  - We routinely perform isokinetic testing on the throwers shoulder and elbow joints. In addition, static objective manual muscle testing using a hand-held dynamometer can be beneficial to document scapular muscle strength values.
  - Although static postural assessment is commonly performed and can aid the clinician assessing the athlete, the clinician will also assess the scapulothoracic rhythm during arm elevation. The clinician will make note of asymmetrical movement patterns during both the concentric and eccentric movements of arm elevation.
- Sport-specific testing
  - A motion analysis of the throwing athlete can be beneficial as the athlete is progressing through the throwing program. This evaluation can help correct improper or inefficient movement patterns of the athlete that could potentially cause injury and decrease performance.

Specific Criteria for Release to Unsupervised Complete Participation in Pitching

- The athlete must meet specific objective criteria:
  - ROM: Range of motion measurements for elbow flexion, extension, pronation, and supination should be measured. Although full elbow range of motion in all movements is sought during the rehabilitation program, it is common for these athletes to lack full motion. Therefore preoperative range of motion measurements is ideal to allow the clinician to understand each athlete's normal motion.
  - Strength: Strength assessment can be performed using manual muscle testing; however, the clinician may use a hand-held dynamometer or isokinetics to allow for a more objective test.
  - Joint stability: Valgus testing of the elbow can be performed to assess the stability of the ligament.
  - Patient's rehab progression: A proper and systematic rehabilitation progression should preclude the patient returning to sporting activity, including upper extremity strengthening and core strengthening exercises, plyometrics, and an interval throwing program.

Table 11-4 Peak Torque-to-Body Weight Ratios

Velocity	Shoulder (ER)	Shoulder (IR)	Shoulder (Abd)	Shoulder (Add)
180°/sec	18% to 23%	28% to 33%	26% to 33%	32% to 38%
300°/sec	12% to 20%	25% to 30%	20% to 25%	28% to 34%

Abd, Abduction; *Add,* adduction; *ER,* external rotation; *IR,* internal rotation.

  - Clinical examination: A thorough examination will also include the assessment of the ulnar nerve, pain free palpation, and shoulder range of motion.
- The athlete must be able to perform sporting activities and functional exercises without pain.
- The athlete must have a satisfactory clinical examination and MMT 5/5 all planes. Satisfactory isokinetic testing (Table 11-4).
- Successful completion of interval throwing program.

Recommended Ongoing Exercises

- Thrower's Ten strengthening program.
- Shoulder flexibility program with emphasis upon internal rotation range of motion.

Evidence

Bernas G, Ruberte Thiele RA, et al: Defining safe rehabilitation for ulnar collateral ligament reconstruction of the elbow: A biomechanical study. *Am J Sports Med* 37:2392–2400, 2009.

This controlled laboratory study reported on the strain in the anterior and posterior bands of the anterior bundle of the reconstructed elbow in eight cadaveric elbows during passive range of motion, 22.2 N isometric flexion and extension contractions, and 3.34 N x m varus and valgus torques. They reported from maximum extension to 50° of flexion 3% or less strain in both bands, no significant strain was noted with pronation and supination or during isometric contractions. Strain was noted approaching 7% in the posterior band at 90°, and increased strain occurred with valgus torque at the elbow. (Level of evidence NA)

Laudner KG, Stanek JM, Meister K: Differences in scapular upward rotation between baseball pitchers and position players. *Am J Sports Med* 35:2091–2095, 2007.

This controlled laboratory study measured the scapular upward rotation with the arm at rest, 60°, 90°, and 120° of elevation in 15 professional baseball pitchers and 15 position players with no recent history of upper extremity injury. They reported less scapula upward rotation (specifically at 60° and 90° elevation) in pitchers as compared with position players. This decrease in scapular upward rotation may place the pitchers at an increased risk of injury to the throwing arm. (Level of evidence NA)

Reinold MM, Wilk KE, Macrina LC, et al: Changes in shoulder and elbow passive range of motion after pitching in professional baseball players. *Am J Sports Med* 36:523–527, 2008.

This controlled laboratory study measured shoulder internal and external rotation and elbow flexion and extension range of motion on the first day of spring training before, immediately after, and 24 hours after pitching in 67 asymptomatic professional baseball pitchers. They reported a significant decrease in shoulder internal rotation (–9.5°), total motion (–10.7°), and elbow extension (–3.2°) were noted immediately after pitching and were present 24 hours after pitching. (Level of evidence NA)

Stanley E, Rauh MJ, Michener LA, et al: Shoulder range of motion measures as risk factors for shoulder and elbow injuries in high school softball and baseball players. *Am J Sports Med* 39:1997–2006, 2011.

This cohort study measured the shoulder range of motion during preseason for high school softball and baseball players and observed them during the season for injury rates. They reported players with a decrease greater than or equal to 25° of IR in the dominant shoulder were at four times greater risk of upper extremity injury as compared with players with a less than or equal to 25° decrease. (Level II evidence)

Vitale MA, Ahmad CS: The outcome of elbow collateral ligament reconstruction in overhead athletes: a systematic review. *Am J Sports Med* 36:1193–1205, 2008.

This systematic review reported on all published reports of UCL reconstruction in overhead athletes to determine what techniques were associated with better outcomes with a minimum of 1-year follow-up resulting in eight studies meeting the criteria. Overall 83% of patients had an excellent result with a complication rate of 10%. The figure-eight technique resulted in a 76% excellent result and an 8% rate of ulnar neuropathy; whereas the docking technique had a 90% excellent result with a 3% rate of postoperative ulnar neuropathy. (Level IIIa evidence)

Multiple Choice Questions

QUESTION 1. To minimize the risk of shoulder and/or elbow injury in a youth pitcher, which of the following would NOT be proper instruction for the athlete?

A. Minimize innings to no more than 100 in competition in a calender year.
B. The pitcher should play catcher when not pitching because of the short throw to the mound.
C. Curveballs should be limited or not thrown at a young age because of inherent stress.
D. Further limitations may need to be imposed upon a skeletally immature athlete.

QUESTION 2. Prone ball drops and wall dribbles are examples of exercises that can be implemented into a rehabilitation program for what training purpose?

A. To build grip strength
B. As a precursor to an interval throwing program
C. To increase local muscle endurance
D. To initiate above the shoulder strengthening exercises.

QUESTION 3. Which of the following activities is commonly used before throwing as part of a rehabilitation program?

A. Shoulder ROM/flexibility exercises
B. A jogging/biking activity for complete body warm-up
C. Two- and one-hand plyometric drills
D. All of the above

QUESTION 4. Altered throwing kinematics can contribute to increased valgus load upon the elbow during throwing. Which of the following kinematic errors could generate increased valgus forces upon the elbow?

A. Late trunk rotation
B. Reduced shoulder external rotation
C. Increased elbow flexion
D. All of the above

QUESTION 5. Which of the following statements is true concerning the relationship of shoulder range of motion and upper extremity injuries?

A. Players with a decrease greater than or equal to 25° of IR in the dominant shoulder were at four times greater risk of upper extremity injury as compared with players with a less than or equal to 25° decrease.
B. Players with a decrease of less than 20° of IR were five times less likely to be injured as compared with players with an increase of 30°.
C. Players with an increase greater than or equal to 25° of IR in the dominant shoulder were at twice the risk of upper extremity injury as compared with players with a less than or equal to 25° increase.
D. Players with an increase of greater than or equal to 5° of IR in the dominant shoulder were at 14 times greater risk of upper extremity injury as compared with players with less than or equal to 5° increase.

Answer Key

QUESTION 1. Correct answer: **B** (see Introduction)

QUESTION 2. Correct answer: **C** (see Phase II)

QUESTION 3. Correct answer: **D** (see Phase III)

QUESTION 4. Correct answer: **D** (see Introduction)

QUESTION 5. Correct answer: **A** (see study by Vitale & Ahmad, 2008)

Chapter 12

Elbow Stiffness

INTRODUCTION

Michael Levinson PT, CSCS, and David Altchek MD

Anatomy

- The elbow is a typical hinge type of joint, and has a normal motion of 0° (extension) to 145° (flexion), although the amount of motion that is required for activities of daily living is approximately 30° to 130°.
- Patients may also have hyperextension beyond 0° of extension in hyperlaxity or other soft tissue disorders.
- The pronation and supination are approximately 80° to 85°. Loss of extension is tolerated less than loss of flexion as patients like to have near full extension (or at least 30° for ADLs).
- Elbow stiffness can affect all aspects of elbow motion, including flexion, extension, supination and pronation.
- There are multiple causes of loss of motion of the elbow and are noted as both intrinsic and extrinsic factors in the following section. These typically cause stiffness of the elbow capsule and loss of volume of the elbow joint, and there are areas of bony overgrowth and osteophytes that may be due to overload or be posttraumatic in nature.
- The capsule and ligaments may also be abnormal, contracted, and thickened.
- The anatomy of the elbow is depicted in Figures 12-1 to 12-3.

Pathophysiology

Intrinsic Factors

- Articular deformities
- Articular surface malalignment
- Fibrosis of the flexor-pronator group
- Contracture of the thin anterior capsule
- Adhesions
- Hemarthrosis resulting from injury to the triceps or brachialis
- Impinging osteophytes
- Loose bodies
- Ulnar nerve entrapment
- Articular degeneration
- Highly congruent elbow joint
- Traversed elbow joint (by muscle rather than tendons)

Traumatic Factors

- Elbow dislocation: hyperextension, axial compression, valgus stress
- Concomitant fractures of the radial head, capitellum or coronoid
- Associated tears of the ulnar or lateral collateral ligaments
- Ischemia and soft tissue swelling
- Extension limited by contracture of the biceps tendon
- Repetitive extension activities (such as throwing or playing tennis) that lead to scarring of the anterior capsule or fibrosis of the flexor-pronator group

Classic Pathological Findings

- Thickened anterior and posterior capsule
- Osteophytes and/or loose bodies
- Loss of range of motion (ROM)
- Loss of upper extremity function
- Gradual increase of elbow pain
- Parasthesia

Clinical Presentation

History

- Significant trauma to the elbow (e.g., dislocation, fractures)

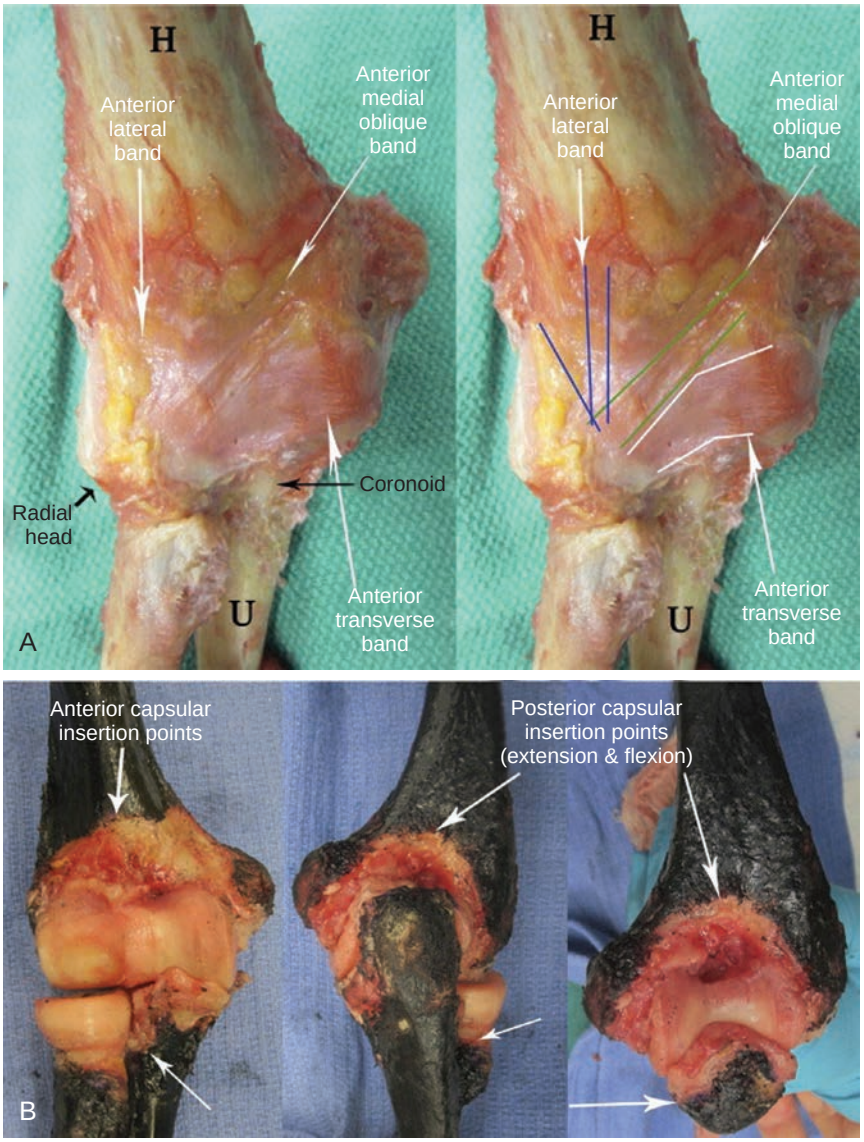

FIGURE 12-1. A, Anterior lateral, anterior medial oblique, and anterior transverse bands of the anterior capsule. **B,** Anterior and posterior view of a painted specimen with the capsule excised, demonstrating the area covered by the capsule. *(From Reichel LM, Morales OA: Gross anatomy of the elbow capsule: A cadaveric study. J Hand Surg. 2013;38:110–116.)*

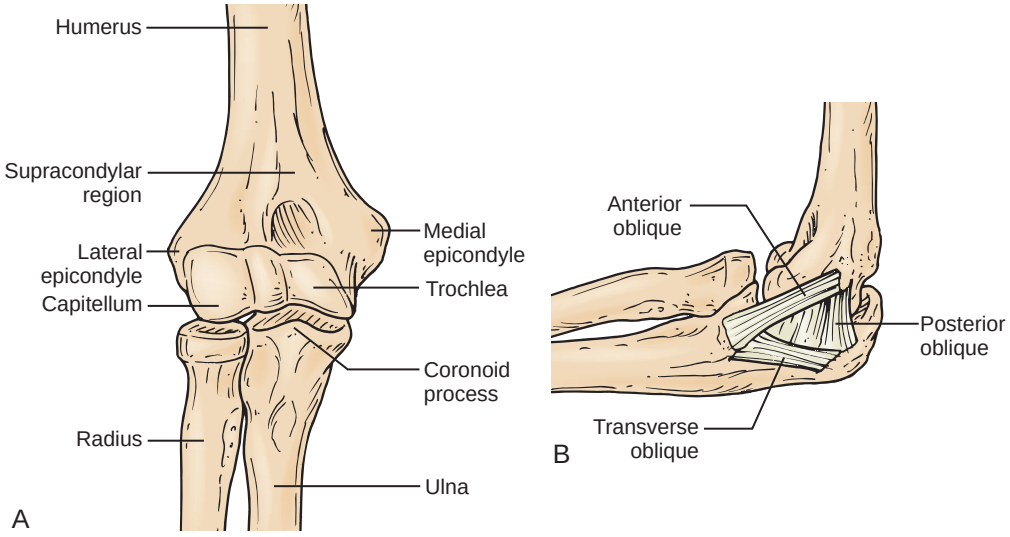

FIGURE 12-2. Anterior view of the elbow. *(Redrawn from Rogachefsky RA, Frey ME, Salcedo V, Santiago FH: The elbow: anatomy, pathology and diagnosis. In O'Young BJ, Young MA, Stiens SA, editors. Physical medicine and rehabilitation secrets, ed 3, 2008, Mosby, pp 352–357.)*

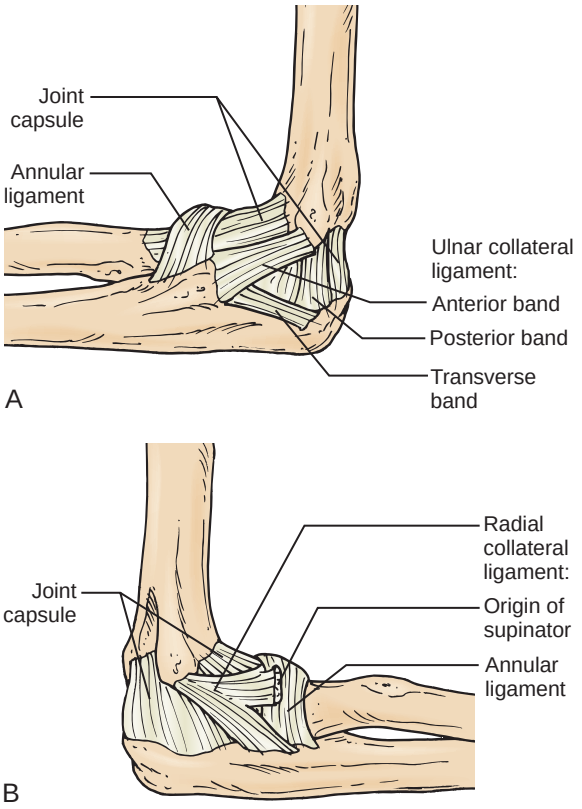

FIGURE 12-3. (**A**) Medial and (**B**) lateral views of the ligaments about the elbow. *(From Miller MD: Core knowledge in orthopaedics: sports medicine, Philadelphia, 2006, Mosby, pp 350–362.)*

- Repetitive extension in sports (e.g., throwing, tennis)
- Gradual loss of ROM with increased pain

Physical Examination

Abnormal Findings

- Progressive loss of range of motion: extension more often than flexion (often ulnohumeral pathology)
- Possible loss of pronation and supination: often radiocapitellar or proximal radial ulnar joint pathology
- Increased pain with progressive ROM loss
- Swelling
- Bony end-feel
- Crepitus
- Muscular spasm
- Mild to moderate pain

Pertinent Normal Findings

- Flexion is limited by the mass of the biceps, tension in the triceps, and articulation of the radius and coronoid.
- Extension is limited by tension of the biceps, anterior band of the UCL, and the olecranon into the olecranon fossa.
- Anterior capsule becomes taut in extension and the posterior capsule becomes taut in flexion.
- Elbow ROM: Extension-Flexion: 0° to 146°; Pronation: 71°; Supination: 84° (AAOS).

