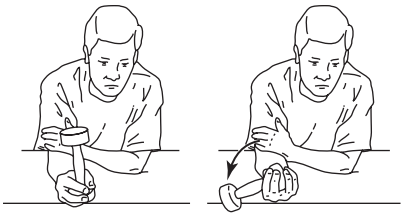
Other Therapeutic Exercises

- Elbow isometrics are initiated at week 3 and progressive resistance exercises are performed, including

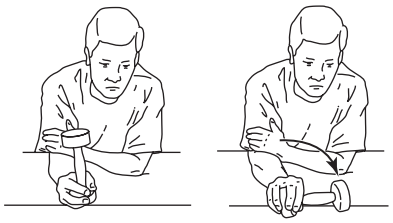
10B. **Wrist Flexion:** Supproting the forearm and with palm facing upward, lower a weight in hand as far as possible and then curl it up as high as possible. Hold for 2 seconds and lower slowly.



10C. **Supination:** Forearm supported on table with wrist in neutral position. Using a weight or hammer, roll wrist taking palm up. Hold for a 2 count and return to starting position. Perform _____ sets of _____ repetitions _____ times daily.



10D. **Pronation:** Forearm should be supported on a table with wrist in neutral position. Using a weight or hammer, roll wrist taking palm down. Hold for a 2 count and return to starting position. Perform _____ sets of _____ repetitions _____ times daily.



11. **Sleeper Stretch:** Lay on the involved or injured side, with involved arm directly out in front (forward flexed to 90°), elbow bent to 90°. With opposite arm apply force to the top of involved arm's wrist forcing the arm to internally rotate towards the table. Hold for 20 seconds and repeat 3 times.

12. **Supine Horizontal Adduction stretch into IR:** Lay supine (on back) with involved arm across chest and elbow bent to 90°. With opposite arm grasp involved arms elbow and pull involved arm across chest until stretch is felt. With uninvolved arms forearm apply a force towards feet onto the involved arm's wrist forcing involved arm into internal rotation. Hold for 20 seconds and repeat 3 times.

FIGURE 11-13, cont'd

shoulder scaption and abduction, ER/IR tubing, scapula retraction, and horizontal abduction.
- Lower extremity exercises can be performed including stationary bike, and machine-based LE strength training equipment (palmaris graft).
- Patients undergoing UCL reconstruction using a gracilis graft can initiate isometric hamstring and gastrocnemius isometrics at week 4 and isotonic exercises at week 6.

Activation of Primary Muscles Involved in Injury Area or Surgical Structures

- Well-arm exercises are performed to promote neuromuscular crossover effect.
- Elbow extension isometrics are performed at week 2 postoperatively.
- Shoulder (scaption, abduction, and ER/IR) and scapular (rows) active movements can begin at week 3.

- Wrist progressive resistive exercises are initiated during week 4 for wrist (flexion, extension, pronation, and supination) and elbow (flexion and extension).

Open and Closed Kinetic Chain Exercises

- The patient should only perform OKC exercises during the immediate postoperative phase for the shoulder girdle.
  - Scaption
  - Abduction
  - Side-lying ER
  - ER/IR tubing
  - Elbow flexion/extension
  - Prone row
  - Prone horizontal abduction
  - Scapular manual resistance exercises

Techniques to Increase Muscle Strength, Power, and Endurance

- Lower extremity strengthening exercises such as lunges, wall sits, knee extensions, and biking to maintain cardiovascular fitness.

TIMELINE 11-2: **Postoperative Rehabilitation Following Ulnar Collateral Ligament Reconstruction Using Autogenous Gracilis Graft (Accelerated ROM)**

PHASE I (weeks 0 to 3)

- Goals:
  - Protect healing tissue
  - Decrease pain/inflammation
  - Retard muscular atrophy
  - Protect graft site—allow healing

Postoperative Week 1

- Brace: Posterior splint at 90 degrees elbow flexion
- ROM:
  - Wrist AROM ext/flexion immediately postoperative
  - Knee active ROM flexion/extension day 1
- Elbow postoperative compression dressing (5 to 7 days)
- Calf (graft site) compression dressing 7 to 10 days
- Exercises:
  - Gripping exercises
  - Wrist ROM
  - Shoulder isometrics (no shoulder ER)
  - Biceps isometrics
  - No involved leg exercises first week
- Cryotherapy: To elbow joint and to graft site below knee
- Crutch: Use one crutch as needed for 3 to 5 days

Postoperative Week 2

- Brace: Elbow ROM 15° to 105° (gradually increase ROM: 5° Ext/10° of Flex per week)
- Exercises:
  - Continue all exercises listed above
  - Elbow range of motion in brace (30° to 105°)
  - Initiate elbow extension isometrics
  - Continue knee ROM exercises
  - Initiate light scar mobilization over distal incision (graft)
- Cryotherapy: Continue ice to elbow and graft site

Postoperative Week 3

- Brace: Elbow ROM 5/10° to 115/120°
- Exercises:
  - Continue all exercises listed above
  - Elbow ROM in brace
  - Initiate active ROM wrist and elbow (no resistance)
  - Initiate light hamstring stretching
  - Initiate active ROM shoulder
- Full can
- Lateral raises
- ER/IR tubing
- Elbow flex/extension
  - Initiate light scapular strengthening exercises
  - Initiate bicycle for lower extremity ROM and strength
  - May initiate light hamstring isometrics

PHASE II (weeks 4 to 7)

- Goals:
  - Gradual increase to full ROM
  - Promote healing of repaired tissue
  - Regain and improve muscular strength
  - Restore full function of graft site

Postoperative Week 4

- Brace: Elbow ROM 0° to 135°
- Exercises:
  - Begin light resistance exercises for arm (1 lb)
  - Wrist curls, extensions, pronation, supination
  - Elbow extension/flexion
  - Progress shoulder program emphasize rotator cuff and scapular strengthening
  - Initiate shoulder strengthening with light dumbbells
  - Isometrics for hamstrings and calf muscles

Postoperative Week 5

- ROM: Elbow ROM 0° to 135°
- Discontinue brace
- Continue all exercises: progress all shoulder and UE exercises (progress weight 1 lb.)

Postoperative Week 6

- AROM: 0° to 145° without brace or full ROM
- Exercises:
  - Initiate Thrower's Ten Program
  - Progress elbow strengthening exercises
  - Initiate shoulder external rotation strengthening
  - Progress shoulder program
  - Initiate isotonic strengthening for graft site hamstrings/calf

Postoperative Week 7

- Progress Thrower's Ten Program (progress weights)

Initiate PNF diagonal patterns (light)

A timeline for rehabilitation after UCL reconstruction using autogenous palmaris longus graft (accelerated ROM) is given in the following section of this chapter.

Neuromuscular Dynamic Stability Exercises

- Joint repositioning drills for elbow and shoulder joint
- LE balance activities such as single leg balance, BOSU squats, star excursion
- Core stabilization exercises such as well arm side-lying planks, rhythmic stabilization drills of trunk.
- Well-arm rhythmic stabilization drills to facilitate neuromuscular crossover effect
- Functional exercises: trunk active mobility, including PNF patterns to maintain mobility in thoracic and lumbar spine and provide neuromuscular coordination training

Milestones for Progression to the Next Phase

- Full pain-free elbow range of motion
- Symptom-free wrist, elbow, shoulder, and scapular active movements
- Good scar mobility along surgical incisions
- Minimal to no joint/distal upper extremity edema
- No medial elbow pain

Phase III (weeks 7 to 10 postop)

- Maintain full elbow ROM.
- Promote healing of repaired soft tissues.

TIMELINE 11-2: **Postoperative Rehabilitation Following Ulnar Collateral Ligament Reconstruction Using Autogenous Gracilis Graft (Accelerated ROM)** (Continued)

PHASE III (weeks 8 to 14)

- Goals:
  - Increase strength, power, endurance
  - Maintain full elbow ROM
  - Gradually initiate sporting activities

Postoperative Week 8

- Exercises:
  - Initiate eccentric elbow flexion/extension
  - Continue isotonic program: forearm and wrist
  - Continue shoulder program—Thrower's Ten Program
  - Manual resistance diagonal patterns
  - Initiate plyometric exercise program
  - (Two-hand plyos close to body only)
  - Chest pass
  - Side throw close to body
  - Continue stretching calf and hamstrings

Postoperative Week 10

- Exercises: Continue all exercises listed above
- Progress plyometrics to two-hand drills away from body
  - Side to side throws
  - Soccer throws
  - Side throws

Postoperative Weeks 12 to 14

- Continue all exercises
- Initiate isotonic machines strengthening exercises (if desired)
  - Bench press (seated)
  - Lat pull down
- Initiate golf, swimming
- Initiate interval hitting program

PHASE IV (weeks 14 to 32)

- Goals:
  - Continue to increase strength, power, and endurance of upper extremity musculature
  - Gradual return to sport activities

Postoperative Week 14

- Exercises:
  - Continue strengthening program
  - Emphasis on elbow and wrist strengthening and flexibility exercises
  - Maintain full elbow ROM
  - Initiate one hand plyometric throwing (stationary throws)
  - Initiate one hand wall dribble
  - Initiate one hand baseball throws into wall

Postoperative Week 16

- Exercises:
  - Initiate interval throwing program (Phase I) [long toss program]
  - Continue Thrower's Ten Program and plyos
  - Continue to stretch before and after throwing

Postoperative Weeks 22 to 24

- Exercises: Progress to Phase II throwing (once successfully completed Phase I)

Postoperative Weeks 30 to 32

- Exercises: Gradually progress to competitive throwing/sports

- Regain and improve muscular strength.
- Restore function at graft donor site.

Clinical Pearl

The patient will maintain full elbow PROM without complaints of pain during this stage while progressing with a strengthening program for the entire upper extremity. The rehabilitation specialist should ensure restoration of full elbow range of motion by using manual techniques including: PROM, manual flexibility exercises, soft tissue mobilizations to the forearm and arm muscular and soft tissues, joint mobilizations (grades II to III) to the humero-ulnar joint. In addition, low-load long-duration (LLLD) stretches can be used to aid in regaining full elbow motion. A rehabilitation program for the overhead athlete should also include strengthening and neuromuscular control drills for the trunk and lower extremity because of the generation and dissipation of forces that occur with the throwing motion. These activities will help minimize the forces imparted at the elbow during the throwing motion.

Protection

- The patient can discontinue the use of a hinged elbow brace.

Management of Pain and Swelling

- The patient may take NSAIDs as needed to control any mild pain or inflammation that may persist.
- A compressionette tubing can be used as well as ESTIM and cryotherapy posttherapy to mitigate inflammation and soreness.

Techniques for Progressive Increase in Range of Motion

Manual Therapy Techniques

- Oscillatory mobilizations (grades I and II) can be performed to neuromodulate pain. If joint restrictions are noted, the rehabilitation specialist can perform joint mobilization techniques (grades II and III) at end range to regain full motion (Figure 11-14).

Soft Tissue Techniques

- Scar mobilization techniques can be performed along incisions to obtain full tissue mobility.

Stretching and Flexibility Techniques for the Musculotendinous Unit

- The rehabilitation specialist should ensure that the patient has good flexibility of the wrist flexors and extensors, as well as maintaining full shoulder mobility in the overhead athlete. The rehabilitation specialist can augment the ROM stretching with LLLD stretch for extension (Figure 11-15), flexion, or active assistive stretches such as wall slides (Figure 11-16).

FIGURE 11-14. Grade III mobilization of the radio-ulnar joint to regain supination.

Other Therapeutic Exercises

- Thrower's Ten Program performed on a stability ball.
- Cardiovascular: The patient can progress with cardiovascular fitness with increased cadence and resistance including treadmill, stationary bike, and upper body ergometer (UBE).
- Well-arm lifting exercises can be progressed to include lifting on upper extremity machines with bench press, rows, lateral shoulder raises, bicep curls, and triceps extension.
- Lower body strengthening and conditioning is progressed to include closed kinetic chain (CKC) (i.e., leg press, lunges, wall sits) and open kinetic chain exercises. (If a gracilis graft is used, patients can initiate light isotonic strengthening for hamstrings and gastrocnemius at 6 weeks and gradually progress with strengthening exercises.)

FIGURE 11-15. Low-load, long duration stretch into elbow extension.

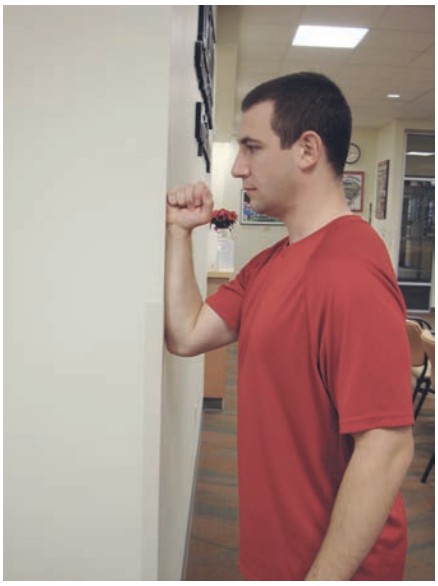


FIGURE 11-16. Wall-slide stretch. The patient is instructed to maintain forearm contact onto the wall while sliding the elbow toward the floor. The patient can also perform contract-relax techniques of the triceps and overpressure by leaning forward with the trunk.

Activation of Primary Muscles Involved in Injury Area or Surgical Structures

- Rotator cuff strengthening exercises will be progressed with the patient performing scaption, abduction, ER/IR tubing, and side-lying ER.
- Scapulothoracic musculature will be progressed during this phase to increase strength.
- The patient will perform prone row into external rotation and prone scaption.
- Biceps and triceps strengthening exercises are progressed as tolerated to include eccentrics at week 8.
- The patient will continue to progress with wrist strengthening exercises (flexion, extension, pronation, supination, and radial and ulnar deviation).

Sensorimotor Exercises

- Rhythmic stabilization drills can be progressed by having the patient perform these in a seated or standing position to facilitate recruitment of the core musculature.
- Lower extremity proprioception and coordination drills can be performed using foam and cones can be beneficial in preparation for the overhead athlete to regain hip and trunk coordinative movement patterns.

Open and Closed Kinetic Chain Exercises

- OKC Thrower's Ten program can begin at week 6.
- For athletes involved in upper extremity weight bearing sports (wrestling, gymnastics, football) CKC exercises should be considered. These activities could be initiated with simple weight shifting with hands on table. CKC exercises could be progressed to ball on wall stabilizations (Figure 11-17) can be performed initially with perturbations applied on proximal arm to minimize stress on the medial elbow and progressed to distal hand.

Techniques to Increase Muscle Strength, Power, and Endurance

- Lower extremity strengthening exercises are progressed with both machine weights and body weight activities.
- The patient can perform aquatic strength training activities for the lower extremity and upper extremity as an adjunct to the current rehabilitation program.
- Endurance training can also be incorporated into the current program by instructing the patient to decrease the rest time between exercises or by performing super sets.

Neuromuscular Dynamic Stability Exercises

- The rehabilitation specialist can begin performing light manual resistance drills for shoulder and scapular musculature.
- PNF patterns can be initiated during this phase using either elastic tubing or manual resistance for the forearm, scapulohumeral, and scapulothoracic musculature.

Plyometrics

- Plyometric exercises can be initiated at week 8.
- The patient will begin two-hand drills performed close to the body (chest pass and side throws) and perform these drills for 2 weeks as part of a progression to two-hand plyometric tosses with arms extending from body.
- The athlete should be instructed to use lower extremity, hip, and trunk movements in synchronization with shoulder movement as a precursor for throwing activity and transfer of forces throughout the kinetic chain.
- The patient can perform ball flips and reverse ball flips at week 8 for forearm musculature (Figure 11-18*A*,*B*).

FIGURE 11-17. Ball on the wall stabilization exercise with the clinician providing perturbations.

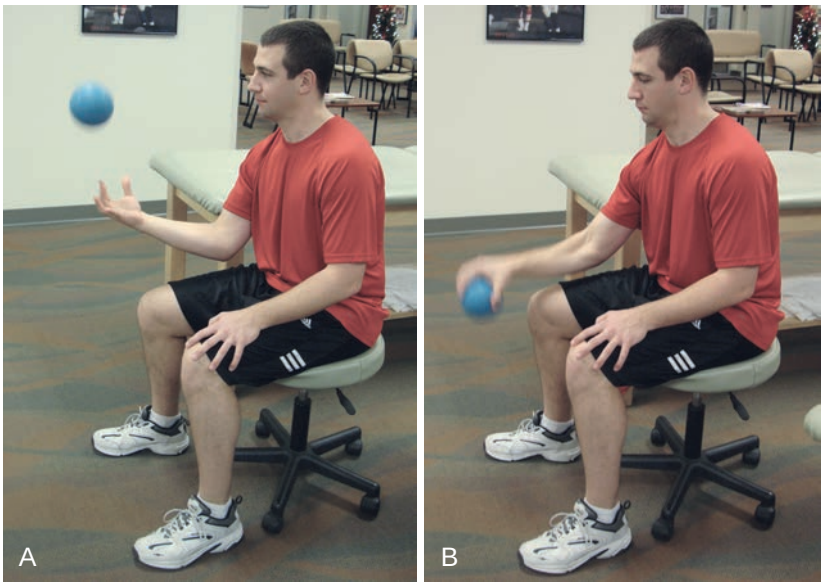

FIGURE 11-18. A,B, Plyometric wrist snaps (wrist flexors) and flips (wrist extensors).

Functional Exercises

- The patient can perform total body strengthening exercises to engage trunk and core musculature to include resistive trunk rotation and total body PNF pattern for synchronization of movement patterns (Figure 11-19).

Milestones for Progression to the Next Phase

- Full pain-free elbow range of motion
- No tenderness or pain with palpation medial elbow
- Adequate strength with manual muscle testing (MMT) greater than 4/5 throughout involved upper extremity
- Satisfactory clinical examination
- Successful completion of two-hand plyometric drills

FIGURE 11-19. Full body PNF D2 pattern.

Phase IV (weeks 11 to 14 postop)

- Normalize and improve upper extremity strength.
- Maintain full elbow range of motion.
- Enhance power and endurance.
- Initiate sports-specific drills.

Clinical Pearl

The clinician should ensure continued treatment of the entire kinetic chain throughout the remainder of the rehabilitation process to prepare a patient for return to sporting activities. Progress the patient to a higher level of physical condition in this phase. For the throwing athlete we emphasize endurance, stabilization, and improving strength. The patient should continue to progress with total body functional training with strength training and establishing coordinative movement patterns during sport-specific drills. Isokinetic testing can be performed before the initiation of an interval throwing program to determine if the athlete is ready to progress with throwing activities.

Protection

- Protection is no longer needed.

Management of Pain and Swelling

- NSAIDs as needed
- The clinician can use cryotherapy posttreatment to mitigate exercise-induced inflammation.

Techniques for Progressive Increase in Range of Motion

Manual Therapy Techniques

- PROM to maintain full wrist, elbow, and shoulder ROM. The clinician can perform grade III and IV mobilizations to ensure full elbow ROM.

Soft Tissue Techniques

- The rehabilitation specialist should continue performing scar massage and soft tissue mobilization techniques to forearm and elbow musculature as deemed necessary.
- Assessment of the glenohumeral and scapular musculature is also warranted for possible trigger points or other fascial restrictions that can develop as the patient is progressing with a functional training program that could impede the throwing motion.
- The clinician can perform manual techniques, or the patient can be instructed in self–soft tissue mobilization techniques with the aid of foam rollers or similar device (Figure 11-20).

Stretching and Flexibility Techniques for the Musculotendinous Unit

- The rehabilitation specialist should continue to maintain full flexibility of the forearm, elbow, and shoulder girdle with both manual and self-stretches.
- The clinician should also assess for any lack of flexibility throughout the entire kinetic chain (trunk, hip girdle, lower extremity).
- The clinician should make certain that adequate flexibility and mobility are present to allow for the proper generation and dissipation of energy for the throwing athlete.
- Ensure shoulder joint ROM is appropriate.

Other Therapeutic Exercises

- Initiate Advanced Thrower's Ten Exercise Program on stability ball.
- Lower extremity lifting is progressed with exercises such as back squat and lunges. The clinician can progress isotonic isolation strengthening exercises for the hamstring and calf musculature for patients that have a gracilis graft.
- The athlete can progress with core stabilization and dynamic movement patterns (Figure 11-21).

FIGURE 11-20. Soft tissue mobilization utilizing a foam roll.

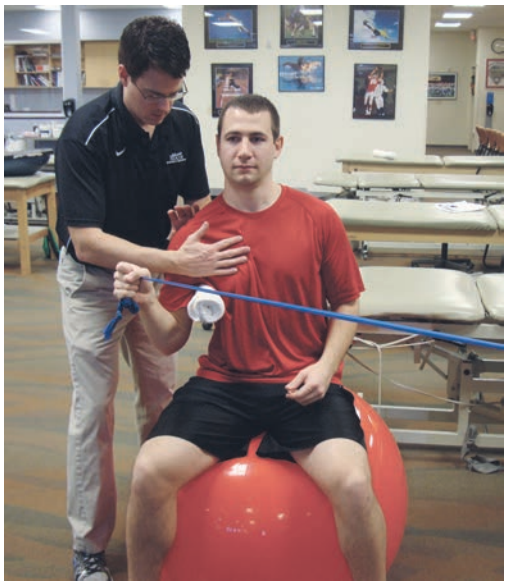

FIGURE 11-21. External rotation tubing while performing core stabilization on a swiss ball.

- Upper extremity lifting exercises are initiated and progressed as tolerated to include seated bench press, lat pull down, and shoulder presses.

Activation of Primary Muscles Involved in Injury Area or Surgical Structures

- The patient will continue with Thrower's Ten strengthening exercises and progress with resistance as tolerated.

Sensorimotor Exercises

- PNF D2 manual resistance exercises can be performed in supine, seated, or standing position (Figure 11-22).