Imaging

- Radiographs: reactive osteophytes on the olecranon and olecranon fossa, osteophytes that may fracture and form loose bodies, heterotrophic ossification, degenerative joint disease, heterotrophic ossification, fractures
- MRI: thickened anterior or posterior capsule

Differential Diagnosis

- Ulnar neuritis: parasthesia and/or weakness in fourth and fifth fingers
- Septic arthritis
- Hemophilia
- Spastic neuropathy
- Complex regional pain syndrome

Treatment

Nonoperative Management

- Active and active assistive range of motion
- Low intensity, long duration stretch for extension
- Joint mobilization techniques
- NSAIDS
- Dynamic splinting at night
- Continuous passive motion (CPM)
- Custom molded orthoses
- Activity modification
- Modalities as needed

Guidelines for Choosing among Nonoperative Treatments

- Poor patient motivation
- Patient will not withstand postoperative rehabilitation
- Medical complications
- Symptoms do not interfere with athletic activities or activities of daily living

Surgical Indications

- Failure of nonoperative treatment to return an athlete to a pre-injury competitive level
- Loss of functional ROM
- Significant pain

Factors That Affect Choice of Treatment

- Functional demands of the patient
- Elbow ROM limiting sport- or work-related activities
- Chronic contracture for up to 1 year
- Loss of functional ROM: 30° to 130°

Aspects of Clinical Decision-Making When Surgery Is Indicated

- Radiographic findings
- Failure of conservative treatment

- Postoperative stiffness
- Posttraumatic stiffness

Evidence

Araghi A, Celli A, Adams R, et al: The outcome of examination (manipulation) under anesthesia on the stiff elbow after surgical contracture release. *J Shoulder Elbow Surg* 19:202–208, 2010.

Two hundred patients underwent surgery for release of stiff elbows. Fifty-one patients underwent examination under anesthesia a mean of 40 days after surgery. Forty-four patients with a minimum of 1-year follow up improved by a mean of 40°.

Hildebrand KA, Patterson SD, King JG: Acute elbow dislocations: simple and complex. *Orthop Clin North Am* 30:63–79, 1999.

The authors evaluated the treatment of simple and complex elbow dislocations. They demonstrated that loss of elbow extension is linked to the length of immobilization.

Morrey BF: Post-traumatic contracture of the elbow: operative treatment, including distraction arthroplasty. *J Bone Joint Surg* 72A:601–618, 1990.

Twenty-six patients who had posttraumatic contracture of the elbow were treated by operative release or by release and distraction arthroplasty. Ninety-six percent of the patients were satisfied with the results. In addition, it was found that almost all stiff elbows have thickened anterior and posterior capsules.

Myden C, Hildebrand KA: Elbow joint contracture after traumatic injury. *J Shoulder Elbow Surg* 20:39–44, 2011.

Twenty-five subjects with traumatic elbow injuries were prospectively followed up to 52 weeks after injury. Using a rehabilitation protocol for each injury type, 22 of 25 subjects achieved full flexion-extension ROM and 24 of 25 reached full pronation-supination ROM. Reoperation was performed in 5 of 25 subjects; in 3 of which, this was because of elbow joint contracture.

Ulrich SD, Bonutti PM, Seyler TM, et al: Restoring range of motion via stress relaxation and static progressive stretch in posttraumatic elbow contractures. *J Shoulder Elbow Surg* 19:196–201, 2010.

In this clinical, retrospective review of patients with posttraumatic loss of elbow range of motion, an orthosis that uses static progressive stretch resulted in increased range of motion in 35 of 37 subjects. Mean satisfaction score was 8.5 of 10 points possible.

Multiple-Choice Questions

QUESTION 1: All of these are considered effective clinical options for restoring range of motion in the contracted elbow except:

A. Joint mobilization
B. Aggressive passive stretching
C. Low-intensity, long-duration stretch
D. Custom-molded orthoses

QUESTION 2: Which of the following would not be confused as differential diagnosis with the stiff elbow?

A. Septic arthritis
B. Spastic neuropathy
C. Lateral epicondylitis
D. Hemophilia

QUESTION 3: Which of these may be radiographic findings associated with the stiff elbow?

A. Osteophytes in the olecranon fossa
B. Heterotrophic ossification
C. Degenerative joint disease
D. All of the above

QUESTION 4: All of these are traumatic conditions that may result in elbow contractures except:

A. Elbow dislocation
B. Medial epicondylitis
C. Ulnar or lateral collateral ligament tears
D. Radial head or coronoid fracture

Answer Key

QUESTION 1. Correct answer: **B** (see Treatment)

QUESTION 2. Correct answer: **C** (see Differential Diagnosis)

QUESTION 3. Correct answer: **D** (see Pathophysiology)

QUESTION 4. Correct answer: **B** (see Traumatic Factors)

POSTOPERATIVE REHABILITATION AFTER ELBOW CAPSULAR RELEASE

Michael Levinson PT, CSCS, and David Altchek MD

Indications for Surgical Treatment

- Nonoperative treatment fails to return an athlete to a preinjury competitive level
- Loss of functional range of motion (*functional* being approximately 30° to 130°)
- Significant pain that interferes with activities of daily living
- Radiographic evidence of osteophytes or loose bodies

Brief Summary of Surgical Treatment

Major Surgical Steps

- Regional anesthesia
- Patient is supine with upper extremity elevated in arm holder, elbow flexed
- Anterior, posterior and posterior lateral capsular release (Figure 12-4)
- Any osteophytes or loose bodies are removed
- All contracted tissue must be addressed
- Care is taken to avoid the ulnar nerve and the posterior interosseous nerve
- Postoperative cortisone injection
- Immediate range of motion

Factors That May Affect Rehabilitation

Anesthetic

- Should not affect rehabilitation

Surgical

- The arthroscopic procedure should allow early rehabilitation intervention.

Other Surgical Techniques and Options

- Open contracture release (Figure 12-5).
- An open procedure may result in further soft tissue trauma. This may delay physical therapy secondary to pain and swelling.

GUIDING PRINCIPLES OF POSTOPERATIVE REHABILITATION

- Understand exactly what was performed during the surgical procedure
- Understand the healing rates of the tissues involved
- Avoid excessive passive stretching and painful ROM
- ROM exercises must emphasize positions which improve congruency of the healing joint
- Understand the criteria for returning to functional and athletic activities

Phase I: Immediate Postoperative Period (days 0 to 14)[1]

Clinical Pearls

- Immediate ROM is critical following this procedure. Aggressive passive ROM should be avoided as it can result in increased swelling and stimulate fibrosis. To restore extension, a low-intensity, long-duration stretch has been proven effective.[1]
- Regional anesthesia may be effective to help start immediate postoperative elbow ROM and gentle continuous passive ROM (if utilized).

Goals

- Educate the patient.
- Modify activity to minimize pain.
- Minimize swelling, pain, and inflammation.
- Begin to restore elbow ROM.

Management of Pain and Swelling

- For pain:
  - Oral pain medications and NSAIDs are prescribed.
  - Activity modification to minimize painful activities is critical.
  - Cryotherapy
- Swelling is controlled with cryotherapy and activity modification.

Techniques for Progressive Increase in Range of Motion

Manual Therapy Techniques

- Grade I and II mobilization techniques

[1]*Prehabilitation, if appropriate, is described in the Nonoperative Rehabilitation section of this chapter.*

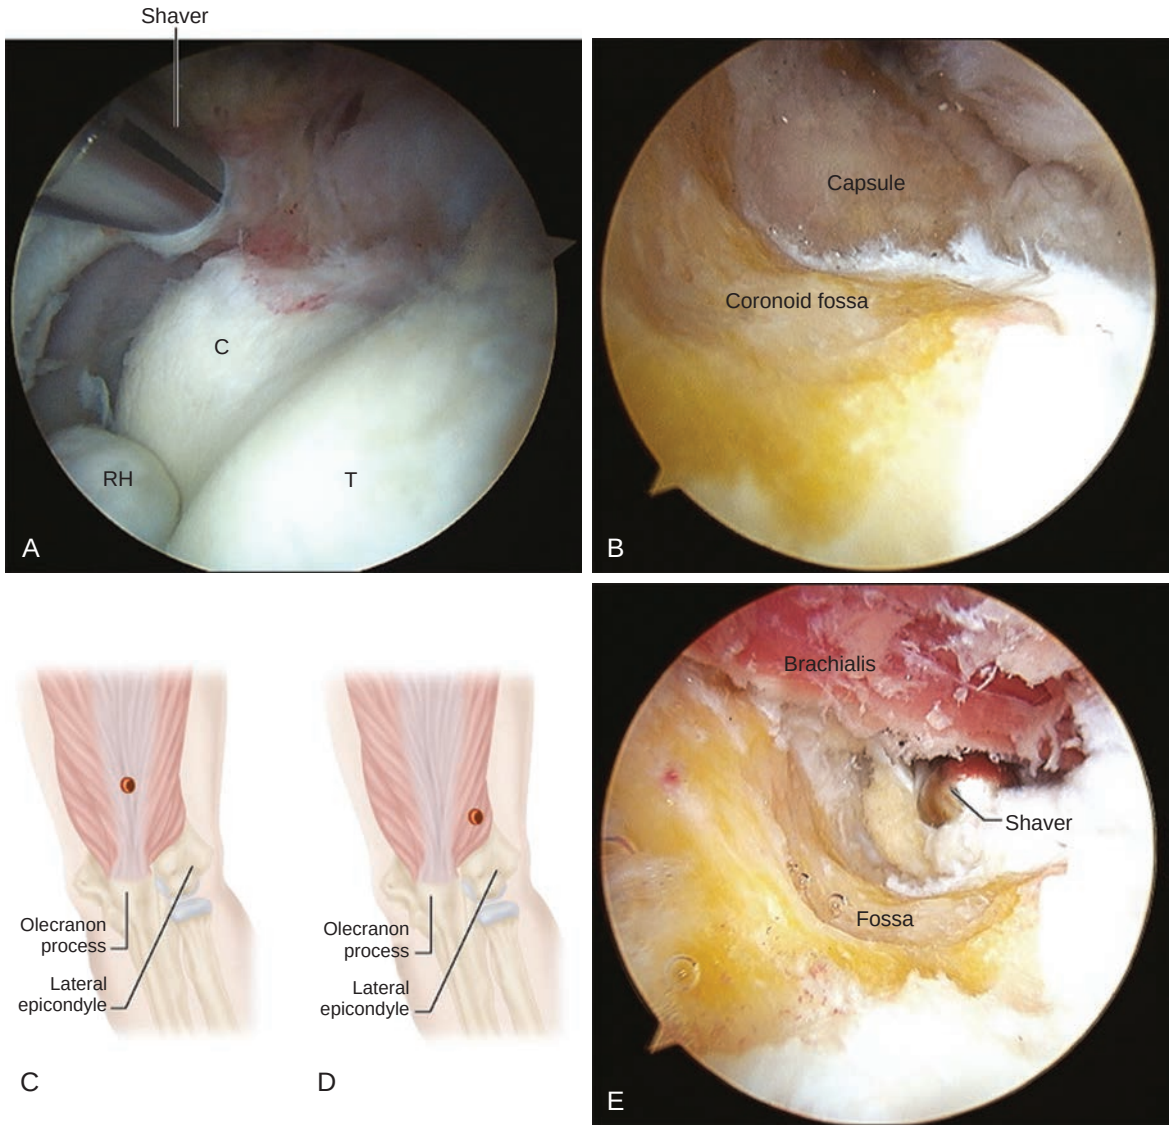

FIGURE 12-4. A, B, Anterior capsular release. Arthroscopic view of a right elbow joint after first obtaining scope entry into the proximal-medial portal, looking laterally. Debridement of synovitis is being performed with the shaver. There is a lack of concavity in the trochlea (T) and capitellum (C) area. (RH, radial head). **B,** Partially completed release. **C–E,** Posterior capsular release. Establish a posterior-central portal for the arthroscope (4 cm proximal to olecranon tip through triceps) **C,** and a posterolateral working portal **D,** (approximately 2 cm proximal to the midpoint between the tip of the olecranon laterally and the lateral epicondyle). Open these widely with a knife down into the olecranon fossa with the elbow extended (protecting the articular surface). The shaver is utilized to debride and open the space, and to remove loose bodies and osteophytes. Elevate the capsule from the distal humerus proximally with a shaver or elevator. Once a view and working space are created, perform all bone recontouring, removing any osteophytes from the olecranon and appropriately deepening the olecranon fossa if indicated. The posterior capsule is released with a basket cutter or arthroscopic elevator on the medial and lateral sides. The release is stopped before the medial aspect of the olecranon fossa (to avoid injury to the ulnar nerve). **E,** An arthroscopic view of the elbow joint after capsulectomy and deepening of the coronoid and radial fossa. The dissection is carried down to the fibers of the brachialis muscle. The posteromedial capsule should be resected in the setting of significant flexion loss (posterior band of the medial collateral ligament). However, this is extremely dangerous and places the ulnar nerve at greatest risk. Alternatively, this capsule can be released after the ulnar nerve has been dissected out through a limited open approach. The posteromedial capsule forms the floor of the cubital tunnel. Perform a final inspection from both portals to ensure adequate release. *(From Ghodadra N, et al: Arthroscopic treatment of elbow stiffness. In Reider B, Terry MA, Provencher MT (eds): Operative techniques: sports medicine surgery. Philadelphia, 2010, Elsevier (Saunders).)*

Stretching and Flexibility Techniques for the Musculotendinous Unit

- Codman exercises are used to increase blood flow to the upper extremity.
- Elbow AROM and AAROM exercises (elbow flexion and extension; forearm pronation and supination) are initiated.
- Low-intensity, long-duration stretch is used to restore extension; aggressive PROM should be avoided (Figure 12-6).
- AROM exercises for the glenohumeral joint are initiated.
- AROM exercises for the wrist (wrist flexion/extension) are performed to prevent stiffness.