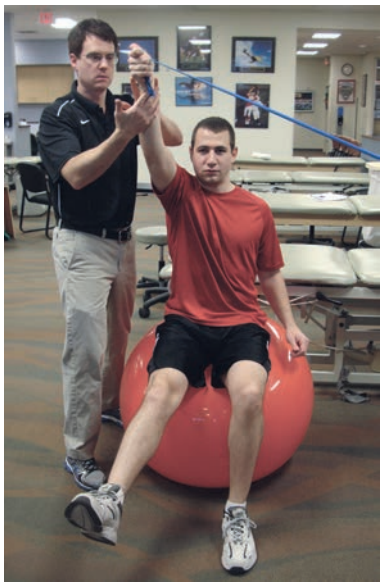

FIGURE 11-22. Manual resistance PNF D2 pattern performed while patient is seated on swiss ball.

Open and Closed Kinetic Chain Exercises

- CKC exercises for upper extremity weight-bearing athletes can be perform to include:
  - Push-ups progression: wall, table, floor
  - Planks: front, side
- Perform plank exercises for the shoulder and UE

Techniques to Increase Muscle Strength, Power, and Endurance

- Manual PNF training can be performed for the distal upper extremity of the forearm and upper arm
- Cardiovascular fitness will be progressed utilizing bike, elliptical, UBE, and jogging program.

Neuromuscular Dynamic Stability Exercises

- Rhythmic stabilization and manual resistance exercises are progressed to include exercises on unsupported surface to engage trunk musculature

Plyometrics

- Two-hand plyometric drills are progressed by performing drills with arms away from body: including side to side, soccer, and side throws (Figure 11-23)

Functional Exercises

- Begin golf activities at week 12.

Sport-Specific Exercises

- Interval training programs (golf, hitting) can be initiated at week 12 (Table 11-2 and Box 11-1).

Milestones for Progression to the Next Phase

- Full pain-free elbow range of motion
- No tenderness or pain with palpation medial elbow—no neurological symptoms
- Adequate strength with manual muscle testing (MMT) 5/5 throughout involved upper extremity
- Satisfactory clinical examination
- Successful completion of two-hand plyometric drills
- Satisfactory isokinetic testing (Table 11-3) or objective MMT

FIGURE 11-23. Two-handed plyometric side-to-side throws. The patient is instructed to incorporate lower extremity/trunk movement with throws.

Table 11-2 Interval Golf Rehab Program

	Monday	Wednesday	Friday

Week 4	15 short irons 10 medium irons 10 long irons 10 drives 15′ rest Repeat	Play 9 holes	Play 9 holes
Week 5	9 holes	9 holes	18 holes

The same principles should be followed with the interval golf program as with the interval baseball program. Proper warm-up, stretching, and strengthening should still be implemented throughout the entire interval golf rehabilitation program. As you start your program, remember that mechanics play an important role in your recovery. If there are any further questions, please contact your physician or rehabilitation specialist.

Do flexibility exercises before hitting. Use ice after hitting. ′, Abbreviation for minute; *chips*, pitching wedge; *short irons*, wedge, 9, 8 irons; *medium irons*, 7, 6, 5 irons; *long irons*, 4, 3, 2 irons; *wood*, 3, 5 woods; *drives*, driver.

BOX 11-1 Interval Hitting Program

Off a Tee Stand

Step 1: 50% effort (15 to 20 swings)
Step 2: 50% effort (two sets of 15 swings)
Step 3: 65% to 70% effort (two sets of 15 swings)
Step 4: 70% to 75% effort (two sets of 20 to 25 swings)
Step 5: 80% to 90% effort (two sets of 25 swings)

Soft Toss Swings

Warm-Up Using a Tee Stand
Step 6: 50% to 60% effort (15 to 20 swings)
Step 7: 65% to 70% effort (two sets of 20 to 25 swings)
Step 8: 80% to 90% effort (two sets of 25 swings)

Batting Practice Swings

Warm-Up with Soft Toss Swings
Step 9: 50% to 65% effort (two sets of 25 swings)
Step 10: 70% to 75% effort (two sets of 30 swings)
Step 11: 80% to 90% effort (two sets of 30 to 35 swings)

Hit three times per week with a day off in between. Perform each step for 2 days before progressing to next step.

Clinical Pearl

A well-constructed and implemented interval sports program is crucial in preparing an athlete for return to competition. The rehabilitation specialist should implement this program into the athlete's current rehabilitation program. A methodical approach, such as having the athlete properly warm-up, stretch, and perform a set of exercises before throwing as part of a preparatory activity, including plyometric activities and followed up with a proper cool down and stretching activity, can augment the athlete safely return to competition. During this phase the plyometrics are used to perform the athlete to throw, then the interval throwing program is used to general improve arm strength, endurance, and so on. Proper throwing mechanics are critical during the ITP.

Phase V (weeks 15 to 26 postop)

- Full pain-free ROM
- MMT 5/5 strength for wrist, elbow, shoulder, and scapular muscles
- Satisfactory clinical examination
- Successful progression of interval sports training program

Management of Pain and Swelling

- NSAIDs as needed for exercise-induced muscle soreness.
- Laser therapy is beneficial to control postexercise soreness.
- The rehabilitation specialist should monitor the athlete's symptoms throughout the interval sports program to ensure the athlete is progressed based on his or her symptoms and tolerance of activity.
- The athlete should be encouraged to ice following an interval sports program to mitigate exercise muscle soreness or exercise induced inflammation.

Techniques for Progressive Increase in Range of Motion

Manual Therapy Techniques

- Full ROM should be monitored throughout the rehabilitation program as the patient should maintain full motion.
- The clinician can perform stretching, joint mobilizations (grades III and IV) as indicated during this phase.

Table 11-3 Satisfactory Isokinetic Values for Overhead Athletes

Bilateral Comparisons

Abd, Abduction; *Add*, adduction; *Ext*, extension; *ER*, external rotation; *Fl*, flexion; *IR*, internal rotation.

Soft Tissue Techniques

- The clinician should assess for any soft tissue restrictions, such as myofascial trigger points that can arise from an increase in activity level.
- The clinician can use instrument assisted techniques to aid in the treatment of any restriction.

Stretching and Flexibility Techniques for the Musculotendinous Unit

- The rehabilitation specialist should perform pre- and postexercise stretching for the wrist, elbow, shoulder, and scapular musculature to allow for proper warm-up and cool-down as the athlete progresses with an interval sporting program.

Other Therapeutic Exercises

- Advanced Thrower's Ten exercises are progressed as indicated.
- Trunk and core exercises can be progressed to include total body movement patterns and drills.
- Lower extremity lifting should be progressed to incorporate strength, power, and endurance training.

Activation of Primary Muscles Involved in Injury Area or Surgical Structures

- The patient will continue with wrist, elbow, and shoulder girdle strengthening activities.
- When rehabilitating an athlete undergoing an interval sports program, the clinician can opt to instruct the athlete to perform one set of exercises before throwing as part of a general warm-up and tissue preparation and complete two sets of exercises following the interval program.

Sensorimotor Exercises

- Rhythmic stabilization drills, core stabilizations with concomitant shoulder girdle strengthening exercises can be performed.

Open and Closed Kinetic Chain Exercises

OKC Exercises

- Rows
- Lat pull down
- Lateral raises
- Shoulder presses

CKC Exercises

- Planks
- Bench press
- Push-ups on unstable surface (Figure 11-24)
- CKC slide board
- Quadruped or push-up position

Techniques to Increase Muscle Strength, Power, and Endurance

- Advance strength training by decreasing sets to six to eight repetitions per set.

FIGURE 11-24. Push-ups performed on a BOSU ball.

- Incorporate endurance training by decreasing recover time with exercises.
- Progress running, cardiovascular training.

Neuromuscular Dynamic Stability Exercises

- The athlete can perform rotator cuff and scapula strengthening exercises in sport-specific position to allow for increase dynamic control and functional training
- PNF exercises will be progressed utilizing both speed and resistance to prepare for athletic activity.

Plyometrics

- Two-hand plyometric drills will be progressed throughout this phase.
  - Chest throws
  - Side-to-Side throws
  - Side throws
  - Soccer throws
- One-hand plyometrics can be initiated at week 14.
  - One-hand plyometric throwing
  - One-hand wall dribble
  - One-hand baseball throws

Functional Exercises

- A swimming program can be continued to be used to perform shoulder therapeutic exercises as well as part of a general conditioning program.

Sport-Specific Exercises

- Flat ground interval throwing program can be initiated at week 16 (Box 11-2).

Milestones for Progression to the Next Phase

- See the following.

Phase VI (weeks 27 to 52 postop)

- Satisfactory clinical examination
- MMT 5/5 strength for all muscles groups

BOX 11-2 Interval Throwing Program: Phase I

Flat Ground Throwing

The Interval Throwing Program (ITP) is designed to gradually return motion, strength, and confidence in the throwing arm after injury or surgery by slowly progressing through graduated throwing distances. The ITP is initiated upon clearance by the athlete's physician to resume throwing, and performed under the supervision of the rehabilitation team (physician, physical therapist, and athletic trainer).

The program is set up to minimize the chance of reinjury and emphasize pre-throwing warm-up and stretching. In development of the interval throwing program, the following factors are considered most important.

1. The act of throwing the baseball involves the transfer of energy from the feet through the legs, pelvis, trunk, and out the shoulder through the elbow and hand. Therefore any return to throwing after injury must include attention to the entire body.
2. The chance for reinjury is lessened by a graduated progression of interval throwing.
3. Proper warm-up is essential.
4. Most injuries occur as the result of fatigue.
5. Proper throwing mechanics lessen the incidence of reinjury.
6. Baseline requirements for throwing include:
   - Pain-free range of motion
   - Adequate muscle power
   - Adequate muscle resistance to fatigue

Because there is individual variability in all throwing athletes, there is no set timetable for completion of the program. Most athletes, by nature, are highly competitive individuals and wish to return to competition at the earliest possible moment. Although this is a necessary quality in all athletes, the proper channeling of the athlete's energies into a rigidly controlled throwing program is essential to lessen the chance of reinjury during the rehabilitation process. The athlete may have the tendency to want to increase the intensity of the throwing program. This will increase the incidence of reinjury and may greatly retard the rehabilitation process. It is recommended to follow the program rigidly because this will be the safest route to return to competition.

During the recovery process the athlete will probably experience soreness and a dull, diffuse aching sensation in the muscles and tendons. If the athlete experiences sharp pain, particularly in the joint, stop all throwing activity until this pain ceases. If pain continues, contact your physician.

WEIGHT TRAINING

The athlete should supplement the ITP with a high-repetition, low-weight exercise program. Strengthening should address a good balance between anterior and posterior musculature so that the shoulder will not be predisposed to injury. Special emphasis must be given to posterior rotator cuff musculature for any strengthening program. Weight training will not increase throwing velocity, but will increase the resistance of the arm to fatigue and injury. Weight training should be done the same day as you throw; however, it should be after your throwing is completed, using the day in between for flexibility exercises and a recovery period. A weight training pattern or routine should be stressed at this point as a "maintenance program." This pattern can and should accompany the athlete into and throughout the season as a deterrent to further injury. It must be stressed that weight training is of no benefit unless accompanied by a sound flexibility program.

INDIVIDUAL VARIABILITY

The ITP is designed so that each level is achieved without pain or complications before the next level is initiated. This sets up a progression in which a goal is achieved before advancement rather than advancing to a specific timeframe. Because of this design, the ITP may be used for different levels of skills and abilities from those in high school to professional levels. Progression will vary from person to person throughout the ITP. Example: One athlete may wish to use alternate days throwing with or without using weights in between; another athlete may have to throw every third or fourth day because of pain or swelling. "Listen to your body. It will tell you when to slow down." Again, completion of the steps of the ITP will vary from person to person. There is no set timetable in terms of days to completion.

WARM-UP

We recommend one set of 10 repetitions of RTC be performed before ITP. Jogging may also assist in warm-up. Jogging increases blood flow to the muscles and joints. Thus increasing their flexibility and decreasing the chance of reinjury. Because the amount of warm-up will vary from person to person, the athlete should jog until developing a light sweat, and then progress to the stretching phase.

STRETCHING

Because throwing involves all muscles in the body, all muscle groups should be stretched before throwing. This should be done in a systematic fashion beginning with the legs and including the trunk, back, neck, and arms. Continue with capsular stretches and L-bar range of motion exercises.

THROWING MECHANICS

A critical aspect of the ITP is maintenance of proper throwing mechanics throughout the advancement. The use of the Crow-Hop method simulates the throwing act, allowing emphasis of the proper body mechanics. This throwing method should be adopted from the set of the ITP. Throwing flat footed encourages improper body mechanics, placing increased stress on the

Continued on following page

BOX 11-2 Interval Throwing Program: Phase I *(Continued)*

throwing arm, and therefore predisposing the arm to reinjury. The pitching coach and sports biomechanic (if available) may be valuable allies to the rehabilitation team with their knowledge of throwing mechanics.

Components of the Crow-Hop method are first a hop, then a skip, followed by the throw. The velocity of the throw is determined by the distance, whereas the ball should have only enough momentum to travel each designed distance. Again, emphasis should be placed upon proper throwing mechanics when the athlete begins Phase II, "Throwing off the Mound" or from the athlete's respective position, to decrease the chance of reinjury.

THROWING

Using the Crow-Hop method, the athlete should begin warm-up throws at a comfortable distance (approximately 30 to 45 ft), and then progress to the distance indicated for that phase (refer to the box that follows). The program consists of throwing at each step two to three times without pain or symptoms before progressing to the next step. The object of each phase is for the athlete to be able to throw the ball without pain the specified number of feet (45 ft, 60 ft, 90 ft, 120 ft, 150 ft, 180 ft), 75 times at each distance. After the athlete can throw at the prescribed distance without pain, he or she will be ready for throwing from flat ground 60 ft, 6 in. in the normal pitching mechanics or return to his or her respective position (step 14). At this point, full strength and confidence should be restored in the athlete's arm. It is important to stress the Crow-Hop method and proper mechanics with each throw. Just as the advancement to this point has been gradual and progressive, the return to unrestricted throwing must follow the same principles. A pitcher should first throw only fast balls at 50%, progressing to 75% and 100%. At this time, he may start more stressful pitches such as breaking balls. The position player should simulate a game situation, again progressing to 50%, 75% and 100%. Once again, if an athlete has increased pain, particularly at the joint, the throwing program should be backed off and re-advanced as tolerated, under the direction of the rehabilitation team.

BATTING

Depending on the type of injury that the athlete has, the time of return to batting should be determined by the physician. It should be noted that stress placed upon the arm and shoulder in the batting motion are very different from the throwing motion. Return to unrestricted use of the bat should also follow the same progression guidelines as seen in the training program. Begin with dry swings progressing to hitting off the tee, then soft toss, and finally live pitching.

SUMMARY

In using the Interval Throwing Program (ITP) in conjunction with a structured rehabilitation program, the athlete should be able to return to full competition status, minimizing any chance of reinjury. The program and its progression should be modified to meet the specific needs of each individual athlete. A comprehensive program consisting of maintenance strength and flexibility program, appropriate warm-up and cool down procedures, proper pitching mechanics, and progressive throwing and batting will assist the baseball player in returning safely to competition.

Phase I for Pitchers

45′ PHASE

Step 1: A) Warm-up Throwing
B) 45′ (25 Throws)
C) Rest 3 to 5 min.
D) Warm-up Throwing
E) 45′ (25 Throws)

Step 2: A) Warm-up Throwing
B) 45′ (25 Throws)
C) Rest 3 to 5 min.
D) Warm-up Throwing
E) 45′ (25 Throws)
F) Rest 3 to 5 min.
G) Warm-up Throwing
H) 45′ (25 Throws)

60′ PHASE

Step 3: A) Warm-up Throwing
B) 60′ (25 Throws)
C) Rest 3 to 5 min.
D) Warm-up Throwing
E) 60′ (25 Throws)

Step 4: A) Warm-up Throwing
B) 60′ (25 Throws)
C) Rest 3 to 5 min.
D) Warm-up Throwing
E) 60′ (25 Throws)
F) Rest 3 to 5 min.
G) Warm-up Throwing
H) 60′ (25 Throws)

90′ PHASE

Step 5: A) 60′ (10 throws)
B) 90′ (20 throws)
C) Rest 3-5 min.
D) 60′ (10 throws)
E) 90′ (20 Throws)

Step 6: A) 60′ (7 throws)
B) 90′ (18 Throws)
C) Rest 3 to 5 min.
D) 60′ (7 throws)
E) 90′ (18 Throws)
F) Rest 3-5 min.
G) 60′ (7 throws)
H) 90′ (18 Throws)

120′ PHASE

Step 7: A) 60′ (5 to 7 throws)
B) 90′ (5 to 7 throws)
C) 120′ (15 Throws)
D) Rest 3 to 5 min.
E) 60′ (5 to 7 throws)
F) 90′ (5 to 7 throws)
G) 120′ (15 Throws)

Step 8: A) 60′ (5 throws)
B) 90′ (10 throws)
C) 120′ (15 Throws)
D) Rest 3 to 5 min.
E) 60′ (5 throws)
F) 90′ (10 throws)
G) 120′ (15 Throws)
H) Rest 3 to 5 min.
I) 60′ (5 throws)
J) 90′ (10 throws)
K) 120′ (15 Throws)

Flat Throwing

A) Throw 60 ft. (10 to 15 throws)
B) Throw 90 ft. (10 throws)
C) Throw 120 ft. (10 throws)
D) Throw 60 ft. (flat ground) using pitching mechanics (20 to 30 throws)

A) Throw 60 ft. (10 to 15 throws)
B) Throw 90 ft. (10 throws)
C) Throw 120 ft. (10 throws)
D) Throw 60 ft. (flat ground) using pitching mechanics (20 to 30 throws)
E) Rest 3 to 5 min.
F) Throw 60 to 90 ft. (10 to 15 throws)
G) Throw 60 ft. (flat ground) using pitching mechanics (20 throws)

Throwing program should be performed every other day, with one day of rest between steps, unless otherwise specified by your physician
Perform each step two times before progressing to the next step.

- Full pain-free ROM
- Successful completion of interval sport program
- Return to prior level of function/sports

Clinical Pearl

In preparation for return to sporting activity, the rehabilitation specialist should perform a complete musculoskeletal screen to assess for any deficits in strength, mobility, stability, or a lack in coordinative movement pattern that may impede in the athlete's progression. In addition, the rehabilitation specialist should evaluate the athlete's throwing mechanics during his or her sporting activity and seek additional consultation if needed for movement analysis. Often a motion analysis is beneficial once the athlete is throwing at the level of 80% of normal performance.

Management of Pain and Swelling

- Ice and/or laser following exercise/activity
- Ice following exercise/activity

Techniques for Progressive Increase in Range of Motion

Manual Therapy Techniques

- Manual techniques can be continued as needed to maintain full ROM using grade III and IV mobilizations.

Soft Tissue Techniques

- Manual soft tissue mobilizations performed as indicated, as well as educating the patient on self–soft tissue mobilization

Stretching and Flexibility Techniques for the Musculotendinous Unit

- Pre-exercise and sport training flexibility as well as posttraining flexibility exercises are encouraged to prepare the athlete for activities as well as reduce soreness following activities. Stretching exercises for shoulder and entire UE.

Other Therapeutic Exercises

- Multijoint/total body movement exercises are performed in conjunction with isolation exercises to increase total body strength and coordinative movement patterns.

Activation of Primary Muscles Involved in Injury Area or Surgical Structures

- Thrower's Ten exercises are continued.

Sensorimotor Exercises

- Lower extremity proprioceptive exercises are performed on unstable surfaces.
- PNF patterns are continued using manual techniques, cables, or medicine balls.
- Upper extremity strengthening can be performed as the athlete stands on unstable surface.

Open and Closed Kinetic Chain Exercises

- The athlete can advance all previous exercises.
- Overhead strength training and Olympic lifting can be implemented if needed.

Techniques to Increase Muscle Strength, Power, and Endurance

- Rehabilitation focus is to restore preinjury level of strength and muscular endurance.

Neuromuscular Dynamic Stability Exercises

- Resistance and dynamic training exercises will be progressed using unstable surface, single leg stance, perturbations, and CKC activities that mimic the athlete's sport.

Plyometrics

- One- and two-handed plyometric drills are continued throughout this phase and can be used as a precursor to the throwing program.
- CKC plyometric push-ups can be progressed for athletes involved in weight-bearing activities.

Functional Exercises

- Sport-specific training drills (running and agility) should be performed to prepare the athlete for return to completion.
- Functional training for weight-bearing athletes with increased impact loading and training drills.

Sport-Specific Exercises

- Following successful completion of Phase I, interval throwing program (Phase II) can begin at week 24 (Box 11-3).

Milestones for Progression to Return to Sport

- See Criteria for Return to Sport.

Criteria for Return to Sport

General Criteria

- Full ROM
- Satisfactory clinical examination

BOX 11-3 Interval Throwing Program: Phase II

Throwing Off the Mound

After the completion of Phase I of the Interval Throwing Program (ITP) and the athlete can throw to the prescribed distance without pain, the athlete will be ready for throwing off the mound or return to his or her respective position. At this point, full strength and confidence should be restored in the athlete's arm. Just as the advancement to this point has been gradual and progressive, the return to unrestricted throwing must follow the same principles. A pitcher should first throw only fast balls at 50%, progressing to 75% and then 100%. At this time, the athlete may start more stressful pitches, such as breaking balls. The position player should simulate a game situation, again progressing at 50%, 75%, and then 100%. Once again, if an athlete has increased pain, particularly at the joint, the throwing program should be backed off and readvanced as tolerated, under the direction of the rehabilitation team.