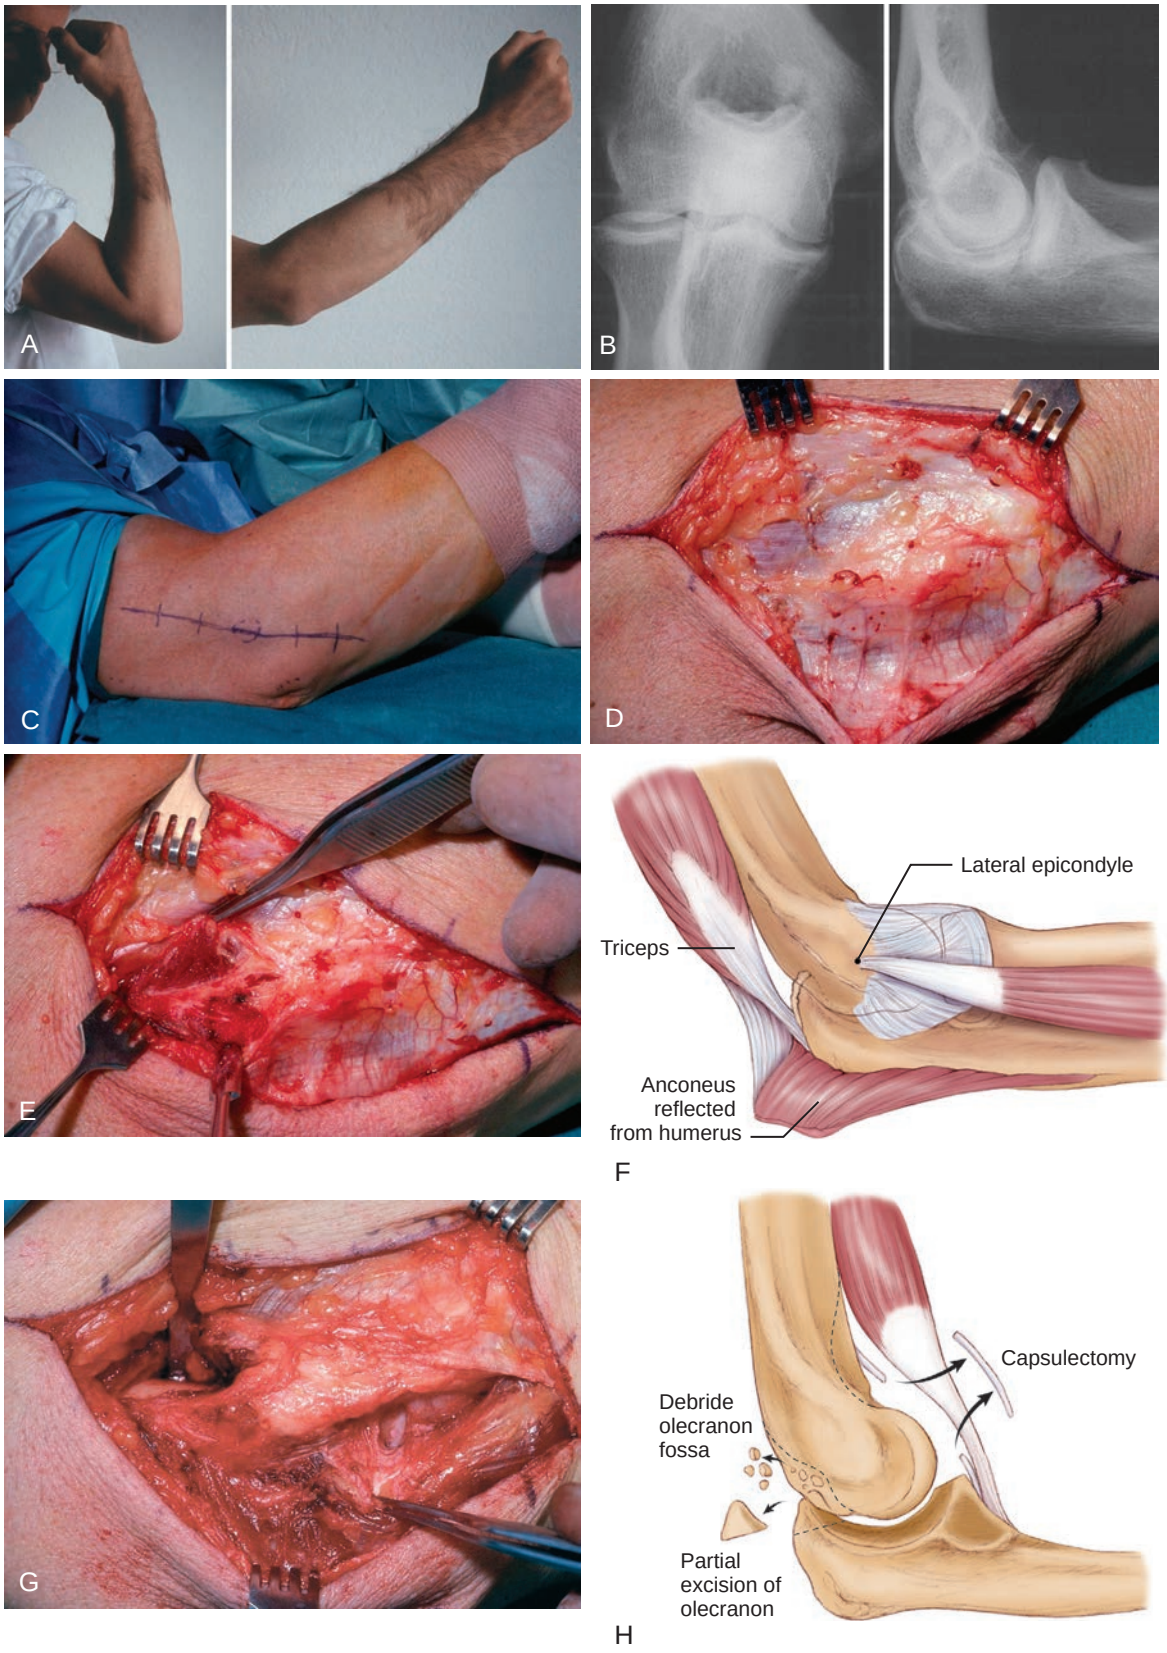

FIGURE 12-5. **A,** A man with a substantial flexion contracture and no ulnar neuropathy after trauma. **B,** Radiographs show mild osteoarthritis. **C,** A lateral skin incision is made. **D,** Full-thickness skin flaps are elevated. **E,** The supracondylar ridge is identified, and the origins of the radial wrist extensors are incised and elevated from the anterior humerus. **F,** The anconeus and the triceps are elevated from the posterior aspect of the humerus and elbow articulation. **G,** The posterolateral capsule (forceps) is excised. **H,** Osteophytes are removed from the tip of the olecranon, and the olecranon fossa is cleared.

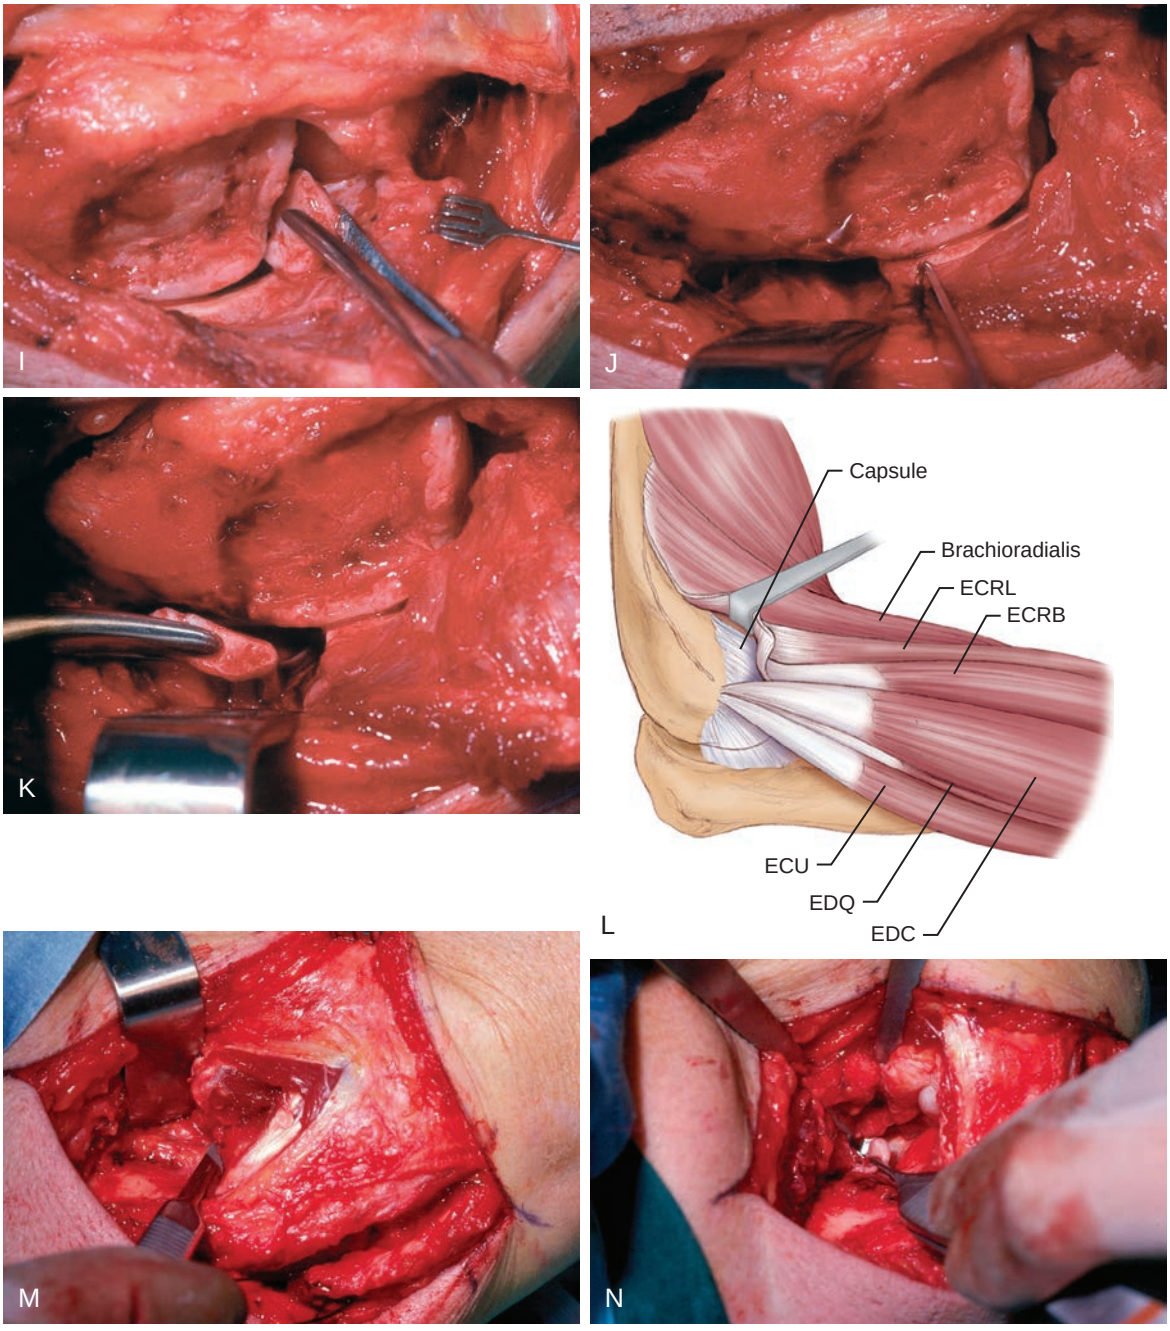

FIGURE 12-5, cont'd I, Loose bodies (forceps) are often found in the posterolateral gutter. **J,** An osteotome is poised to cut the olecranon tip. **K,** Removal of the olecranon tip. **L,** Anteriorly, the interval between the extensor carpi radialis brevis (ECRB) and the extensor digitorum communis (EDC) is developed to better expose the anterior elbow capsule. **M,** The anterior elbow capsule is excised. ECRL, Extensor carpi radialis longus; ECU, extensor carpi ulnaris; EDQ, extensor digiti quinti. **N,** A loose body (forceps) was also found in the anterior part of the joint.

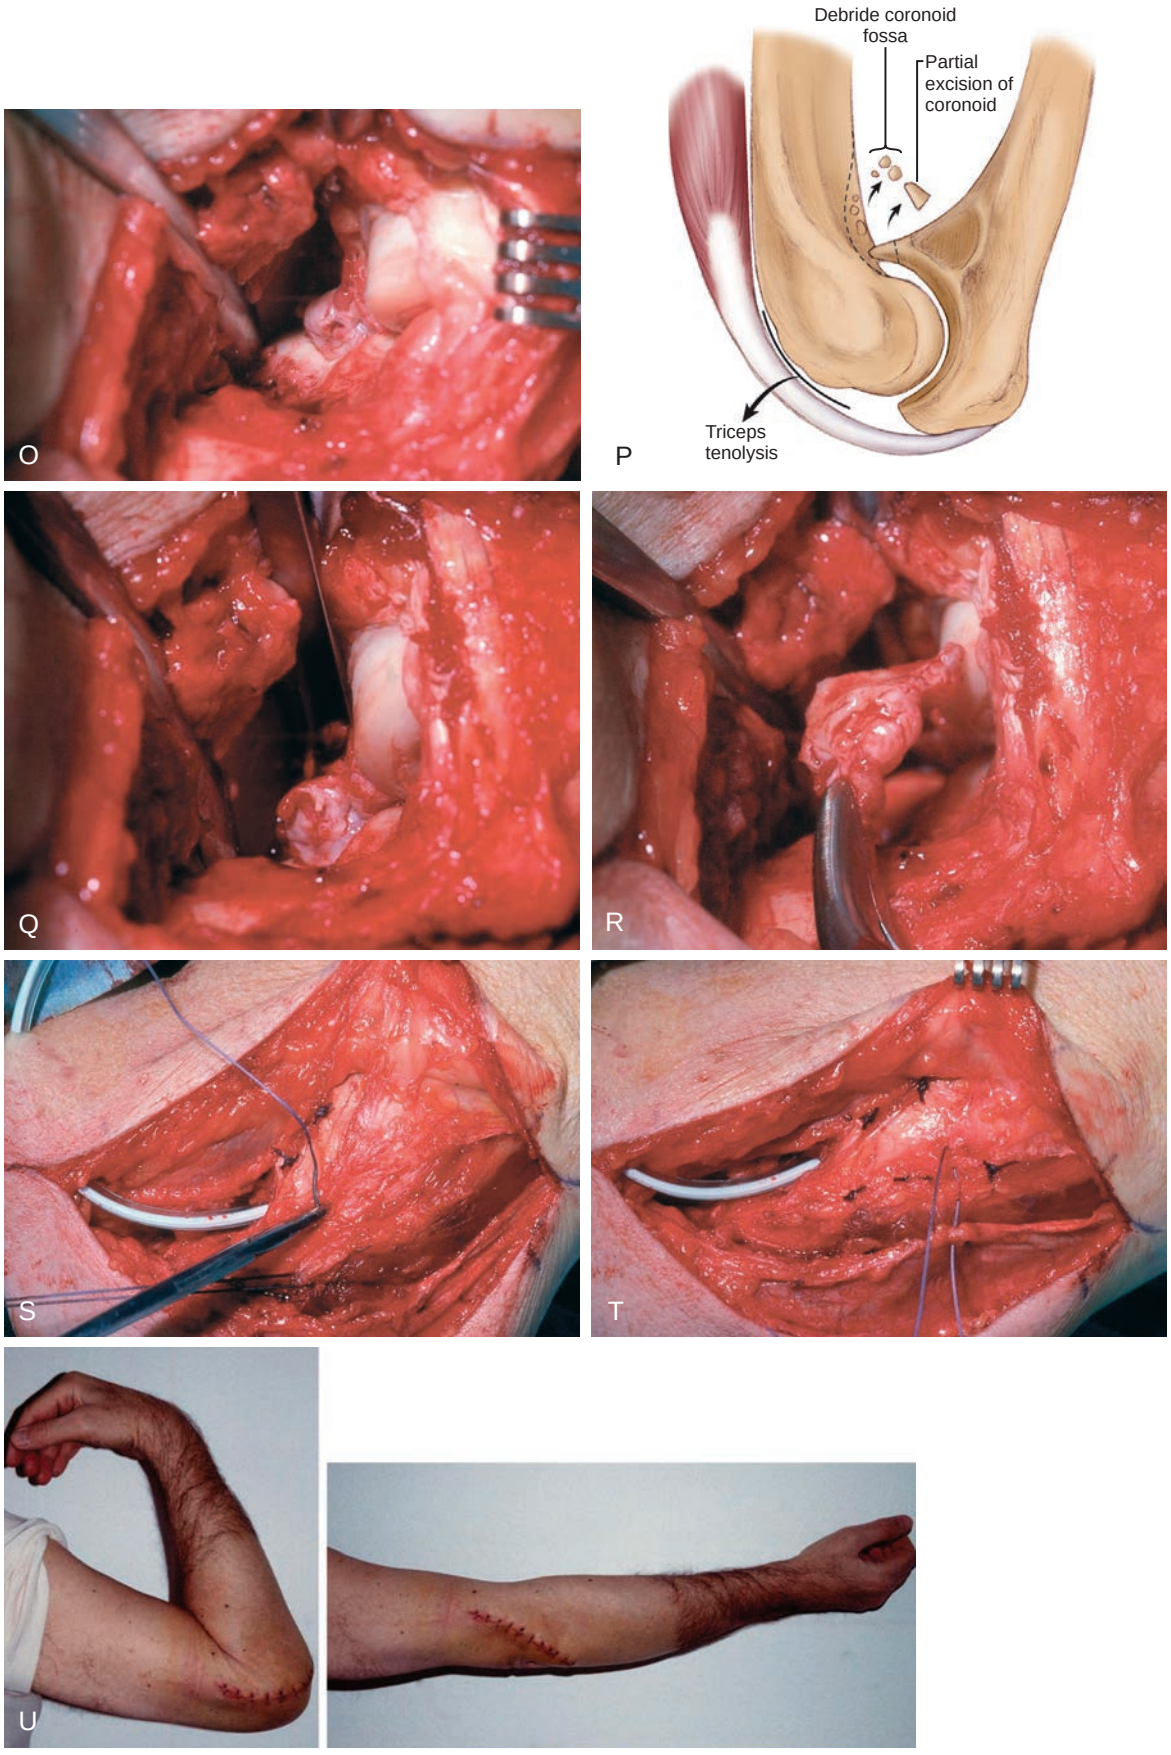

FIGURE 12-5, cont'd O, The elbow after excision of the anterior capsule. **P,** At this point, the coronoid tip is excised and the coronoid fossa is cleared out. **Q,** An osteotome is poised to cut the coronoid tip. **R,** Removal of the olecranon tip (forceps). **S,** The anterior interval is closed, in this case over a suction drain. **T,** Closure of the posterior interval. **U,** Final motion was excellent. *(From Ring D, Fernandez D: Open elbow contracture release. Ch 48. In: Cole, BJ, Sekiya JK (eds): Surgical techniques of the shoulder, elbow, and knee in sports medicine, ed 2. Philadelphia, 2013, Elsevier pp 509–518.)*

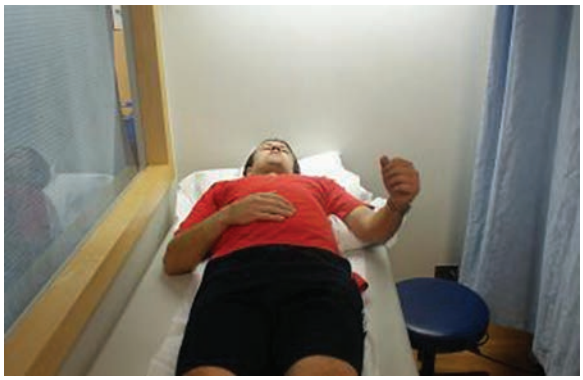

FIGURE 12-6. Low intensity, long duration stretch for elbow extension. Lying supine. Towel roll under the humerus.

Other Therapeutic Exercises

- Once the sutures are removed, the patient may begin to use a stationary bicycle, but avoid leaning heavily on the surgical upper extremity.

Milestones for Progression to the Next Phase

- Minimal pain and swelling

Phase II: Weeks 2 to 6 Postoperatively

Clinical Pearl

When continuing to restore elbow range of motion, certain joint mobilization techniques may be helpful. For example, ulnohumeral distraction or radiohumeral distraction can be effective techniques.

Goals

- Continue to restore functional elbow ROM.
- Continue to reduce pain, swelling and inflammation.
- Continue to modify activity.
- Begin to restore scapula and shoulder strength.

Management of Pain and Swelling

- Continue cryotherapy and NSAIDS as needed.

Techniques for Progressive Increase in Range of Motion

Manual Therapy Techniques

- Continue joint mobilization as needed (Figure 12-7).

Stretching and Flexibility Techniques for the Musculotendinous Unit

- Continue AROM and AAROM for the elbow.
- Continue low intensity, long duration stretch for elbow extension.

FIGURE 12-7. Joint mobilization. Posterior gliding of the proximal ulna on the distal humerus to improve elbow extension.

TIMELINE 12-1: **Postoperative Rehabilitation after Elbow Capsular Release**

PHASE I (weeks 1 to 2)	PHASE II (weeks 3 to 6)	PHASE III (weeks 6 to 10)
• PT modalities • ROM: elbow, wrist, shoulder • Codman exercises • Low-intensity, long-duration stretch for elbow extension • Joint mobilization • Stationary bicycle after sutures are removed	• PT modalities • Elbow AROM/ AAROM • Shoulder and wrist AROM • Low-intensity, long-duration stretch • Joint mobilization as needed • Manual scapula and shoulder strengthening with proximal resistance	• PT modalities as needed • Elbow AROM and AAROM • Joint mobilization as needed • TBS/TAS/TLS activities as recommended and tolerated • TAS: Scapular exercises—PREs • Glenohumeral exercises—PREs • Rotator cuff exercises—PREs • Rhythmic stabilization exercises proximal to the elbow

- Continue AROM for the wrist.
- Continue AROM for the glenohumeral joint

Other Therapeutic Exercises

- Initiate scapula and shoulder strengthening with manual resistance proximal to the elbow joint (e.g., sidelying scapula stabilization).
- Continue the stationary bicycle while avoiding leaning heavily on the surgical upper extremity.

Milestones for Progression to the Next Phase

- Minimal pain and swelling
- Elbow ROM sufficient to progress to isotonic upper-extremity strengthening

Phase III: Weeks 6 to 10 Postoperatively

Clinical Pearl

- If the patient is having difficulty restoring elbow extension, a light resistance band or light weight may be applied distally. The resistance should be light enough that it is tolerable for an extended period of time (Figure 12-8).

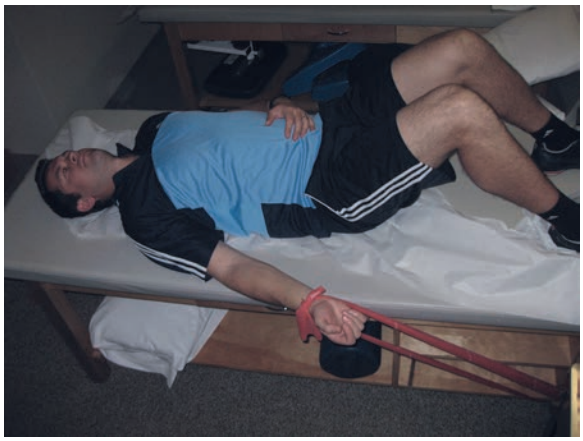

FIGURE 12-8. Low intensity, long duration stretch with elastic resistance.

Goals

- Continue to restore functional elbow ROM.
- Continue to restore scapula and shoulder strength.
- Continue to reduce pain, swelling and inflammation.

Management of Pain and Swelling

- For pain:
  - Cryotherapy
  - TENS may be utilized if significant pain persists
- For swelling:
  - Cryotherapy
  - Behavior modification

Techniques for Progressive Increase in Range of Motion

Manual Therapy Techniques

- Continue joint mobilization.

Stretching and Flexibility Techniques for the Musculotendinous Unit

- Continue AROM and AAROM for the elbow.
- Continue low-intensity, long-duration stretch for elbow extension (add light resistance if needed).
- Continue AROM for the wrist.

TIMELINE 12-1: **Postoperative Rehabilitation after Elbow Capsular Release** (Continued)

PHASE IV (weeks 10 to 14)	PHASE V (weeks 14 to 24)	PHASE VI (weeks 24 to 52)
• PT modalities as needed • Elbow AROM: full Joint mobilization as needed • Forearm stretching • Shoulder flexibility TBS/TAS/TLS activities as recommended and tolerated • Scapular exercises—PREs • TAS: biceps/triceps PREs Glenohumeral exercises—PREs • Rotator cuff exercises—PREs • IR/ER at 90°- 90° • Rhythmic stabilization with long lever arm and in overhead position • PNF exercises	• Elbow AROM: maintain full motion Mobilizations as needed • Full upper-extremity flexibility program • Hip and trunk flexibility program • TBS/TAS/TLS activities as recommended and tolerated • Scapular exercises—PREs TAS: biceps/triceps PREs Glenohumeral exercises—PREs • Rotator cuff exercises—PREs • Light forearm PREs • PNF exercises • Hip and trunk PREs Rhythmic stabilization exercises • BodyBlade when available • Plyometrics: two-arm progressing to one-arm • Overhead strengthening exercises • Sport-specific interval program begins	• Elbow ROM: maintain full motion • Full upper extremity, lower extremity and trunk flexibility program • TBS/TAS/TLS activities as recommended and tolerated • Scapular exercises—PREs • TAS: biceps/triceps PREs • Glenohumeral exercises—PREs • Rotator cuff exercises—PREs • IR/ER exercises at 90° • Forearm PREs • PNF exercises • Rhythmic stabilization exercises • Core and lower extremity PREs • Return to play

Other Therapeutic Exercises

- If symptoms and ROM allow, isotonic strengthening for the shoulder and scapula may be initiated using elastic resistance or light weights. This may include the rhomboids, serratus, upper, middle and lower trapezius, latissimus, deltoid, and rotator cuff.

Neuromuscular Dynamic Stability Exercises

- Rhythmic stabilization exercises for the shoulder may be initiated. Resistance should be initiated proximal to the elbow.

Milestones for Progression to the Next Phase

- Good proximal strength base
- Pain free with exercises and activities of daily living

Phase IV: Weeks 10 to 14 Postoperatively

Clinical Pearl

For the athletic population, aside from the elbow contracture, there are often selective losses of shoulder flexibility. These should be addressed during this phase, before advancing the athlete functionally.

Goals

- Restore normal shoulder and scapula strength.
- Begin to restore shoulder flexibility where needed.
- Begin to restore elbow strength.
- Begin to restore forearm flexibility.
- Begin to restore upper extremity endurance.

Management of Pain and Swelling

- Cryotherapy

Techniques for Progressive Increase in Range of Motion

Manual Therapy Techniques

- Continue joint mobilization if required.

Soft Tissue Techniques

- Gently massage soft tissue if required.

Stretching and Flexibility Techniques for the Musculotendinous Unit

- Continue AROM and AAROM for the elbow.
- Continue low-intensity, long-duration stretch for elbow extension if required.
- Initiate pain-free forearm stretching.
- Address any shoulder flexibility deficits: use standard goniometry and standard shoulder stretches based on findings.

FIGURE 12-9. Elbow flexion with elastic resistance.

Other Therapeutic Exercises

- Progress gradually with scapula and shoulder strengthening as tolerated.
- If rotator cuff strength is good and scapulothoracic function appears normal, strengthening of the rotator cuff in the overhead position may begin (e.g., IR/ER strengthening at 90°).

Activation of Primary Muscles Involved in Injury Area or Surgical Structures

- If range of motion allows, elbow extension and flexion strengthening are initiated using light weights or elastic resistance (Figures 12-9 and 12-10).

FIGURE 12-10. Elbow extension with elastic resistance.

Sensorimotor Exercises

- Initiate PNF patterns based on the demands of the patient: D1 flexion/ extension, D2 flexion/ extension.

Techniques to Increase Muscle Strength, Power, and Endurance

- As range of motion allows, initiate upper-body ergometry.

Neuromuscular Dynamic Stability Exercises

- Progress rhythmic stabilization to long lever arm. Progress to overhead positions as tolerated. Begin with proximal resistance and progress to more distal resistance. Begin with shoulder in a neutral position and progress to greater elevations to challenge the upper extremity more.

Milestones for Progression to the Next Phase

- Good upper extremity flexibility
- Good shoulder and scapula strength base

Phase V: Weeks 14 to 24 Postoperatively

Clinical Pearl

Sport-specific or work-specific activities should only be initiated after the patient demonstrates functional elbow ROM. The patient should be pain free and have normal upper body strength and flexibility. In the case of an athlete, normal neuromuscular function should be established through drills such as plyometrics before beginning a sport-specific program.

Goals

- Restore forearm strength.
- Restore normal neuromuscular function.
- Begin sport specific or activity specific activities without pain.
- Restore full body strength, flexibility, and endurance.

Techniques for Progressive Increase in Range of Motion

Manual Therapy Techniques

- Joint mobilization techniques if needed

Soft Tissue Techniques

- Soft tissue massage if needed

Stretching and Flexibility Techniques for the Musculotendinous Unit

- Stretching should be continued for the entire upper extremity. In addition, for the athlete any lower body and trunk flexibility deficits should be addressed.

Other Therapeutic Exercises

- For the athletic patient (e.g., a tennis player), a full core and lower extremity program should be incorporated (for the tennis player, a strong emphasis is placed on hip and trunk strength).

Activation of Primary Muscles Involved in Injury Area or Surgical Structures

- Elbow flexion and extension strengthening should be progressed. For the overhead athlete, emphasis should be placed on eccentric activity and building endurance in these muscles (that is, biceps curls and triceps extensions emphasizing the eccentric component).
- Forearm strengthening can be initiated; however, resistance should be relatively light with an emphasis on building endurance and not over working the flexor/ pronator.

Techniques to Increase Muscle Strength, Power, and Endurance

- Continue upper body ergometry to build endurance. Isokinetics can also be used for the upper extremity to build power and endurance.

Neuromuscular Dynamic Stability Exercises

- Rhythmic stabilization should be progressed to all functional positions. When available, the BodyBlade can be used, progressing to all positions of the functional range of motion. Begin in a neutral rotation and abduction position and progress to more functional positions that reproduce the demands of the activity.

Plyometrics

- May begin if the patient is asymptomatic, and has a normal strength base and function range of motion and flexibility.
- Plyometrics should be functionally specific. For the tennis player, the progression can be the following: chest pass, side-to-side wood chops, overhead soccer pass, one hand external rotation in neutral, 90° to 90° position (90° of abduction and 90° of external rotation) (Figures 12-11 to 12-15).

Functional Exercises

- Deceleration exercises should be performed with a Plyoball.

FIGURE 12-11. Plyometric chest pass.

FIGURE 12-12. Plyometric side to side wood chops.

FIGURE 12-14. Plyometric one hand external rotation.