SUMMARY

In using the Interval Throwing Program (ITP) in conjunction with a structured rehabilitation program, the athlete should be able to return to full competition status, minimizing any chance of reinjury. The program and its progression should be modified to meet the specific needs of each individual athlete. A comprehensive program consisting of a maintenance strength and flexibility program, appropriate warm-up and cool-down procedures, proper pitching mechanics, and progressive throwing and batting will assist the baseball player in returning safely to competition.

Stage I: Fastballs Only

Step 1: Interval throwing
15 throws off mound 50%
Step 2: Interval throwing
30 throws off mound 50%
Step 3: Interval throwing
45 throws off mound 50%
Step 4: Interval throwing
60 throws off mound 50%
Step 5: Interval throwing
70 throws off mound 50%
Step 6: 45 throws off mound 50%
30 throws off mound 75%
Step 7: 30 throws off mound 50%
45 throws off mound 75%
Step 8: 65 throws off mound 75%
10 throws off mound 50%

Stage II: Fastballs Only

Step 9: 60 throws off mound 75%
15 throws in batting practice
Step 10: 50 to 60 throws off mound 75%
30 throws in batting practice
Step 11: 45 to 50 throws off mound 75%
45 throws in batting practice

Stage III

Step 12: 30 throws off mound 75% (warm-up)
15 throws off mound 50% breaking balls
45 to 60 throws in batting practice (fastball only)
Step 13: 30 throws off mound 75% (warm-up)
30 breaking balls 75%
30 throws in batting practice
Step 14: 30 throws off mound 75% (warm-up)
60 to 90 throws in batting practice (Gradually increase breaking balls)
Step 15: Simulated game: Progressing by 15 throws per workout (pitch count)

Use interval throwing 120' phase as warm-up except for step 12, 13, 14. All throwing off the mound should be done in the presence of your pitching coach to stress. (Use speed gun to aid in effort control.) Copyright © 2004 by the Advanced Continuing Education Institute, LLC. All Rights Reserved. Any redistribution or reproduction of any materials herein is strictly prohibited.

- Completion of sport-specific program
- Satisfactory isokinetic testing
- Clearance by MD

Sport-Specific Criteria

- The clinician should assess for any asymmetries or deficits that could potentially impede an athlete's return to competition (shoulder GIRD and shoulder TROM).
  - Bilateral comparison of shoulder range of motion
  - Scapular muscular strength
  - Mobility and stability of the trunk
  - Biomechanical faults with throwing

After Return to Sport

Continuing Fitness or Rehabilitation Exercises

- Continued maintenance program for throwing athlete during the season (usually every other day)
- Total body endurance training to minimize fatigue related injuries

Exercises and Other Techniques for Prevention of Recurrent Injury

- The rehabilitation specialist should implement both an in-season and off-season program of which the goals and aims will differ.
  - The in-season program should emphasize maintaining strength, flexibility, range of motion, and neuromuscular control in order to aid the athlete in the recovery and preparation of athletic competition.
  - The off-season program should focus on athletic preparation and enhancement through the combination of strength, agility, power, endurance, and sport-specific training.
- Maintain proper shoulder ROM (especially, prevent GIRD and normalize TROM).
- Maintain scapular position and posture.

Evidence

Bernas GA, Ruberte Thiele RA, Kinnaman KA, et al: Defining safe rehabilitation for ulnar collateral ligament reconstruction of the elbow: A biomechanical study. *Am J Sports Med* 37:2392–2400, 2009.

This controlled laboratory study evaluated the strain on the ulnar collateral ligament in eight cadaveric elbows following ulnar collateral ligament reconstruction using a gracilis tendon graft. Differential variable reluctance transducers were used to measure strain on the anterior and posterior bands during elbow passive range of motion, 22.2 N isometric flexion and extension contractions, and 3.34 N x m varus and valgus torques at 90° flexion. The authors reported at 0 to 50 degrees flexion produced 3% or less strain, strain at 90° flexion of 7%, no significant strain with forearm rotation, and an significant increase in strain with valgus torques. (Level of evidence NA)

Cain EL, Jr, Andrews JR, Dugas JR, et al: Outcome of ulnar collateral ligament reconstruction of the elbow in 1281 athletes: Results in 743 athletes with minimum 2-year follow-up. *Am J Sports Med* 38:2426–2434, 2010.

This retrospective outcome study reported on the outcomes of athletes and return to play following UCL reconstruction minimum 2-year follow-up (average 38.4 months, range 24 to 130 months). Eighty-three percent were able to return to their previous level of competition or higher. The average time for the initiation of throwing was 4.4 months and return to full competition was 11.6 months. The protocol described in this chapter was used in this study with 83% of the patients returning to preinjury level. (Level IV evidence)

Davidson PA, Pink M, Perry J, et al: Functional anatomy of the flexor pronator muscle group in relation to the medial collateral ligament of the elbow. *Am J Sports Med* 23:245–250, 1995.

This controlled laboratory study evaluated the anatomical relationship of the pronator teres, flexor carpi radialis, flexor digitorum superficialis, and flexor carpi ulnaris muscles to the ulnar collateral ligament at 30, 90, and 120 degrees of elbow flexion in 11 cadaveric elbows. The flexor carpi ulnaris is functionally important because it is the predominant musculotendinous unit overlying the UCL, whereas the flexor digitorum superficialis muscle has a large bulk and a near proximity, making these specific muscle groups important to provide stability to the medial aspect of the elbow in the throwing athlete. (Level of evidence NA)

Fleisig GS, Bolt B, Fortenbaugh D, et al: Biomechanical comparison of baseball pitching and long-toss: Implications for training and rehabilitation. *J Orthop Sports Phys Ther* 41:296–303, 2011.

The authors performed a biomechanical analysis of 17 healthy college baseball pitchers throwing from a mound, 37 m, 55 m, and maximum distance long toss. They reported horizontal trajectory flat-ground throwing produced similar biomechanical patterns to pitching; whereas maximum-distance throws had increased torques and changes in kinematics. These torques are especially true at the medial elbow and onto the UCL. The authors advised caution of maximum distance throwing during rehabilitation and training. (Level of evidence NA)

Werner SL, Fleisig GS, Dillman CJ, et al: Biomechanics of the elbow during baseball pitching. *J Orthop Sports Phys Ther* 17:274–278, 1993.

This controlled laboratory study evaluated the biomechanics of seven healthy pitchers. During pitching a medial shear force of 300 N and a compressive force of 900 N are imparted upon the elbow. A valgus stress of 64 N x m occurs at the elbow during the acceleration phase of throwing. This study demonstrates the stresses that occur during throwing and the importance of optimal strength and endurance of the upper extremity kinetic chain. (Level of evidence NA)

Multiple Choice Questions

QUESTION 1. The hinged brace is used to accomplish what goal(s)?

A. Protect the reconstructed ligament.
B. Gradually increase PROM.
C. Restrict activities at the elbow joint.
D. All of the above

QUESTION 2. Criteria for implementing an interval throwing program includes all of the following except

A. full, pain-free elbow ROM.
B. shoulder isokinetic test ER/IR ratio of 45%.
C. negative valgus instability.
D. successful completion of one- and two-hand plyometric program.

QUESTION 3. When is it safe to initiate isotonic strengthening exercises for hamstring/calf following UCL reconstruction utilizing gracilis graft?

A. Week 2
B. Week 4
C. Week 6
D. Week 8

QUESTION 4. Plyometrics (two-hand drills) can be safely initiated at what time frame postoperatively?

A. Week 4
B. Week 8
C. Week 12
D. None of the above

QUESTION 5. UCL reconstruction surgery in the throwing athlete results in what percentage returning back to preinjury sport level?

A. 50%
B. 74%
C. 84%
D. 100%

Answer Key

QUESTION 1. Correct answer: **D** (see Box A, Phase II)

QUESTION 2. Correct answer: **B** (see Phase IV)

QUESTION 3. Correct answer: **C** (see Phase III)

QUESTION 4. Correct answer: **B** (see Phase III)

QUESTION 5. Correct answer: **C** (see Evidence, Cain et al., 2010)

BEYOND BASIC REHABILITATION: RETURN TO PITCHING AFTER ULNAR COLLATERAL LIGAMENT RECONSTRUCTION

E. Lyle Cain, Jr., MD, Kevin E. Wilk, PT, DPT,
and Todd R. Hooks, PT, OCS, SCS, ATC, MOMT, MTC, CSCS, FAAOMPT

ASPECTS OF PITCHING THAT REQUIRE SPECIAL ATTENTION IN REHABILITATION

- Pitching is a repetitive activity that produces extremely high stresses upon the elbow, including a valgus force of 64 Nm, which exceeds the tensile strength of the UCL.
- Increased valgus forces have been shown to occur with improper pitching mechanics, including late trunk rotation, reduced shoulder external rotation, and increased elbow flexion.
- Youth baseball pitchers who pitch more than 100 innings in a year, pitch when fatigued, and also play catcher have been shown to have an increased risk of elbow injury; therefore proper education is critical for these athletes.

Introduction

Injury to the ulnar collateral ligament (UCL) is common among baseball pitchers and is increasingly being reported in youth baseball players and high school players. Because of the inherent valgus stresses placed upon the elbow that exceed the ultimate tensile strength of the UCL with pitching, a comprehensive rehabilitation program is crucial to enable the athlete to return to play. Current surgical reconstruction and rehabilitation techniques have provided good results with return-to-play criteria.

Literature

In the first report of UCL reconstruction, Jobe et al.[1] reported a 62.5% success rate, with complications mainly related to the ulnar nerve. Since that initial report, several authors have documented improved success and fewer complications through use of a muscle-splitting technique, and modifications of the original surgical reconstructive fixation.

Rohrbough et al.[2] reported on the docking technique, with 33 of 36 (92%) patients able to return to their prior level of competition.

Recently Cain et al.[3] reported on the outcomes of 643 patients following UCL reconstruction, with an 83% return to the same or higher level of competition rate.

Phase I: Advanced Strength and Conditioning Programs

Periodization

- Athletes seen postoperatively, whether in a clinic or training room, following UCL reconstruction typically will follow a linear periodization program because of the precautions that are inherent upon the reconstructed ligament during the acute phases of rehabilitation.
- Therefore during the early phases of treatment while the ligamentization process is occurring, the athlete will focus on the initial phases of the linear periodization model of hypertrophy and strength gains. The athlete will perform forearm, glenohumeral, and scapulothoracic strengthening exercises for increased vascularity and hypertrophy and to allow tissue preparation for the advanced strengthening exercises, which are typically begun at 8 weeks postoperatively.
- Plyometric activities can be initiated at 8 weeks postoperatively and mark a transition into power training, functional movement patterns, and conditioning as the athlete is able to progress to machine-based isotonic strengthening exercises to allow further gains for the phasic major muscle groups of the upper extremity.
- The athlete will continue with this training as an interval throwing program is begun at approximately 16 weeks postoperatively.
- The clinician will implement various mesocycle and microcycle training programs throughout the rehabilitation program, including the implementation of a hitting program (which may be begin around week 12 to 14) and introduction of an isotonic machine-based strength-based strengthening program.
- The clinician should be aware of the natural healing process of the reconstructed ligament and ensure that the rehabilitation and return-to-play program abides by these healing parameters.