- Tossing a Plyoball over the shoulder and catching it and decelerating the arm. This may be progressed from a kneeling position to a standing position as the athlete uses the larger body parts to absorb stress from the upper extremity.

Sport-Specific Exercises

- Upon completing a plyometric program without symptoms, a sport-specific interval program may be initiated.
- The program should be progressed individually. The program should be progressed by the number of repetitions and level of plyometric activity.

Milestones for Progression to the Next Phase

- Normal upper extremity flexibility
- Normal upper extremity strength, power endurance as measured by manual muscle testing, isokinetics, and functional testing such as tolerating plyometrics
- Normal lower extremity and trunk strength and flexibility. Normal lower extremity goniometry and special tests such as a Thomas Test and hamstring flexibility are used
- Completion of a sport-specific interval program

Phase VI: Weeks 24 to 52 Postoperatively

Clinical Pearl

When returning to sport, the athlete may develop certain selective strength and flexibility deficits that may slow progress and lead to reinjury. These deficits should be monitored closely and addressed with a full body strength and flexibility program. In addition, elbow range of motion should be carefully monitored to avoid recurrence of contracture.

Goals

- Avoid reinjury.
- Maintain elbow range of motion.
- Maintain strength and flexibility.
- Return to play.

Management of Pain and Swelling

- Cryotherapy after play

FIGURE 12-13. Plyometric overhead soccer pass.

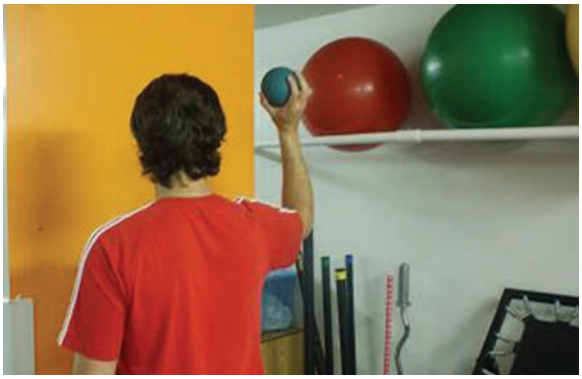

FIGURE 12-15. Plyometric one hand 90-90 position.

Techniques for Progressive Increase in Range of Motion

- Maintain full body flexibility program with the return to play.

Other Therapeutic Exercises

- Maintain full upper body, lower body and core strengthening with return to play. Decrease volume of work as play continues. In this phase, any deficits should be addressed.

Plyometrics

- Plyometrics should be phased out as play begins.

Sport-Specific Exercises

- Return to play.

Criteria for Return to Sport

General

- Pain free
- Functional elbow range of motion
- Completion of sport-specific interval program without symptoms

Sport-Specific

- Overhead athlete: normal shoulder flexibility, scapula symmetry, normal rotator cuff ratio of ER/IR of 66%.

After Return to Sport

Continuing Fitness or Rehabilitation Exercises

- Lower extremity, core strengthening and flexibility training
- Full upper extremity strengthening and flexibility training
- Elbow and forearm flexibility

Exercises and Other Techniques for Prevention of Recurrent Injury

- Improve mechanics.
- For overhead athletes, learn to use the larger body parts to absorb stresses to the upper extremity.
- Avoid activities in training that aggravate elbow symptoms.

Evidence

Ball CM, Meunier M, Galatz LM, et al: Arthroscopic treatment of post-traumatic elbow contracture. *J Shoulder Elbow Surg* 11:624–629, 2002.

In this retrospective study, 14 patients who underwent elbow arthroscopic capsular release were reviewed at a minimum of 1 year. All patients had improved function and range of motion. Satisfaction on a visual analog scale was 8.4/10 (Level IV evidence)

Bionna D, Lee GC, Driscoll SW: Arthroscopic restoration of terminal elbow extension in high-level athletes. *Am J Sports Med* 38:2509–2515, 2010.

In this retrospective review, 26 athletes whose chief complaint was limited elbow extension underwent arthroscopic contracture release. All 26 elbows improved objectively and subjectively. Twenty-two patients returned to their sport at the same level. (Level IV evidence)

Jones SG, Savoie FH III: Arthroscopic capsular release of flexion contractures (arthrofibrosis) of the elbow. *Arthroscopy* 9:277–283, 1993.

Twelve patients with flexion contractures of the elbow were managed by arthroscopic capsular release and debridement of the olecranon fossa. The mean flexion contracture improved from 38° to 3°. All patients reported a decrease in pain level. (Level IV evidence)

Sharma S, Rymaszewski LA: Open arthrolysis for post-traumatic stiffness of the elbow. *J Bone Joint Surg Br* 89B:778–781, 2007.

In this retrospective study, 25 patients with posttraumatic elbow stiffness were treated by open arthrolysis. The mean range of motion improvement was 55° at 1 year. The improvement was maintained over a mean follow-up period of 7.8 years. (Level IV evidence)

Timmerman LA, Andrews JR: Arthroscopic treatment of post-traumatic elbow pain and stiffness. *Am J Sports Med* 22:230–235, 1994.

In this retrospective study, 19 cases of posttraumatic arthrofibrosis of the elbow were treated with arthroscopic debridement and manipulation. At an average of 29 months, there was a mean improvement of extension from 29° to 11°. Flexion improved 123° to 134°.(Level IV evidence)

Multiple-Choice Questions

QUESTION 1: Following capsular release for an elbow contracture, when should range of motion exercises begin?

A. Two weeks postoperatively
B. Immediately
C. Four weeks postoperatively
D. Six weeks postoperatively

QUESTION 2: In the first 2 weeks after surgery, physical therapy may include all of the above except:

A. Codman exercises
B. Low-intensity, long-duration stretch for elbow extension
C. Forearm strengthening
D. Elbow AROM

QUESTION 3: If elbow ROM allows, resistive elbow exercises may be initiated during which phase?

A. Two to 6 weeks postoperatively
B. Six to 10 weeks postoperatively

C. Ten to 14 weeks postoperatively
D. Fourteen to 24 weeks postoperatively

QUESTION 4: Which of the following is the criterion for initiating a plyometric program?

A. Functional elbow ROM
B. Minimal discomfort in the elbow
C. Normal shoulder flexibility
D. Normal upper extremity strength

QUESTION 5: All of the above are used for restoring elbow ROM after capsular release except:

A. Joint mobilization techniques
B. Elbow AROM and AAROM
C. Aggressive passive stretching by the PT
D. Low-intensity, long-duration stretch for extension

Answer Key

QUESTION 1: Correct answer: **B** (see Brief Summary of Surgical Treatment)

QUESTION 2: Correct answer: **C** (see Phase I)

QUESTION 3: Correct answer: **C** (see Phase IV)

QUESTION 4: Correct answer: **D** (see Phase V)

QUESTION 5: Correct answer: **C** (see Phase I)

Chapter 13

Forearm Nerve Entrapments

INTRODUCTION

Robert C. Manske, PT, DPT, MEd, ATC, SCS, CSCS, and
Mark Stovak, MD, FACSM, FAAFP, CAQSM

Epidemiology

The epidemiology of forearm nerve entrapments is dependent upon type.

- Median
  - Carpal tunnel syndrome
    - Most common nerve entrapment in upper extremity
    - Twice as common in females
    - Most commonly between ages of 45 and 54 years of age
    - Can occur frequently during pregnancy
    - Common in fast-pitch softball pitchers
    - May be related to occupational, gripping, or other athletic pursuits
  - Pronator syndrome
    - Common in athletes such as fast-pitch softball pitchers
  - Anterior interosseous nerve (AIN) entrapment
    - Entrapped in forearm
- Radial (least common form of nerve entrapment)
  - Radial tunnel syndrome
    - Only 1% to 2% of upper extremity entrapments
    - Most commonly in fourth to sixth decades of life
  - Posterior interosseous nerve (PIN) entrapment
    - Often misdiagnosed as tennis elbow
    - Seen in throwing sports
  - Superficial branch (Wartenberg's syndrome)
    - Common with handcuffs or wrist straps
- Ulnar
  - Cubital tunnel
    - Second most common entrapment location in upper extremity
    - More commonly seen in males than females
    - Common in throwing athletes but can also be seen in skiing, weight lifting, and racquet sports
  - Guyon's canal
    - Often seen in bicyclists from gripping handlebars (especially off-road)

Pathophysiology

Intrinsic Factors

- Median
  - Repetitive or overuse
  - Underlying disease such as diabetes mellitus, thyroid myxedema, rheumatological disease, acromegaly, amyloidosis, renal dialysis, and alcoholism increase risk
  - Size of median nerve and contents inside carpal tunnel exceed that of space available or are too large
  - Large forearm musculature increases risk of pronator syndrome or AIN entrapment
- Radial
  - Vulnerable to injury at several points along anatomical course:
    - Proximally at axilla
    - Shaft of humerus in spiral groove (Saturday night palsy)
    - Compression by lateral head of triceps
    - At radial tunnel by fibrous bands or edge of extensor carpi radialis brevis—PIN
    - Arcade of Frohse, sometimes called the supinator arch, is a fibrous arch over the PIN
    - Supinator muscle—PIN
    - Between brachioradialis and extensor carpi radialis longus—PIN
    - Superficial branch at distal radial forearm
- Ulnar
  - Vulnerable to injury at several points along anatomical course:
    - Proximally at axilla
    - Arcade of Struthers, a canal formed by a short band of fibrous tissue proximal to medial epicondyle
    - Medial head of triceps muscle
    - Medial epicondyle
    - Ulnar groove
    - Cubital tunnel

- Flexor aponeurosis
- Guyon's tunnel, a bony tunnel in the proximal wrist formed by the pisiform and the hamate bones

Extrinsic Factors

- Median
  - Direct trauma—AIN
  - Overuse injury causing swelling to finger/wrist/forearm musculature
  - Vibration at the hand and wrist
- Radial
  - Direct trauma to distal radial forearm—superficial branch
  - Fracture of humeral shaft—proximal radial nerve
  - Compression from hypertrophy of muscles/tennis elbow straps—PIN
- Ulnar
  - Direct trauma—Guyon's canal
  - Traction following ulnar collateral ligament insufficiency
  - Fracture callus

Traumatic Factors

- Median
  - Carpal tunnel syndrome
  - Direct trauma
  - Compression by other tendons of extrinsic finger flexors
  - Fractures
- Radial
  - Direct trauma to distal radial forearm—superficial branch
  - Direct trauma to proximal arm—Saturday night palsy
  - Fracture of humeral shaft
- Ulnar
  - Direct trauma in axilla—crutches
  - Direct trauma in hand/wrist—Guyon's canal
  - Compression from muscles/tendons (medial head of triceps)
  - Fracture callus
  - Bone spurs
  - Pressure from combined movements of wrist extension and elbow flexion

Classic Pathological Findings

- Median
  - Carpal tunnel syndrome
    - Aching, burning and paraesthesia in thumb, forefinger, middle finger, and wrist
    - Symptoms worse at night
    - Grip weakness
    - Weakness in hand and wrist
    - Thenar muscle atrophy if chronic
    - Loss of two-point discrimination
    - Pain with fast-pitch softball
  - Pronator syndrome
    - Forearm pain with similar symptoms
  - AIN
    - Weakness of flexion of first and second DIP joints so cannot make the O-sign
- Radial
  - Proximal injury
    - Weakness of elbow flexion or extension
    - Mild weakness of wrist/finger extension
    - Loss of sensation of posterior arm, forearm, and hand
    - Wrist drop
  - PIN
    - Forearm pain despite its being a purely motor nerve
  - Superficial branch
    - Radial wrist and index finger/thumb numbness/tingling
- Ulnar
  - Sensory changes fourth and fifth digits
  - Hypothenar muscular atrophy if chronic
  - Pincer grip weak—Froment sign
  - Problems opening jars
  - Fatigue with repetitive hand finger motions

Clinical Presentation

History

- Median
  - Trauma or repetitive activities
  - Sports or vocation that involves repetitive gripping/vibration
  - Sports or vocation that involves repetitive supination or pronation
- Radial
  - Compression at axilla such as falling asleep with arm over back of chair
  - Repetitive wrist and forearm movements
  - Repetitive gripping, pinching, or grasping activities
- Ulnar
  - Trauma or repetitive activities
  - Throwing or overhead sports that require elbow flexion/extension
  - Occupation involving repetitive elbow flexion/extension
  - Repetitive gripping/vibration

Physical Examination

Abnormal Findings

- Median
  - Carpal tunnel syndrome
    - Paraesthesia and numbness in hand (fingers 1 to 3) and wrist
    - Atrophy of abductor pollicis brevis if chronic
    - Positive Phalen's test (Figure 13-1A)
    - Positive Tinel's test (Figure 13-1B)
    - Hypertrophy of pronator teres muscle (pronator teres syndrome)
    - Weakness of flexion first and second finger DIP joints (AIN)
- Radial
  - Posterior interosseus nerve
    - Dull ache in lateral elbow
    - Pain over extensor mass

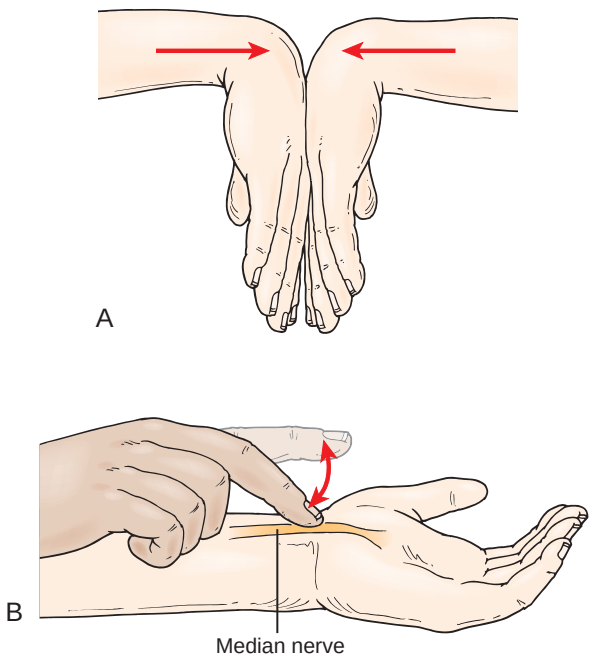

FIGURE 13-1. A, Diagram of Phalen's test. **B,** Diagram of Tinel's test. *(Redrawn from Brotzman SB: Hand and wrist injuries: Nerve compression syndromes. In Brotzman SB, Manske RC, editors: Clinical orthopaedic rehabilitation, ed 3. Philadelphia, 2011, Elsevier, Fig 1-24AB.)*

  - Pain with resisted supination
  - Pain with extension of middle finger
  - Paraesthesia over dorsal hand and radial forearm (superficial branch)
- Ulnar
  - Cubital tunnel syndrome
    - Pain to palpation/Tinel's sign of medial elbow in cubital fossa
    - Paraesthesia in ulnar side of fourth and fifth digits
    - Loss of fine motor control of hand and fingers
    - Pain to palpation/Tinel's sign at Guyon's canal

Pertinent Normal Findings

- Median, radial, and ulnar
  - Normal sensation in remaining fingers
  - Usually no signs of autonomic nervous system dysfunction

Imaging

- Median, radial, and ulnar
  - Electrodiagnostic studies—both electromyography/nerve conduction study (EMG/NCS)
  - Routine radiographic series to evaluate for bone spurs
  - Ultrasonography for tenosynovitis or nerve swelling
  - Magnetic resonance imaging

Differential Diagnosis

- Median
  - Anterior interosseous syndrome—jersey finger
  - Pronator syndrome—medial epicondylitis
  - Carpal tunnel syndrome—flexor tendon tenosynovitis
  - Brachial neuritis
  - Humeral supracondylar process syndrome
  - Medial epicondylitis
  - Myopathies
  - Thoracic outlet syndrome
  - Tumor or space-occupying lesion
- Radial
  - PIN—lateral epicondylitis
  - Brachial neuritis
  - De Quervain's/intersection tenosynovitis
  - Humeral supracondylar process syndrome
  - Myopathies
  - Thoracic outlet syndrome
  - Tumor or space-occupying lesion
- Ulnar
  - Cubital tunnel syndrome—subluxing ulnar nerve
  - Brachial neuritis
  - Cervical radiculopathy
  - Medial epicondylitis
  - Myopathies
  - Thoracic outlet syndrome
  - Tumor or space-occupying lesion—Guyon's canal
  - Ulnar artery aneurysms or thrombosis—Guyon's canal