Program Design/Performance Training Program

Sport-Specific Concepts of Integrated Training

- Training continuum
  - A program that incorporates core training and hip and lower extremity training. This program can be initiated early during the rehabilitation program (usually at about 4 to 6 weeks postoperatively). Often stability ball exercises are used to incorporate trunk, core, and lower extremity into the program.
- Flexibility and mobility for joint stability
  - The clinician should ensure that the athlete maintains full range of motion and flexibility of the entire upper extremity throughout the advanced phases of rehabilitation.

FIGURE 11-25. Grade III mobilization to regain elbow extension. The clinician applies a dorsal translation to the proximal ulna while stabilizing the humerus to regain extension range of motion.

- As physical demands are increased upon the arm during the rehabilitation program, an athlete may have difficulty maintaining full elbow range of motion. The athlete will perform pre- and post-workout flexibility exercises for the forearm flexors and extensors, biceps, and triceps musculature.
- In addition, the clinician should continually monitor the glenohumeral and scapulothoracic soft tissue throughout the rehabilitation program.
- The clinician can also ensure full elbow range of motion is maintained during the advanced strengthening phase by performing grade III and IV mobilizations. Mobilizations at end range can be performed at this later stage in the rehabilitation because of adequate ligament healing. Mobilizations can be performed for flexion and/or extension as deemed appropriate by the clinician. Humeroulnar and humeroradial mobilizations can be performed for extension with a force applied dorsally on the proximal radial or ulna (Figure 11-25). A scooping technique can be used to regain full elbow flexion (Figure 11-26). Soft tissue mobilization and stretching programs should be implemented daily into the rehabilitation program.

FIGURE 11-26. The clinician grasps the proximal ulna and applies a distraction/proximal scooping motion to assist in regaining lost elbow flexion.

- Training with optimum posture
  - Postural position training can be performed by having the athlete perform upper extremity strengthening exercises while in a functional position. The athlete can perform exercises with a split stance or single leg stance and perform prone stability ball exercises.
  - The primary emphasis when rehabilitating a throwing athlete will be on the posterior rotator cuff and scapular musculature with exercise training.
  - The athlete should strive to improve shoulder girdle strength, endurance, and power to ensure proper mechanics and to reduce the risk of shoulder injury following elbow surgery.
- Sensorimotor and balance training
  - Lower extremity proprioception exercises can be either integrated into upper extremity strength training or performed in isolation depending upon the aims and the phase of treatment.
  - Upper extremity proprioception and neuromuscular controls drills can be performed, including rhythmic stabilizations drills at 90/90 and PNF patterns performed while seated on a stability ball.
  - To enhance body proprioception and train the sensorimotor system the exercises may be performed on a stability ball to challenge the patient's entire body. The program we use is referred to as the advanced Thrower's Ten program.[4]
- Core training
  - Core training involves both mobility and stability training. The clinician should ensure the athlete has proper mobility in the thoracic and lumbar spine. The athlete may be instructed to perform mobility exercises, including thoracic rotation, and

TIMELINE 11-3: **Return To Pitching Following Ulnar Collateral Ligament Reconstruction Using Autogenous Palmaris Longus Graft (Accelerated ROM)**

PHASE I (weeks 0 to 3)

- Goals:
  - Protect healing tissue
  - Decrease pain/inflammation
  - Retard muscular atrophy
  - Protect graft site—allow healing

Postoperative Week 1

- Brace: Posterior splint at 90° elbow flexion
- ROM:
  - Wrist AROM ext/flexion immediately postoperative
- Elbow postoperative compression dressing (5 to 7 days)
- Wrist (graft site) compression dressing 7 to 10 days as needed
- Exercises:
  - Gripping exercises
  - Wrist ROM
  - Shoulder isometrics (no shoulder ER)
  - Biceps isometrics
- Cryotherapy: to elbow joint and to graft site at wrist

Postoperative Week 2

- Brace: Elbow ROM 25° to 100° (gradually increase ROM: 5° Ext/10° of Flex per week)
- Exercises:
  - Continue all exercises listed above
  - Elbow ROM in brace (30° to 105°)
  - Initiate elbow extension isometrics
  - Continue wrist ROM exercises
  - Initiate light scar mobilization over distal incision (graft)
- Cryotherapy: Continue ice to elbow and graft site

Postoperative Week 3

- Brace: Elbow ROM 10° to 120°
- Exercises:
  - Continue all exercises listed above
  - Elbow ROM in brace
  - Initiate active ROM wrist and elbow (no resistance)
  - Initiate light wrist flexion stretching
  - Initiate active ROM shoulder:
  - Full can
  - Lateral raises
  - ER/IR tubing
  - Elbow flex/extension
  - Initiate light scapular strengthening exercises
  - May incorporate bicycle for lower extremity strength and endurance

PHASE II (weeks 4 to 7)

- Goals:
  - Gradual increase to full ROM
  - Promote healing of repaired tissue
  - Regain and improve muscular strength
  - Restore full function of graft site

Postoperative Week 4

- Brace: Elbow ROM 0° to 125°
- Exercises:
  - Begin light resistance exercises for arm (1 lb)
  - Wrist curls, extensions, pronation, supination
  - Elbow extension/flexion
  - Progress shoulder program emphasizing rotator cuff and scapular strengthening
  - Initiate shoulder strengthening with light dumbbells

Postoperative Week 5

- ROM: Elbow ROM 0° to 135°
- Discontinue brace
- Maintain full ROM
- Continue all exercises: Progress all shoulder and UE exercises (progress weight 1 lb)

Postoperative Week 6

- AROM: 0° to 145° without brace or full ROM
- Exercises:
  - Initiate Thrower's Ten program
  - Progress elbow strengthening exercises
  - Initiate shoulder external rotation strengthening
  - Progress shoulder program

Postoperative Week 7

- Progress Thrower's Ten Program (progress weights)
- Initiate PNF diagonal patterns (light)

A timeline for rehabilitation after UCL reconstruction using autogenous gracilis graft (accelerated ROM) is given in the previous section of this chapter.

quadruped exercises, to help promote mobility and allow for dissociation of adjacent body segments.
  - Core stability exercises that are performed in prone, side-lying, quadruped, and supine position can be continued as deemed appropriate by the rehabilitation specialist. These exercises can be progressed to include rotational and diagonal pattern exercises for the upper extremity while having the athlete sit on a stability ball or in a standing position.
  - Additional side-lying ER can be performed on a stability ball using a HALO trainer (Figure 11-27).
- Cardiorespiratory training
  - Endurance training should be progressed to include aerobic and anaerobic training that can be performed for both the upper and lower extremity. Cardiorespiratory training should be initiated early in the rehab program (usually at 2 to 3 weeks postoperatively).
- Multiplanar training activities
  - D2 PNF pattern exercises are performed to increase functional strength of the upper extremity and allow integration of movement patterns. These exercises can be performed using Thera tubing or manual resistance.
- Training for optimum muscle balance
  - Although a balanced program for the rotator cuff and scapular musculature is employed during the postoperative program, posterior cuff training is emphasized because of the inherent weakness of the posterior cuff. This can be accomplished during the

TIMELINE 11-3: **Return To Pitching Following Ulnar Collateral Ligament Reconstruction Using Autogenous Palmaris Longus Graft (Accelerated ROM)** (Continued)

PHASE III (weeks 8 to 14)

- Goals:
  - Increase strength, power, endurance
  - Maintain full elbow ROM
  - Gradually initiate sporting activities

Postoperative Week 8

- Exercises:
  - Initiate eccentric elbow flexion/extension
  - Continue isotonic program: forearm and wrist
  - Continue shoulder program—Thrower's Ten program
  - Manual resistance diagonal patterns
  - Initiate plyometric exercise program
  - (Two-hand plyos close to body only)
  - Chest pass
  - Side throw close to body
  - Continue stretching calf and hamstrings

Postoperative Week 10

- Exercises: Continue all exercises listed above
- Program plyometrics to two-hand drills away from body
  - Side to side throws
  - Soccer throws
  - Side throws

Postoperative Weeks 12 to 14

- Continue all exercises
- Initiate isotonic machines strengthening exercises (if desired)
  - Bench press (seated)
  - Lat pull down
- Initiate golf, swimming
- Initiate interval hitting program

PHASE IV (weeks 14 to 32)

- Goals:
  - Continue to increase strength, power, and endurance of upper extremity musculature
  - Gradual return to sport activities

Postoperative Week 14

- Exercises:
  - Continue strengthening program
  - Emphasis on elbow and wrist strengthening and flexibility exercises
  - Maintain full elbow ROM
  - Initiate one hand plyometric throwing (stationary throws)
  - Initiate one-hand wall dribble
  - Initiate one-hand baseball throws into wall

Postoperative Week 16

- Exercises:
  - Initiate interval throwing program (Phase I) (long toss program)
  - Continue Thrower's Ten Program and plyos
  - Continue to stretch before and after throwing

Postoperative Weeks 22 to 24

- Exercises: Progress to Phase II throwing (once Phase I successfully completed)

Postoperative Weeks 30 to 32

- Exercises: Gradually progress to competitive throwing/sports

FIGURE 11-27. Sidelying external rotation performed on a stability ball with modified support.

training program by a multitude of variations in the rehabilitation program, including performing additional sets or number of exercises that emphasize the posterior rotator cuff.
    - Unilateral muscular ratios of thrower's shoulder are imperative. We routinely examine and focus on ER/IR ratios, ER/Abd ratios, scapular retraction/protraction ratios, and scapular elevation/depression. These values can be found in articles by Wilk et al.[5,6]
- Training for optimum muscle functional strength:
    - Isotonic strength training exercises are performed to improve total arm strength and emphasize the phasic musculature. The athlete can perform seated chest press, lat pull down, and seated rows. The primary emphasis of this strength training will be on the scapular musculature.
    - In addition, the core of the body and LE is critical to train.
- Training for optimum muscle functional power:
    - Power training exercises are performed to train for explosive movement. Power training should involve both lower and upper body training. Power training exercises are performed with maximum intensity for a few repetitions.
    - The athlete can perform these exercises with a medicine ball with the behind the back throw (Figure 11-28), ball slams (Figure 11-29), and lunge throws (Figure 11-30).
- Neuromuscular dynamic stability exercises:
    - Rhythmic stabilization exercises are performed with the shoulder in the 90/90 position. The athlete is instructed to maintain a static position while the clinician provides perturbations to the athlete with the eyes open or closed (Figure 11-31).
- Training for speed, agility, and quickness:
    - The athlete can perform high-speed neuromuscular exercises for the involved upper extremity. This can be performed using manual resistance or Thera tubing as the clinician maintains constant tension throughout the range of motion (Figure 11-32).
    - Training at high speeds prepares the athlete for sporting activity by increasing eccentric control and learning to dissipate the forces that are imparted upon the elbow during overhead activities such as throwing.
- Plyometric training
    - Two-hand plyometric drills can be performed for strength and conditioning training either against a wall or plyoback, depending upon availability. The athlete is encouraged to integrate lower extremity and trunk movements during the exercise.
    - These exercises are performed 8 to 10 repetitions to provide advanced strength training. These exercises are initiated with arms close to body and are progressed to arms away from body. The athlete can

FIGURE 11-28. Behind the back toss is performed by having the athlete grasp a medicine ball in a squatting position and explosively stand with extending arms overhead to throw the ball behind the back.

FIGURE 11-29. Ball slams are performed by having the athlete raise a medicine ball overhead followed by throwing the ball toward the ground as hard as possible.

FIGURE 11-31. 90/90 Rhythmic stabilization drills performed during ER tubing exercise.

perform chest pass, side throws, and overhead throws.
  - The two-hand drills are initiated at 12 weeks postoperatively, whereas one-hand drills are usually initiated at 14 weeks postoperatively. The actual timeframes are based on objective criteria such as ROM, elbow stability, functional progression, and rehab progression.
- Functional training
  - The athlete can perform high speed strengthening exercises for throwing shoulder using a Thera-Band or surgical tubing while the clinician provides constant elastic tension throughout the range of motion. This exercise is designed to provide high speed strength training and incorporate eccentric deceleration training.
  - Functional training is usually initiated at 12 to 14 weeks postoperatively but is based on fulfilling specific criteria.
- Sport-specific training:
  - The athlete can perform medicine ball overhead and side throws using a step lunge with training focus on generating power with the lower extremity through leg drive.
  - The most common athlete undergoing UCL reconstruction is the throwing athlete; therefore sport-specific training begins with one-hand baseball-style throws with a lightweight Plyoball (1 lb) at 14 to 16 weeks postoperatively.

Olympic Lifts Used in the Training Program

- Snatch: not safe for UCL rehabilitation
- Clean and jerk: not safe for overhead athletes
- Power clean: not safe for overhead athletes

Training Principles Used in the Design of the Program

- The strength and conditioning program follows the principle of variation. The initial phases of rehabilitation focus on regaining full elbow range of motion and strength training.
- As the athlete progresses into a throwing program, the intensity and frequency of the program is adjusted to account for the increased workout.
- The athlete will typically perform strengthening exercises on the same day as throwing and perform core

FIGURE 11-30. Forward lunges are performed by having the athlete lunge forward while simultaneously throwing the ball forward.

FIGURE 11-32. High speed Thera tubing manual resistance exercise. The clinician maintains a constant tension throughout the motion as the athlete performs the high speed exercise.

stability, lower extremity exercises, and cardiovascular training on alternating days.
- The program will be individualized based on the overhead athlete's sport, age, position, and time of injury. It is important to make changes based on the patient's age.

Application of Acute Training Variables

- Repetitions: 10 to 15
- Sets: three
- Rest interval: recovery times can vary depending upon the exercise format performed, and can be incorporated into the treatment such as with active recovery when the athlete is performing superset exercises. The athlete can also use a return to resting respiratory rate during high-intensity strength training.
- Intensity: moderate to high intensity in later stages of rehabilitation program
- Repetition tempo:
  - Repetition tempos can be varied throughout the rehabilitation program. Typically a set of exercise performed during the strengthening phase of treatment will last 30 to 50 seconds.
  - A 3-0-1-2 tempo can be used during the later stages of treatment, where the athlete will lower the weight over 3 seconds, no rest at the bottom of the movement, and concentrically raise the arm in 1 second, and perform a 2-second isometric hold at the top of the exercise movement.
- Training frequency: Upper extremity strengthening exercises are typically performed 3 times per week (and can be performed during the interval throwing program if applicable) and the athlete can perform core training, lower extremity, and conditioning training on alternate days.
- Training duration: Training durations of 2 to 3 hours are typical when including warm-up, flexibility, and manual techniques. Training volume: A high volume of exercises will be performed during the rehabilitation program, with repetitions varying depending upon the muscle group. Typically for posterior rotator cuff and scapular musculature the athlete may perform three to five exercises with each exercise performed at three sets of 10 to 20 repetitions depending upon the treatment goal, lending upon a high volume of exercises.
- Specific exercises used in the training
  - Thrower's Ten exercise
  - Prone bilateral horizontal abduction, extension, scaption, and row into ER on stability ball
  - Latissimus pull-down
  - Seated rows
  - Seated bench press

Phase II: Performance Enhancement Training Techniques

Periodization

- The performance enhancement training can be implemented using a mesocycle periodization method.
- A pre-throwing mesocycle program consists of a series of microcycle exercises to prepare the athlete for throwing by ensuring the athlete has full range of motion, flexibility, strength, and proprioceptive sense.
- The next mesocycle, the throwing program phase, is further broken down into microcyles that focus on generating, controlling, and dissipating the forces that occur during throwing.
- The athlete will also perform microcycles that focus on plyometric activities, power training, endurance exercises, and body movement coordination exercises.

Program Design/Performance Training Program

Sport-Specific Concepts of Integrated Training

- Flexibility/joint mobility for joint stability
  - Pre- and postexercise flexibility activities are encouraged to prevent any DOMS related tightness and decreased muscle flexibility. The clinician can also perform soft tissue mobilization exercise with joint motion to increase mobility of the soft tissue.
  - The clinician should assess the mobility of the elbow to determine if the restriction is joint or soft tissue related. The clinician can perform joint mobilization activities if a restriction is noted. The clinician can perform grade III and IV mobilizations. If a joint restriction is noted into flexion, the athlete can also perform wall slides to increase range of motion into elbow flexion.
- Training with optimum posture
  - Postural and position awareness are important for the overhead athlete to optimize athletic performance and decrease risk of injury. The athlete can perform scapular retraction exercises on a stability ball, lawnmower diagonal chops in a split stance.
- Sensorimotor and balance training
  - Neuromuscular control and proprioception training can be performed for the lower and upper extremity. The clinician can incorporate shoulder diagonal pattern exercises while in a single leg stance.
  - Lower extremity proprioception training can be performed with upper or lower extremity movement drills to shift the center of gravity for increased proprioception training.
- Core training
  - The athlete can progress concomitantly performing isometric core exercises with upper extremity isotonic exercises to integrating the core with upper and/or lower extremity therapeutic exercises.
  - The athlete can perform diagonal pattern flexion/extension activities to provide isotonic strengthening and neuromuscular education to the trunk musculature.
- Cardiorespiratory training
  - Although cardiovascular fitness is important for the athlete, local muscular endurance exercises can also be integrated into the rehabilitation program.
  - The athlete can perform time bouts of exercises to provide endurance training for the rotator cuff musculature. Plyometric prone ball drops and rainbow

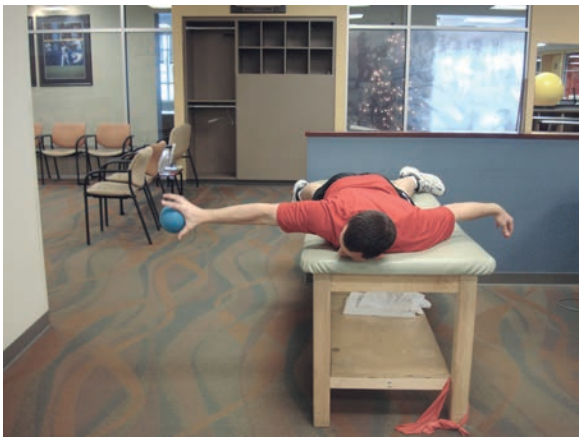

FIGURE 11-33. Prone ball flips. This exercise is used to increase local endurance.

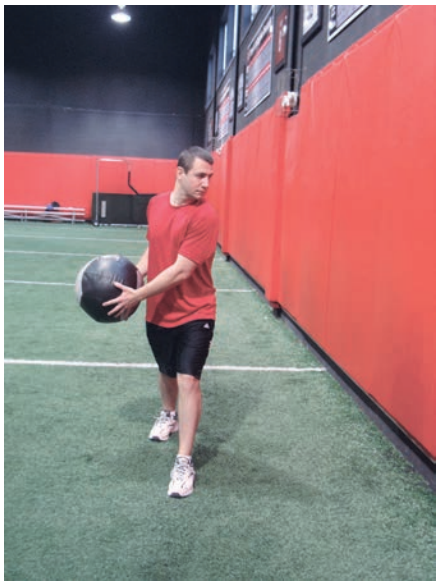

FIGURE 11-34. Rotational side throws. The athlete lunges forward while rotating the trunk and throwing a medicine ball across the body.

wall dribbles can be implemented with sets beginning at 30 seconds and can be progressed to 1 minute as tolerated (Figure 11-33).

- Multiplanar training activities
  - PNF D2 flexion and extension can be performed unilaterally and bilaterally. The athlete can also perform diagonal movement exercises for the trunk and entire body to allow for coordination training and facilitation of neurophysiological motor learning.
- Training for optimum muscle balance
  - Posterior cuff and scapular musculature are emphasized throughout rehabilitation. Manual resistance exercises can be performed including side-lying ER, prone row, and prone horizontal abduction.
- Training for optimum muscle functional strength
- Lower extremity strengthening exercises are performed to optimize the generation of forces for forces with throwing. The athlete can perform leg press, multiangle hip, and lunge exercises.
- Training for optimum muscle functional power
  - The athlete can perform lower extremity specific power exercises such as box hops, scissor jumps, and sled pushes; upper extremity drills such as medicine ball underhand throws, rotational side throws (Figure 11-34), and step throws can be performed to engage lower extremity and trunk in power generation.
- Neuromuscular dynamic stability exercises
  - Rhythmic stabilization drills can be performed with the athlete in a single leg stance with the arm in a 90/90 position. The athlete can perform diagonal movement pattern exercises incorporating the trunk and lower extremity with manual perturbations and stabilizations applied to the core and upper extremity.
- Training for speed, agility, quickness
  - High speed exercises using Thera-Band and/or speed pulleys can be used to prepare the athlete for throwing activities.
  - The athlete should also participate in lower extremity agility exercises such as ladder and cone drills, and high/low hurdles for hip activation (Figure 11-35).
- Plyometric training
  - Lower extremity plyometric drills are performed to isolate and train the athlete in explosive movements in preparation of throwing. Skipping, hop skips (Figure 11-36), and drop jumps (Figure 11-37) can be performed to improve explosive power of the lower extremity.
- Functional training
  - Exercises that incorporate hip and core activities with upper extremity movements can be performed to allow for the integration and coordination of activities. The athlete can perform lunges with rotational underhand medicine ball chop throws onto a wall.

FIGURE 11-35. High/low hurdles. The athlete performs step overs and squats under the high and low hurdles, respectively, for hip mobility and control.

FIGURE 11-36. Hop skips. The athlete performs a skip with a bounding hop on alternate landings.

- Sport-specific training
  - The athlete can perform strengthening exercises to simulate baseball specific activities such as throwing and batting by performing resistance training in a simulated stance and movement.