Treatment

Nonoperative Management

- Median, radial, and ulnar
  - Counterforce bracing
  - Splinting/casting to reduce swelling and active inflammation
  - Electrical modalities to treat pain and swelling
  - Ice for pain control and prevention of swelling
  - Soft-tissue stretching and mobilization to reduce tension/fibrosis in muscles surrounding nerves
  - Neural mobilization or nerve gliding techniques
  - Total arm strengthening and localized strengthening for dynamic control
  - Avoid or eliminate aggravating factors
  - Ergonomic assessment for work
  - Sports biomechanical assessment (tennis racquet assessment, throwing assessment)
  - Antiinflammatory medications—nonsteroidal antiinflammatory drugs (NSAIDs)/steroids
  - Perineural steroid injections
  - Iontophoresis or phonophoresis
  - Neurolysis

Guidelines for Choosing Among Nonoperative Treatments

- Choose the best option for each patient in an individualized fashion by involving the patient in the decision-making process
- Need to discern if the etiology of the entrapment is inflammatory or mechanical or both and the underlying etiology before deciding on a management plan

Surgical Indications

- Median, radial, and ulnar
  - No absolute surgical indications—it is always the patient's decision
  - Relative surgical indications
    - Severe or worsening neurological symptoms
    - Failure to respond to appropriate conservative treatment
    - Unexplained symptoms inconsistent with pathology
    - EMG/NCS showing moderate to severe nerve injury that is consistent with the symptoms

Aspects of History, Demographics, or Exam Findings That Affect Choice of Treatment

- Treatment options are based on the best options for pain management, correction of the underlying etiology of the problem, and rehabilitation to help prevent future reoccurrences from the preceding list
- Avoid NSAIDs/steroids if history of abdominal pain/ulcers/gastritis/gastrointestinal (GI) bleed
- If pain with neural tension testing—add nerve glides

Aspects of Clinical Decision Making When Surgery Is Indicated

- Muscle atrophy/weakness
- Inability to work secondary to the loss of function or pain
- Worsening symptoms despite appropriate conservative care
- Moderate or severe nerve damage by EMG/NCT

Evidence

El Miedany Y, Ashour S, Youssef S, et al: Clinical diagnosis of carpal tunnel syndrome: Old tests-new concepts. *Joint Bone Spine* 75(4):451–457, 2008.

Two-hundred and thirty-two patients with carpal tunnel syndrome and 182 control subjects were assessed to examine relationship between clinical manifestations with outcomes of diagnostic tools and physical examination procedures. One-hundred and seventy-seven out of 232 (76.3%) had abnormal nerve conduction studies. Forearm symptoms and tenosynovitis confirmed by ultrasound examination was found in 51.3% of cases. No difference was seen on comparing anthropometric measures in the affected hands with control group hands. Sensitivity of Tinel's, Phalen's, reverse Phalen's, and carpal tunnel compression tests was higher for diagnosis of tenosynovitis than for the diagnosis of carpal tunnel syndrome. Similarly higher specificity of these tests was found with tenosynovitis than for carpal tunnel syndrome. (Level III evidence)

Finanneschi F, Filipou G, Milani P, et al: Ulnar nerve compression neuropathy at Guyon's canal caused by crutch walking: Case report with ultrasonographic nerve imaging. *Arch Phys Med Rehabil* 90(3):522–524, 2009.

A case report of Guyon's syndrome after the bilateral use of forearm crutches. Crutch palsy can be neurapraxic in nature with clinical recovery. This case study presents history following a pattern of recovery of nerve function. In this case establishment of a diagnosis of focal compression neuropathy through a combination of clinical assessment and neurophysiological studies was used. An additional application of ultrasound imaging was used to verify the diagnosis and track recovery. (Level IV evidence)

Karata A, Apaydin N, Uz A, et al: Regional anatomic structures of the elbow that may potentially compress the ulnar nerve. *J Shoulder Elbow Surg* 18:627–631, 2009.

This study examined 12 cadaver upper limbs to determine length of any fibrous bands and their distance to medial epicondyle. On five cases a fibrous band ran from medial intramuscular septum to cross over ulnar nerve. Mean length of band was 5.7 cm. In four cases ulnar nerve was covered with muscle fibers from flexor digitorum superficialis and flexor carpi ulnaris. In five cases there were fibrous thickenings, and in eight cases there were vascular structures crossing the ulnar nerve. These anatomical variances could cause recurrent symptoms following surgical release of attachment sites. (Level IV evidence)

Multiple Choice Questions

QUESTION 1. Which upper extremity nerve entrapment is most commonly entrapped along the lateral head of the triceps at the lateral intermuscular septum?

A. Radial
B. Median
C. Ulnar
D. Musculocutaneous

QUESTION 2. A 17-year-old baseball pitcher complains of medial elbow discomfort that occurs with repetitive throwing. His other complaint is of loss of sensation in the fourth and fifth digits. This history would most likely correspond to compression of which upper extremity nerve?

A. Radial
B. Median
C. Ulnar
D. Musculocutaneous

QUESTION 3. A 16-year-old softball player complains of proximal forearm pain that has been exacerbated by increasing intensity and number of fast-pitch softball pitches. What would be her most likely pathology?

A. Carpal tunnel syndrome
B. Cubital tunnel syndrome
C. Arcade of Struthers' syndrome
D. Pronator syndrome

QUESTION 4. What is the first and foremost primary immediate goal in treatment of any of the upper extremity nerve entrapment syndromes?

A. Total arm strengthening
B. Regaining lost forearm power
C. Elimination of aggravating activities
D. Getting sports assessment

QUESTION 5. A 56-year-old female recreationally competitive tennis player is being seen for complaint of forearm and hand pain and numbness and tingling. She reports that additionally she seems to lose her

grip during serves and hard volleys. You notice immediately that she has atrophy of the thenar muscles on the involved side. This would most likely be caused by entrapment of which peripheral nerve?

A. Radial
B. Median
C. Ulnar
D. None of the above

Answer Key

QUESTION 1. Correct answer: **A** (see Pathology: Intrinsic Factors)

QUESTION 2. Correct answer: **C** (see Clinical Presentation)

QUESTION 3. Correct answer: **D** (see Epidemiology and Classic Findings)

QUESTION 4. Correct answer: **C** (see Treatment)

QUESTION 5. Correct answer: **B** (see previous sections)

NONOPERATIVE REHABILITATION FOR FOREARM NERVE ENTRAPMENTS

Robert C. Manske, PT, DPT, MEd, ATC, SCS, CSCS, and
Mark Stovak, MD, FACSM, FAAFP, CAQSM

GUIDING PRINCIPLES OF NONOPERATIVE REHABILITATION

- Pain—Every attempt should be made to decrease pain and symptoms of nerve entrapments.
- Sensation—Serial assessment of sensation can guide the nonoperative rehabilitation indicating either worsening or lessening of entrapment and compression.
- Strength—Maintain or advance strength and minimize strength loss caused by associated entrapped nerves.
- Function—Restore function through gaining or maintaining motion and strength.

Phase I (weeks 0 to 6 dependent on acuteness of injury and degree of neurological involvement)

Protection

- Bracing, casting, or splinting may be helpful to rest extremity and provide support to allow decreased inflammation and swelling.

Management of Pain and Swelling

- RICE: rest, ice, compression, elevation
- Modalities such as pulsed ultrasound, electrical stimulation, iontophoresis or phonophoresis may be also helpful.

Techniques for Progressive Increase in Range of Motion

Manual Therapy Techniques

- Gentle active assistive range of motion as tolerated

Soft-Tissue Techniques

- Gentle distal to proximal massage to create retro drainage from swollen tissues

Stretching and Flexibility Techniques for the Musculotendinous Unit

- Very gentle stretching to affected area because neurological tissue is very unforgiving if stretched too far and symptoms exacerbated

Other Therapeutic Exercises

- Cardiovascular exercise (bike)
- Upper extremity total arm strength
- Total body strength

Activation of Primary Muscles Involved

- Gentle active or active assistive range of motion exercises as tolerated
- Total arm strength to proximal muscles of arm and shoulder as tolerated

Milestones for Progression to the Next Phase

- Minimal to no swelling
- Pain free range of motion
- Improvement of strength

Phase II (weeks 6 to 12)

Protection

- Protection of bracing and splinting gradually removed

Management of Pain and Swelling

- RICE and ultrasound, electrical stimulation

Techniques for Progressive Increase in Range of Motion

Manual Therapy Techniques

- Progression from active assistive to active range of motion
- Gentle joint mobilization techniques to increase passive joint mobility

Soft-Tissue Techniques

- Dependent upon degree of swelling. May continue as per Phase I if swelling and edema persist.

Stretching and Flexibility Techniques for the Musculotendinous Unit

- Gentle stretching of forearm and wrist musculature if tolerated without an increase in symptoms
- Nerve glide or flossing techniques to increase nerve mobility or decrease adhesions around peripheral nerves

Other Therapeutic Exercises

- Continue as Phase I
- May begin elliptical or treadmill as tolerated

Activation of Primary Muscles Involved

- Concentric submaximal isometric followed by submaximal isotonic progressive resistive exercises with light weight or bands. Start exercises such as wrist extensor muscles by initiating strengthening with isometrics, which if tolerated can be followed by isotonic movements through a safe range of motion for wrist extension.
- Exercises done in cardinal planes; for example, starting isotonic exercises in frontal plane only versus using total arm movements that might incorporate multiple planes of movement of the forearm
- Putty exercises
- Gripping (ball squeeze)
- Rice bucket exercises

Open and Closed Kinetic Chain Exercises

- Place hand wrist on table top and slowly and gently load in various weight-bearing directions

Techniques to Increase Muscle Strength, Power, and Endurance

- Continue to progress total arm strength by working proximal musculature. Ensure proper proximal muscle control by working elbow flexors, extensors, and glenohumeral and scapular shoulder muscles

Functional Exercises

- Grasping, pushing, and pulling motions
- Holding sports/vocational equipment for short durations in effort to build endurance

Milestones for Progression to the Next Phase

- No swelling
- No pain
- Full range of motion
- No loss of sensation
- 4/5 manual muscle test of affected muscles

TIMELINE 13-1: **Nonoperative Rehabilitation of Upper Extremity Nerve Entrapment Syndromes**

PHASE I (weeks 0 to 6)	PHASE II (weeks 6 to 12)
• Sling, splint, brace • RICE: rest, ice, compression, elevation • Physical Therapy (PT) modalities • Gentle AAROM forearm, hand, and wrist • Distal to proximal massage • Very gentle stretching • Cardiovascular exercises • Total body strengthening (TBS) • Upper extremity total arm strengthening (TAS) • Total leg strength (TLS) • Rotator cuff exercises, progressive resistive exercises (PREs) • Scapular exercises (PREs)	• Sling, splint, brace as needed but gradually removed • PT modalities as needed • Progress from AAROM to AROM • TBS/TAS/total leg strength (TLS) activities as recommended and tolerated • Rotator cuff exercises (PREs) • Scapular exercises (PREs) • Concentric submaximal isometric exercises • Progression to submaximal isotonic progressive resistive exercises • Putty exercises • Gripping exercises • Rice bucket exercises • Gently load hand and wrist in closed kinetic chain positions • Gentle pushing, pulling motions • Light weight wrist flexion/extension, pronation/supination

Phase III (weeks 12 to 18)

Management of Pain and Swelling

- As previously described if pain and swelling continue

Techniques for Progressive Increase in Range of Motion

Manual Therapy Techniques

- As previously described if needed
- If limitation of motion are capsular (joint restrictions) in nature, can begin joint mobilization techniques to restore normal joint arthrokinematics

Soft-Tissue Techniques

- As previously described if needed

Stretching and Flexibility Techniques for the Musculotendinous Unit

- As previously described if needed
- Should be able to tolerate gentle stretching now without re-exacerbation

Other Therapeutic Exercises

- Begin trunk/core strengthening with emphasis on requirements for activities of sports or vocation
- Continued cardiovascular conditioning
- Continued total arm strength as tolerated

Activation of Primary Muscles Involved

- Submaximal isotonic progressive resistive exercises with light weight or bands
- Concentric or eccentric wrist extension exercises with 3-lb weights or red resistance band, three sets of 20 repetitions

Open and Closed Kinetic Chain Exercises

- Progressively load upper extremity in more provocative patterns
- Start leaning on wall, to bilateral upper extremity in quadruped, to unilateral extremity in tripod

Techniques to Increase Muscle Strength, Power, and Endurance

- Increase strength and endurance as tolerated by modulating dosage of exercises as appropriate for activities of daily living and sports

Plyometrics

- Gentle plyometric "type" exercises with light weights, bilaterally progressing to unilaterally.
- Bilateral chest pass into PlyoBack device, throwing and catching chest height with two hands, light weight. When this becomes easier, athlete can progress to unilateral pass to PlyoBack device.

Functional Exercises

- Incorporate more functional movement specific tasks (D2 flexion/extension patterns for shoulder while gripping band for forearm exercise; swinging hammer without full weight hammer head).

Sport-Specific Exercises

- Incorporate more functional movement specific tasks (D2 flexion/extension patterns for shoulder while gripping band for forearm exercise).
- Begin with gentle throwing or hitting motions.
- Motions may be done initially without ball (baseball, softball) or racquet (tennis) progressing to motions with equipment.

TIMELINE 13-1: **Nonoperative Rehabilitation of Upper Extremity Nerve Entrapment Syndromes** (Continued)

PHASE III (weeks 12 to 18)	PHASE IV (weeks 18 to 24)
• D/C sling, splint, or brace • PT modalities as needed • AROM, AAROM, PROM—full • Mobilizations as needed • Trunk and core exercises as tolerated • TBS/TAS activities as recommended and tolerated • Rotator cuff exercises (PREs) • Scapular exercises (PREs) • "Plyometric-like" exercises • Light weight, bilateral progressing to unilateral • Functional exercises (90/90 shoulder) for throwers • Putty exercises • Gripping exercises • Rice bucket exercises • Pushing and pulling-type exercises • Wrist flexion/extension and pronation and supination PREs	• AROM, AAROM, PROM full • TBS/TAS/TLS activities as recommended and tolerated • Mobilizations as needed • Trunk and core exercise as tolerated • Rotator cuff exercises (PREs) • Scapular exercises (PREs) • Plyometric exercises • Functional exercises • Proprioceptive neuromuscular facilitation (PNF) exercises • Progress Closed kinetic chain (CKC) exercises • Sports progression as tolerated

- Gentle golfing motions can be started swinging 50% effort progressing to 75% over several visits or weeks.
- Use elastic tubing around tennis racquet while moving into positions of cocking for forehand and backhand tennis strokes.

Milestones for Progression to the Next Phase

- No swelling
- No pain
- Full range of motion
- No loss of sensation
- 5/5 strength of affected muscles

Phase IV (weeks 18 to 24)

Management of Pain and Swelling

- As previously described if pain and swelling continue

Techniques for Progressive Increase in Range of Motion

Manual Therapy Techniques

- As previously described if needed
- If limitations of motion are capsular (joint restrictions) in nature, can begin joint mobilization techniques to restore normal joint arthrokinematics

Soft-Tissue Techniques

- As previously described if needed

Stretching and Flexibility Techniques for the Musculotendinous Unit

- As previous if needed. Should be able to tolerate gentle stretching now without re-exacerbation.