Training Principles Used in the Design of the Program

- The rehabilitation program to return an overhead athlete following UCL reconstruction to return to throwing will use the specific adaptation to imposed demands (SAID) principle.
- The initial or acute phases of treatment will focus on the restoration of normal range of motion, flexibility, and baseline strength. In this phase the athlete is placed on the advanced Thrower's Ten program.
- As the athlete is progressed throughout the rehabilitation, functional movement patterns are incorporated into the athlete's rehabilitation program to prepare the athlete for sport-specific training exercises.
- An interval throwing program is introduced into the treatment program to gradually introduce the stresses that incur with throwing.
- It is important that the clinician ensures baseline strength, flexibility, stability, and correct movement patterns are achieved before the institution of the highly specific act of throwing is introduced into the athlete's program.

FIGURE 11-37. Drop jumps. The athlete steps off a box landing on both feet and immediately jumps as high as possible.

Application of Acute Training Variables

- Repetitions: 8 to 10
- Sets: three
- Rest interval: 20 seconds to 1 minute depending upon the intensity of exercises performed.
- Intensity: high
- Repetition tempo: Performance enhancement exercises are performed at functional speeds to mimic sporting activity.
- Training frequency: The athlete can perform high demand activities such as plyometric drills 2 to 3 times per week, and perform functional sport specific drills on alternate days to allow for active recovery and avoid overtraining injuries.
- Training duration: 45 to 60 minutes of training to allow for optimal performance of training effect
- Training volume: The volume of the athlete's rehabilitation program will progressively increase; as such, the clinician should make certain to avoid overtraining by allowing for sufficient rest breaks, by alternating the muscle groups trained during a rehabilitation session, and by alternating the intensity of the exercises.
- Specific exercises used in the training
  - Plyometric external and internal rotation at 90° abduction with Thera tubing
  - Forward and lateral lunges
  - Box step ups with shoulder press

Phase III: Sport-Specific Training

Periodization

- The rehabilitation program of an athlete following UCL reconstruction consists of two mesocycle periodization programs termed the "interval throwing program."
- This program is further broken down into two components, Phase I and Phase II. These mesocycle programs are designed to systemically progress an athlete with a return to sporting activity and minimizing the chance of reinjury by gradually introducing the stresses that occur with throwing on the reconstructed elbow.
- The athlete begins with Phase I (level ground throwing) that is initiated at 45 feet and is gradually progressed to 120 or 180 feet (player and position dependent) and upon successful completion is allowed to begin Phase II (throwing off the mound).
- Phase II is progressed similarly to Phase I through systematically increasing the intensity, pitch count, and the types of pitches. The pitcher will generally begin at an intensity of 50% progressing to 75%, 90%, and 100% over a 4- to 6-week period. These mesocycle periodizations of treatment allow a gradual introduction of forces and strains upon the throwing arm, thus providing the athlete a regiment to increase strength, proper body mechanics, and confidence of throwing throughout this progression.

Program Design/Performance Training Program

Sport-Specific Concepts of Integrated Training

- Flexibility/joint mobility for joint stability
  - The athlete should perform flexibility and range of motion activities pre- and post-workout for the throwing arm, trunk, and lower extremities.
- Training with optimum posture
  - In addition to the Thrower's Ten program, the athlete will perform exercises with the shoulder and elbow in a functional position. The athlete can perform ER/IR exercises with the shoulder at 90° abduction and lawnmower rows for scapula musculature.
- Sensorimotor and balance training
  - Lower extremity mobility exercises, such as high and low hurdles, can be performed to integrate hip functional mobility. The athlete can perform rotator cuff strengthening exercises in a single limb stance to integrate lower extremity balance training with upper extremity exercises.
- Core training
  - Abdominal strengthening exercises are performed, including planks and crunches; in addition the athlete should perform trunk extension exercise for the erector spinae musculature. Diagonal pattern core strengthening exercises can be performed to replicate the throwing motion.
- Cardiorespiratory training
  - The athlete should continue with both aerobic and anaerobic conditioning. The athlete is encouraged to alternate the type of conditioning program to avoid overtraining injuries. The athlete can perform aquatic conditioning activities, running hills, or exercising on cardio equipment.
- Multiplanar training activities
  - Multiplanar total body strengthening and coordination exercises are implemented to allow functional training for baseball specific activities. The athlete can perform these exercises using a speed cable column, kettle bells, or medicine balls. The athlete is encouraged to synchronize the lower extremity and trunk throughout the movement.
- Training for optimum muscle balance
  - The athlete will perform a comprehensive shoulder strengthening program with emphasis upon the posterior cuff and scapular musculature because of the high demands incurred during throwing. The athlete can perform additional sets and/or number of exercises for these muscle groups during training.
- Training for optimum muscle functional strength
  - Athlete will progress into a maintenance program as the throwing program is progressed and throughout the baseball season. The athlete can perform a set of the Thrower's Ten exercises before throwing as a warm-up activity, and following a throwing session can perform an additional set or two of exercises as part of a maintenance program.
- Training for optimum muscle functional power
  - Plyometric drills are performed with and without the use of a plyoback. The athlete will increase the weight of the ball and perform sets of six to eight repetitions. The athlete can perform chest, side-to-side, and overhead throws onto a plyoback, as well as lunge throws and cradle underhand tosses using a medicine ball.
- Neuromuscular dynamic stability exercises
  - The athlete can perform joint reproduction/reaction drills during the rotator cuff strengthening exercises. These exercises can incorporate proprioceptive and kinesthetic awareness into the strengthening program.
- Training for speed, agility, and quickness
  - The athlete can perform supine manual band resistance exercises for the rotator cuff and scapulothoracic joint: external rotation, horizontal abduction, shoulder extension, shoulder flexion, D2 flexion, and extension (Figure 11-38). These exercises will be performed at high speeds as the clinician maintains constant tension upon the Thera tubing.
- Plyometric training
  - Two-hand plyometric exercises are continued.
    - Chest, side to side, side throws, overhead throws
  - Single arm plyometrics are performed to replicate the throwing motion and gradually introduce stresses upon the elbow in preparation for throwing.
- Sport-specific training
  - As the interval-throwing program is progressed, the clinician should ensure the athlete is throwing with proper body mechanics including a crow-hop. The use of a crow-hop method encourages proper throwing mechanics by incorporating the lower extremity and trunk.

FIGURE 11-38. Manual Thera tubing resistance. The clinician maintains constant tension upon the Thera tubing as the athlete performs the exercise at a high speed.

Training Principles Used in the Design of the Program

- The rehabilitation specialist should ensure that every athlete is progressed through the interval throwing program using the principle of individualization.
- Most athletes are eager to return to competition as early as possible; therefore some may feel that they can expedite the throwing program. This program is

designed to re-educate the athlete in the proper mechanics of throwing by energy transfer and absorption throughout the throwing motion.
- The interval-throwing program is designed to allow each athlete to progress through each step of the program without pain or complications from throwing before the next step in the program. This program is designed to allow individual variability of each athlete based upon skill level, athletic ability, clinical presentation, and tolerance of activities, while minimizing the chance of re-injury and setbacks.

Application of Acute Training Variables

- A pre-warm up regimen is important throughout the implementation of the throwing program. A prethrowing program consists of a total body warm up and stretching program, followed by one set of the interval throwing program and plyometric exercises. These exercises and activities are designed to provide proper tissue preparation for throwing activities. The prethrowing set of exercises can be performed with a low to moderate weight, and high repetitions.
- The athlete may also choose to perform these exercises with an increased cadence and decreased rest time between exercises with the aim of increasing local blood flow to the glenohumeral and scapulothoracic musculature.
- The athlete will complete the remaining two sets of Thrower's Ten and plyometric drills after the throwing program. The clinician may choose to instruct the athlete to increase weight, repetitions, and cadence for the remaining two sets of strengthening and plyometric drills.
- Plyometric exercises can consist of two- and one-handed drills both below and above shoulder height. The athlete can also perform neuromuscular control drills while the shoulder is maintained at a 90/90 position. Wrist ball flips can also be performed for plyometric drills targeting the forearm musculature.
- Repetitions: six to ten
- Sets: three
- Rest interval: Rest intervals will increase as the intensity of exercise increases. As a result, the athlete may rest up to 5 minutes between sets during a throwing program.
- Intensity: high
- Repetition tempo: The athlete can perform therapeutic exercises with a faster tempo without a pause at the eccentric-isometric phase of the exercise in order to induce a stretch reflex for explosive strength and power training.
- Training frequency: three times per week of sport specific training with core, lower extremity and cardiovascular endurance performed on alternating days
- Training duration: A thorough rehabilitation program to allow sufficient time for warm-up, flexibility, strengthening exercises, plyometrics, and manual techniques may require approximately 2 hours to complete.
- Training volume: The volume of the athlete's rehabilitation program will progressively increase; as such the clinician may adjust the athlete's program by alternating days exercises are performed to minimize the volume of exercises as well as provide rest.
- Specific exercises used in the training
  - Thrower's Ten exercises
  - Advanced Thrower's Ten program
  - Plyometric drills
    - Two-hand: chest, overhead, side throws, step throws, rotational underhand
    - One-hand: 90/90, light toss
  - Machine-based strengthening exercises: lat pull down, rows, shoulder press
  - Core stabilization exercises: planks, side planks, cable chops

Sports Performance Testing

General Information

- General history
  - The clinician should determine the athlete's goals for returning back to play, which can assist the clinician in establishing a comprehensive rehabilitation program.
  - The clinician should determine if the athlete has had any change in throwing mechanics, velocity, or pitching frequency.
  - Determine if the athlete has had prior history of shoulder injury or time missed because of shoulder pain.
  - The athlete's history of prior rehabilitation for any preceding injuries should be determined and outcome following rehab, including the use of a return to sports throwing program.
- Subjective questionnaires
  - The SF 36 form can be used to determine general health status.
  - The Kerlan-Jobe Orthopaedic Clinic Shoulder and Elbow Score and the American Shoulder and Elbow Surgeons scoring system are commonly used to assess the functional status of an athlete.
- Sports injury history
  - The clinician should determine if the injury to the UCL occurred acutely during a pitch or is chronic in nature with no known injury to the athlete.
  - The clinician should also determine if the athlete has any prior injuries/surgeries to the shoulder or current ailments that could hinder outcome.
  - Surgical history: The clinician should gain knowledge of the athlete's current operative procedure, either via operative note or communication with MD.
  - The clinician should also obtain history of any prior elbow or shoulder surgical procedure and outcome following surgery.
- Chronic conditions/medication
  - The clinician should note if the athlete is taking any antiinflammatory medication that could possibly mask the athlete's symptoms. Current or prior history of extended corticosteroid use (either oral or local injection) should be determined.

Specific Criteria for Progression to the Next Stage: Determining Readiness for Pitching

- Static/dynamic postural assessments
  - The clinician should perform a thorough static and dynamic testing of the athlete to determine baseline functional level and periodically throughout the rehabilitation program to assess progress and response to treatment.
  - The clinician can evaluate static posture in both the frontal and sagittal plane to note for any postural deficits in the lower extremity, trunk, and upper extremity that could potentially lead to injury.
  - The athlete can also perform dynamic movement drills such as deep squat and lunges.
  - Upper extremity dynamic assessments of the scapulohumeral rhythm should also be performed to evaluate for asymmetrical movements of the scapula with arm elevation.
- Dynamic muscle performance testing