Other Therapeutic Exercises

- Continued trunk/core strengthening with emphasis on requirements for activities of sports or vocation
- Continued cardiovascular conditioning
- Continued total arm strength as tolerated using larger movements and proximal musculature, such as during upper body ergometer or push up progressions

Activation of Primary Muscles Involved

- Submaximal isotonic progressive resistive exercises with light weight or bands
- Continuance of program to maintain or increase strength and/or endurance as needed for full unrestricted return to activity. This program should be continued until the patient has full unrestricted strength and the ability to return to previous activity.

Open and Closed Kinetic Chain Exercises

- Progression as previously described
- Increased resistance from heavier dumbbells, thicker resistance bands, or more provocative position such as overhead movements, movements away from body. Can also add loaded exercises, such as pushups with feet elevated 12 inches or pushups with clap between.

Techniques to Increase Muscle Strength, Power, and Endurance

- Increase strength and endurance as tolerated by modulating dosage of exercises as appropriate for activities of daily living and sports.
- Increase speed and/or resistance with exercises as appropriate to allow increased power during activities. Use light tubing while swinging bat or racquet in simulated game-type situations.

Plyometrics

- If tolerated, "gentle plyometric-type" exercises in previous stage can progress to heavier weights and unilateral exercises
- Increase weight of Plyoball to add resistance and overload. Additionally, Plyoball can be done in more provocative positions such as overhead motions.

Functional Exercises

- Incorporation of more functional movement specific tasks (e.g., use of actual hammer or saw)
- All done in slow progression from 50% to 75% to 100% effort
- One set of 25 repetitions progressing to up to three sets of 25 repetitions at each intensity level

Sport-Specific Exercises

- Incorporation of more functional movement specific tasks (throwing baseball, football, swinging bat)
- All done in slow progression, from 50% to 75% to 100% effort
- One set of 25 repetitions progressing to up to three sets of 25 repetitions at each intensity level

Milestones for Progression to Advanced Sport-Specific Training and Conditioning

- No swelling
- No pain
- Full range of motion
- No loss of sensation
- 5/5 strength of affected muscles

Criteria for Abandoning Nonoperative Treatment and Proceeding to Surgery or More Intensive Intervention

- Continued pain
- Continued swelling
- Continued numbness and tingling

- No return of strength
- Progression of symptoms

Tips and Guidelines for Transitioning to Performance Enhancement

- Ensure that symptoms do not return.
- Slow progression if any neurological symptoms return.
- These symptoms could show up as excessive fatigue, burning, loss of sensation, or feelings of clumsiness.
- Gradual slow progression is always more reliable than a rushed, hurried approach to return to function without creating setbacks.

Performance Enhancement and Beyond Rehabilitation: Training/Trainer and Optimization of Athletic Performance

- Gradual progression to full return of functional activities involving total body movement patterns with no return of symptoms
- Hitting or serving progressions. Use of weight equipment or bands or cables to challenge muscular control of trunk and full body

Specific Criteria for Return to Sports Participation: Tests and Measurements

- No swelling
- No pain
- Full range of motion
- No loss of sensation
- 5/5 strength of affected muscles

Evidence

Garfinkel MS, Singhal A, Katz WA, et al: Yoga-based intervention for carpal tunnel syndrome. A randomized trial. *JAMA* 280(18):1601–1603, 1998.

A randomized, single-blind, controlled study that studied 42 employed or retired individuals with carpal tunnel syndrome. Subjects were assigned to a yoga group or a control group. Yoga group subjects received a yoga-based intervention consisting of 11 yoga postures designed for strengthening, stretching, and balance in each joint in upper body along with relaxation given twice weekly for 8 weeks. Control group patients were offered a wrist splint to supplement their current treatment. Outcome measures included grip strength, pain intensity, sleep disturbance, Phalen's and Tinel's signs, and median nerve motor and sensory conduction time. Subjects in the yoga group had significant improvement in grip strength and pain reduction, whereas these were not significant for control the group. Yoga group had significantly more improvement in Phalen's sign. No difference was seen in Tinel's sign, and median nerve motor and sensory conduction time. (Level II evidence)

Irvine J, Chong SL, Amirjani N, et al: Double-blind randomized controlled trial of low-level laser therapy in carpal tunnel syndrome. *Muscle Nerve* 40:182–187, 2004.

Double-blinded randomized controlled trial of low-level laser therapy in fifteen carpal tunnel syndrome patients. Patients randomly assigned to either control group (8) or treatment group (7). Both groups received treatment three times per week for 5 weeks. Control groups were treated with sham treatment, whereas the treatment group received 860 nm gallium/aluminum/arsenide laser at a dosage of 6 J/cm^2 over the carpal tunnel. Primary outcomes were subjective outcomes. All participants completed study with no adverse effects. Significant symptomatic improvement occurred in both controls and patients. However, there was no significant difference in outcome measures between the two groups. Thus, low-level laser therapy is no more effective in the reduction of symptoms of carpal tunnel syndrome. (Level II evidence)

Lopes MM, Lawson W, Scott T, et al: Tendon and nerve excursion in the carpal tunnel in healthy and CTD wrists. *Clin Biomech* 26(9):930–936, 2011.

Study looked at size of median nerve and excursion of flexor digitorum superficialis tendon via use of Doppler ultrasound imaging. Twenty-five participants, including 16 healthy, six self-reported with cumulative trauma disorders, and three wheelchair users, were analyzed. The median nerves in symptomatic wrists were larger than healthy wrists by 4.2 mm^2 (right) and 4.1 mm^2 (left) proximally to less than 1.4 mm^2 distally. Tendon excursion differences in healthy wrists ranged from 0.7 mm to 4.3 mm, whereas those in the symptomatic wrists ranged over 22.2 mm. (Level III evidence)

Oskay D, Meric A, Kirdi N, et al: Neurodynamic mobilization in the conservative treatment of cubital tunnel syndrome: Long-term follow-up of 7 cases. *J Manipulative Physiol Ther* 33(2): 156–163, 2010.

This is a case series that describes the effect of nerve mobilization techniques in a standard conservative management of cubital tunnel syndrome. Seven patients with cubital tunnel syndrome participated in the study. Physical therapy treatments consisted of cold application, pulsed ultrasound, nerve mobilization techniques, strengthening exercises, postural adaptations, patient education, and ergonomic modifications. Outcome measurements included strength, pain scales, sensation testing, and objective outcome scales. Pain; Tinel's sign; and Disability of Arm, Shoulder and Hand index scores were decreased, whereas grip and pinch strength increased in the observation period of these patients. (Level IV evidence)

Oztas O, Turan B, Bora I, et al: Ultrasound therapy effect in carpal tunnel syndrome. *Arch Phys Med Rehabil* 79(12):1540–1544, 1998.

Investigation to assess overall effects of repeated ultrasound treatment in carpal tunnel syndrome. A patient-blinded, placebo-controlled, pre- and posttreatment trial assessing 18 women (30 hands) with diagnosis of carpal tunnel syndrome. Three groups each with 10 cases were randomly established. Groups included continuous ultrasound, with intensities of 1.5 W/cm^2 (group a), 0.8 W/cm^2 (group b), and 0.0 W/cm^2 (group c). Outcome measures were clinical exam and electrophysiological tests before and after treatment. Statistically significant improvement was obtained in clinical tests in all groups. Pain, pain/paresthesia at night/day, and frequency of awakening at night all improved. There was no difference in electrophysiological studies. (Level II evidence)

Multiple Choice Questions

QUESTION 1. In which phase may forearm muscle stretching be contraindicated when utilizing conservative treatment for nerve entrapments?

A. Phase I
B. Phase II
C. Phase III
D. Phase IV

QUESTION 2. During early phases of rehabilitation, when a decrease in the offending activity is required as part of treatment approach, which of the following forms of immobilization would be beneficial for a forearm nerve entrapment?

A. Splint
B. Brace
C. Sling
D. Any of the above

QUESTION 3. Which of the following rehabilitation concepts would apply to a 22-year-old college pitcher with chronic ulnar nerve compression resulting from attenuation of the medial collateral ligament of the elbow?

A. Cardiovascular conditioning
B. Total arm strengthening
C. Total body strengthening
D. All of the above

QUESTION 4. A 17-year-old female tennis player is being seen for radial tunnel syndrome. She has been slowly improving to the point where she wants to start swinging her racquet again. What criteria should be met before she begins a tennis interval program?

A. 80% return of flexibility
B. Less than 4/10 complaint of pain
C. 5/5 strength of affected muscles
D. Minimal forearm swelling after therapy

QUESTION 5. Joint mobilization techniques to elbow, forearm, or wrist may be appropriate for a patient with a forearm nerve entrapment when the following condition occurs:

A. Stretching becomes too painful
B. No response to passive overpressure
C. Motion limitation is from contractile tissue
D. Motion limitation is from capsular tissue

Answer Key

QUESTION 1. Correct answer: **A** Phase I (see Phase I).

QUESTION 2. Correct answer: **D** Any of the above (see Phases I and II)

QUESTION 3. Correct answer: **D** All of the above (see all Phases of Rehabilitation)

QUESTION 4. Correct answer: **C** Should have return of full strength (see Milestones to Progress to Phase IV)

QUESTION 5. Correct answer: **D** Motion limitation is from capsular tissue (see Phase IV)

Chapter 14

Forearm Tendinitis

INTRODUCTION

Robert C. Manske, PT, DPT, MEd, ATC, SCS, CSCS, and
Mark Stovak, MD, FAAFP, FACSM, CAQSM

Epidemiology

The epidemiology of forearm tendinitis is dependent upon its type.

Intersection Syndrome

Overuse syndrome of the area in which occurs a crossover of the first and second dorsal compartments of the wrist. First compartment consists of the abductor pollicis longus (APL) and extensor pollicis brevis (EPB) and second compartment consisting of the extensor carpi radialis longus (ECRL) and the extensor carpi radialis brevis (ECRB).

- Prevalence of 11.9% in group of 42 skiers with symptoms developing within first 2 days of activity
- Found equally in men and women
- Most common in rowers, so it is often called "rower's wrist"; caused by repetitive feathering of the oar out of the water

De Quervain's Syndrome

A thickening of the sheath encompassing the tendons of the EPB and the APL

- Prevalence equal among races
- More common in women than men
- Often seen in new mothers resulting from their lifting their babies repetitively

Humeral Epicondylitis

This is an overuse inflammatory condition causing pain and dysfunction at the common extensor or flexor origin. Also, there may be a chronic degeneration, regeneration with microtears of the tendinous tissue, resulting in tendinosis.

- Affects tennis players (5% to 10%) of those diagnosed
- 1% to 2% of general population affected
- Lateral epicondylitis (tennis elbow) more common than medial epicondylitis (golfer's elbow)
- Median age of affected persons is 41 years of age
- Incidence in tennis players higher if they play more than 2 hours per day
- Equal male-to-female ratio
- Older patients more likely to have chronic symptoms

Pathophysiology

Intrinsic Factors

Intersection Syndrome

- Repetitive overuse
- Friction between muscle bellies of first extensor compartment tendon (APL and EPB) and adjacent tendons of the second extensor compartment (Figure 14-1)
- Entrapment stenosis
- Tightness of sheath of ECRL and ECRB tendons
- Adventitial bursa

De Quervain's Syndrome

- Repetitive overuse
- Entrapment of EPB and the APL as they pass deep to extensor retinaculum
- First dorsal compartment entrapment of tendons

Humeral Epicondylitis

- Repetitive overuse
- Lateral epicondylitis (tennis elbow): primary muscles involved are the ECRL and ECRB; secondary muscle involved is the extensor digitorum communis (Figure 14-2)

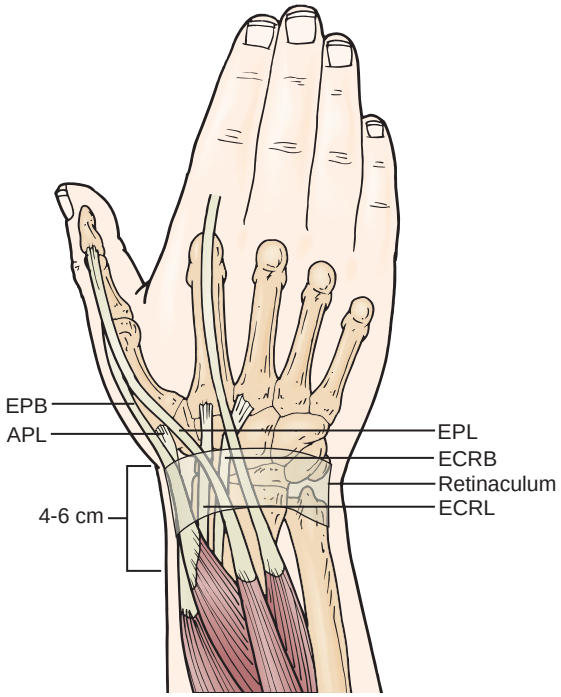

FIGURE 14-1. Intersection syndrome at a point 4 to 6 cm proximal to the wrist joint. *APL,* abductor pollicis longus; *ECRB,* extensor carpi radialis brevis; *ECRL,* extensor carpi radialis longus; *EPB,* extensor pollicis brevis. *(Redrawn from Cox K, Brotzman SB: Hand and wrist injuries: Intersection syndrome of the wrist. In Brotzman SB, Manske RC, eds: Clinical orthopaedic rehabilitation: An evidence-based approach. 3rd ed. Philadelphia: Elsevier; 2011.)*

- Medial epicondylitis (golfer's elbow): primary muscles involved are the forearm flexors, including the flexor carpi radialis longus, flexor carpi ulnaris, and pronator teres (Figure 14-3)

Extrinsic Factors

Intersection Syndrome

- Single bout of acute overuse
- Chronic repetitive overuse

De Quervain's Syndrome

- Single bout of acute overuse
- Chronic repetitive overuse
- Activities that require gripping and ulnar deviation

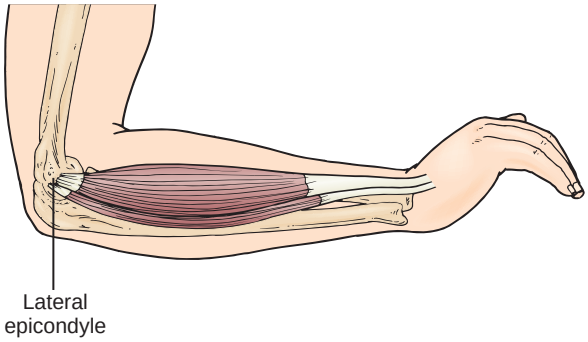

FIGURE 14-2. Lateral epicondylitis.

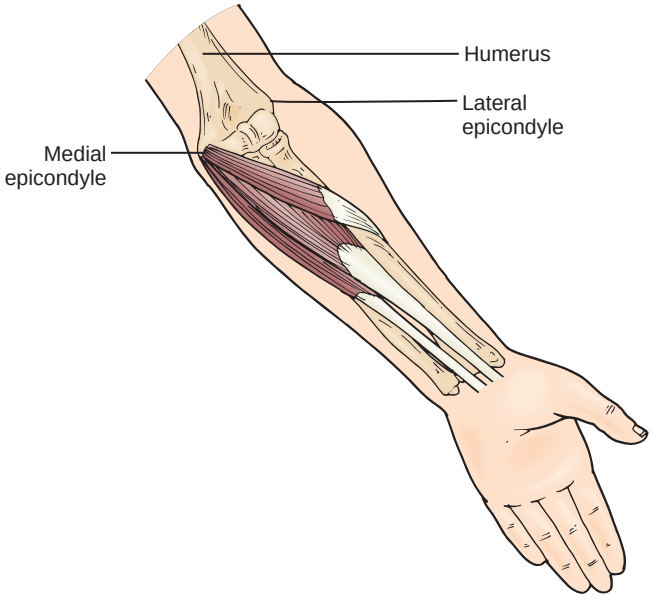

FIGURE 14-3. Medial epicondylitis.

Humeral Epicondylitis

- Repetitive gripping
- Repetitive supination/pronation at forearm
- Novice tennis players because of poor form

Traumatic Factors

Intersection Syndrome

- Acute single incident
- Repeated wrist extension
- Repetitive wrist motions in any plane
- Pressure over distal wrist

De Quervain's Syndrome

- Blow to wrist
- Repetitive ulnar deviation

Humeral Epicondylitis

- Concentric/eccentric overload
- Insidious onset
- Repetitive wrist extension

Classic Pathological Findings

Intersection Syndrome

- Pain and swelling in region 4 to 8 cm proximal to Lister's tubercle, dorsal aspect of forearm
- Pain with thumb extension and abduction
- Pain with wrist extension
- Crepitus with wrist movements
- Location where first and second extensor compartment tendons cross
- Palpation may produce crepitus
- Palpation painful
- Erythema
- Edema
- Squeaking sound with wrist motion

- Known as "squeakers"; common in rowers and those involved in grip activities

De Quervain's Syndrome

- Tenderness at APL, EPB (first dorsal compartment)
- Pain on radial side of wrist
- Pain may radiate up into forearm
- Pain with resisted thumb movements
- Squeaky feeling (snowball crepitus caused by tenosynovitis) with thumb movements
- Motion may produce crepitus
- Palpation may produce crepitus
- Palpation painful
- Erythema
- Edema or swelling on radial side of wrist

Humeral Epicondylitis

- Tenderness at medial or lateral epicondyle
- Pain with repetitive wrist motions including extension and radial deviation
- Pain with resisted wrist extension or supination
- Pain aggravated with strong gripping
- Pain with passive stretch during wrist motions
- Pain may radiate down into forearm
- Grip strength reduced

Clinical Presentation

History and Physical Examination

Intersection Syndrome

- Acute single episode such as a weekend of skiing, bowling, rowing
- Repetitive unaccustomed overuse such as machinist
- Secretaries
- Carpenters
- Maintenance workers
- Filing workers
- Rice-harvesting workers
- Weightlifters
- Rowing or canoeing
- Raking
- Shoveling
- Pain and swelling in region 4 to 8 cm proximal to Lister's tubercle
- Pain with thumb extension and abduction
- Pain with wrist extension
- Squeaky sound with wrist movements
- Location where first and second extensor compartment tendons cross
- Motion may produce crepitus
- Palpation may produce crepitus
- Palpation painful
- Erythema
- Edema

De Quervain's Syndrome

- Acute single episode
- Repetitive unaccustomed overuse
- Repetitive wrist radial deviation
- Repetitive thumb palmar or radial abduction
- Pain with resisted thumb movements
- Squeaky feeling with thumb movements
- Motion may produce crepitus
- Palpation may produce crepitus
- Palpation painful
- Erythema
- Edema or swelling on radial side of wrist

Humeral Epicondylitis

- Athletic individuals
- Baseball players
- Tennis players
- Swimmers
- Laborers who have to frequently grip tools
- Plays sports or recreation greater than 2 hours per day
- Pain with active motions of elbow and forearm

Abnormal Findings

Intersection Syndrome

- Squeak with radial-ulnar deviation of the wrist with crepitus
- Localized swelling at the intersection of the first/second dorsal compartments
- Tenderness at intersection of the first/second dorsal compartments

De Quervain's Syndrome

- Tenderness at the first dorsal compartment
- Localized swelling to the first dorsal compartment
- Positive Finkelstein's test

Humeral Epicondylitis

- Tenderness at musculotendinous junction just distal to the medial and lateral epicondyles
- Pain with wrist flexion (medial epicondylitis) and wrist extension or power grip (lateral epicondylitis)
- Cyrix's muscle tendon unit testing

Pertinent Normal Findings

Intersection Syndrome

- Negative Tinel's sign at posterior interosseous nerve, median nerve, and ulnar nerve

De Quervain's Syndrome

- Negative Tinel's sign at posterior interosseous nerve, median nerve, and ulnar nerve

Humeral Epicondylitis

- Negative Tinel's sign at posterior interosseous nerve, median nerve, and ulnar nerve

Imaging

- Routine radiographic series
- Ultrasonography
- Magnetic resonance imaging

Differential Diagnosis

Intersection Syndrome

- De Quervain's tenosynovitis
- Wrist ligament sprain

- Forearm muscle strain
- Arthritis of first carpometacarpal (CMC) joint
- Fracture of radial styloid
- Fracture of scaphoid
- Ganglion cyst
- Infection
- Soft tissue neoplasm
- Entrapment of the superficial radial sensory nerve
- Cellulitis
- Forearm contusion

De Quervain's Syndrome

- Intersection syndrome
- Scaphoid fracture
- Thumb CMC arthritis
- Thumb metacarpophalangeal arthritis
- Superficial radial sensory nerve irritation
- Posterior interosseous nerve entrapment
- C6 radiculopathy
- Forearm contusion

Humeral Epicondylitis

- Posterior interosseous syndrome
- Radial tunnel syndrome
- Pronator syndrome
- Synovitis
- Chondromalacia of radiocapitellar joint
- Lateral collateral ligament sprain
- Ulnar collateral ligament sprain or tear
- Cervical spine pathology
- C6–C7 nerve root compression causing radiculopathy
- Ulnar nerve entrapment
- Elbow bursitis
- Elbow fracture
- Elbow arthritis

Treatment

Nonoperative Management

Intersection Syndrome

- Activity/recreation modification
- Work modification
- Splinting
- Physical therapy
- Forearm stretching
- Electrical stimulation
- Ultrasound
- Iontophoresis
- Phonophoresis
- Oral NSAID
- Topical ice massage
- Steroid injection

De Quervain's Syndrome

- Activity/recreation modification
- Work modification
- Splinting
- Physical therapy
- Forearm stretching
- Electrical stimulation
- Ultrasound
- Iontophoresis
- Phonophoresis
- Oral nonsteroidal antiinflammatory drug (NSAID)
- Topical ice massage
- Steroid injection

Humeral Epicondylitis

During the initial 4 weeks, when pathology is a peritendinitis:

- Activity/recreation modification
- Work modification
- Splinting
- Physical therapy
- Forearm stretching
- Electrical stimulation
- Ultrasound
- Iontophoresis
- Phonophoresis
- Oral NSAID
- Topical ice massage
- Steroid injection in tendon sheath

After 4 weeks, when pathology is a tendinosis:

- Eccentric exercises beneficial once inflammation resolves
- Forearm stretching
- Physical therapy
- Cross-friction massage
- Augmented soft tissue mobilization/Graston technique/gua sha
- Extracorporeal shockwave therapy
- Percutaneous tenotomy
- Autologous blood injection
- Prolotherapy injection
- Platelet-rich plasma injection
- Sclerosing injection (polidocanol)

Guidelines for Choosing Among Nonoperative Treatments

- Intersection syndrome and De Quervain's tenosynovitis are best treated to reduce the inflammation present causing the crepitus.
- The treatment of choice is steroid injection and avoiding the movement pattern that led to the inflammation.
- All of the other treatments listed in the preceding are also reasonable options.

Surgical Indications

There are no absolute surgical indications. It is always the patient's decision. Relative surgical indications are listed in the following.

Intersection Syndrome

- Failure of conservative measures after 6 months
- Inability to work secondary to the loss of function or pain
- Worsening symptoms despite appropriate conservative care

De Quervain's Syndrome

- Failure of conservative measures after 6 months
- Inability to work secondary to the loss of function or pain

- Worsening symptoms despite appropriate conservative care

Humeral Epicondylitis

- Failure of conservative measures after 6 months
- Inability to work secondary to the loss of function or pain
- Worsening symptoms despite appropriate conservative care

Aspects of History, Demographics, or Exam Findings That Affect Choice of Treatment

- Treatment options are based on the best options for pain management, correction of the underlying etiology of the problem, and rehabilitation to help prevent future reoccurrences from the preceding list.
- Avoid NSAIDs/steroids if there is a history of abdominal pain, ulcers, gastritis, or gastrointestinal bleeding.
- Timing of humeral epicondylitis determines most likely pathology and treatment method.

Aspects of Clinical Decision Making When Surgery Is Indicated

- Failure of conservative measures after 6 months
- Inability to work secondary to the loss of function or pain
- Worsening symptoms despite appropriate conservative care

Evidence

Knobloch K, Spies M, Busch KH, et al: Sclerosing therapy and eccentric training in flexor carpi radialis tendinopathy in a tennis player. *Br J Sports Med* 41(12):920–921, 2007.

Case study of 35-year-old tennis player from pain rating of 9/10 visual analog scale (VAS) at the flexor carpi ulnaris tendon with adjacent calcification in close proximity to the pisiform bone. Doppler assessment revealed neovascularization at the origin of pain. Sclerosing therapy using polidocanol under laser Doppler guidance was initiated, with immediate decreased capillary blood flow by 25% within resolution of neovascularizations. Immediately afterward, sclerosing pain on VAS dropped from 9/10 to 4/10. Following a short period of rest, eccentric training of forearm muscles was initiated. After 12 weeks a functional complete recovery and complete resolution of pain had occurred. (Level IV evidence)

Peters-Veluthamaningal C, Winters JC, Groenier KH, et al: Randomised controlled trial of local corticosteroid injections for de Quervain's tenosynovitis in general practice. *BMC Musculoskeletal Disord* 10:131, 2009.

This study evaluated the effectiveness of local corticosteroid injections for de Quervain's tenosynovitis by general practitioners. Eleven general practitioners enrolled 21 wrists in 21 patients. Short-term outcomes were assessed (1 week postinjection) in a randomized, placebo-controlled trial. Long-term effectiveness was evaluated in an open prospective cohort study of responders during a 12-month follow-up. Treatment was randomized into one to two local injections of either triamcinolonacetonide (treatment) or 1 NaCl 0.9% (placebo). The triamcinolonacetonide group had better results for short-term outcomes, including treatment response, perceived improvement, and severity of pain but not for the Dutch-AIMS-HFF. Long-term responses were sustained for severity of pain and scores of Dutch AIMS-2-HFF but not for perceived improvement. Authors report short-term benefits of corticosteroid injections for patients with de Quervain's tenosynovitis are better than with placebo. (Level I evidence)

Sasinopoulos D, Stasinopoulos I, Pantelis M, et al: Comparison of effects of a home exercise programme and a supervised exercise programme for the management of lateral elbow tendinopathy. *Br J Sports Med* 44(8):579–583, 2010.

This study compared the effectiveness of a home and supervised exercise program for lateral elbow tendinopathy. Seventy patients with chronic lateral elbow tendinopathy were placed into either home exercise or supervised exercise program five times per week for 4 weeks. Outcome measures were pain and function. At the end of treatment (12 weeks), there was a decline in pain and increase in function of both groups compared with baseline. The supervised treatment group had significant increases in function and decreases in pain at the 3-month follow up. (Level II evidence)

Walton MJ, Mackie F, Fallon M, et al: The reliability and validity of magnetic resonance imaging in the assessment of chronic lateral epicondylitis. *J Hand Surg Am* 36(3):475–479, 2011.

This study of 21 consecutive subjects with diagnosis of lateral epicondylitis assessed the observer reliability of magnetic resonance imaging (MRI) to detect this condition. Moderate to severe signal changes were consistent with tendinosis in 189 of 21 patients. Significant interobserver reliability and intraobserver agreement were demonstrated for MRI interpretation of grade of tendinosis and length of tendon separation. (Level I evidence)

Multiple Choice Questions

QUESTION 1. In which compartment(s) does intersection syndrome occur?

A. First and second
B. Second and third
C. Third and fourth
D. Only first

QUESTION 2. A 32-year-old factory worker has been diagnosed with intersection syndrome. What is a classic symptom that would indicate or point to intersection syndrome being his pathology?

A. Acute injury from golfing
B. Numbness and tingling in radial nerve distribution
C. History of repetitive radial and ulnar deviation
D. Increased symptoms with elbow extension overpressure

QUESTION 3. You suspect your new hand/wrist pain patient has de Quervain's syndrome. Which of the following symptoms would be seen in a patient with de Quervain's syndrome?

A. Tenderness at APL, EPB
B. Pain on radial side of wrist
C. Pain may radiate up into forearm
D. Pain with resisted thumb movements
E. All of the above

QUESTION 4. What is the first and foremost primary immediate goal in treatment of any of the upper extremity tendonitis or bursitis?

A. Total arm strengthening
B. Regaining lost forearm power
C. Elimination of aggravating activities
D. Getting sports assessment

Answer Key

QUESTION 1. Correct answer: **A** (see Pathology)

QUESTION 2. Correct answer: **C** (see Clinical Presentation)

QUESTION 3. Correct answer: **E** (see Classic Pathological Findings)

QUESTION 4. Correct answer: **C** (see Treatment)

NONOPERATIVE REHABILITATION FOR FOREARM TENDINITIS

Robert C. Manske, PT, DPT, MEd, ATC, SCS, CSCS, and
Mark Stovak, MD, FAAFP, FACSM, CAQSM

GUIDING PRINCIPLES OF NONOPERATIVE REHABILITATION

- Pain—Every attempt should be made to decrease pain and symptoms of forearm overuse.
- Strength—Maintain and increase strength and minimize loss due to forearm overuse.
- Function—Restore function through gaining or maintaining motion and strength.

Phase I (weeks 0 to 2)

Protection

- Counterforce bracing or splinting may be helpful to rest extremity and provide support to allow decreased inflammation and swelling.
- Do not want to rely on this because it can lead to atrophy and contractures.
- Activity modification very important to allow relative rest from offending activity.

Management of Pain and Swelling

- RICE: rest, ice, compression, elevation
- Modalities such as pulsed ultrasound, electrical stimulation, and ionto/phonophoresis may be helpful.

Techniques for Progressive Increase in Range of Motion

Manual Therapy Techniques

- Gentle active assistive range of motion as tolerated.

TIMELINE 14-1: **Nonoperative Rehabilitation of Forearm Tendinitis**

PHASE I (weeks 0 to 2)	PHASE II (weeks 2 to 4)
• Sling, splint, brace • RICE: rest, ice, compression, elevation • Physical therapy modalities • Gentle active assisted range of motion (AAROM) forearm, hand, and wrist • Distal to proximal massage • Very gentle stretching • Cardiovascular exercises • Total body strengthening (TBS) • Upper extremity total arm strengthening (TAS) • Total leg strength (TLS) • Rotator cuff exercises—progressive resistive exercise (PREs) • Scapular exercises—PREs	• Sling, splint, brace as needed but gradually removed • PT modalities as needed • Progress from AAROM to AROM • TBS/TAS/TLS activities as recommended and tolerated • Rotator cuff exercises—PREs • Scapular exercises—PREs • Concentric submaximal isometric exercises • Progression to submaximal isotonic progressive resistive exercises • Putty exercises • Gripping exercises • Rice bucket exercises • Gently load hand and wrist in closed kinetic chain positions • Gentle pushing, pulling motions • Light weight wrist flexion/extension, pronation/supination

Soft Tissue Techniques

- Gentle distal to proximal massage to create retro drainage from swollen tissues

Stretching and Flexibility Techniques for the Musculotendinous Unit

- Very gentle stretching to affected area. Try to achieve or maintain full active range of motion (AROM)/passive range of motion (PROM).

Other Therapeutic Exercises

- Cardiovascular exercise (bike)
- Upper extremity total arm strength
- Total body strength

Activation of Primary Muscles Involved

- Gentle active or active assistive range of motion exercises as tolerated
- Total arm strength to proximal muscles of arm and shoulder and elbow as tolerated

Milestones for Progression to the Next Phase

- Minimal to no swelling
- Pain free range of motion
- Improvement of strength

Phase II (weeks 2 to 4)

Protection

- Protection of bracing and splinting gradually removed

Management of Pain and Swelling

- RICE and ultrasound, electrical stimulation

Techniques for Progressive Increase in Range of Motion

Manual Therapy Techniques

- Progression from active assistive to active range of motion

Soft Tissue Techniques

- Depend on degree of swelling. May continue as per Phase I if swelling and edema persists. If tolerable, may begin more deep tissue massage to decrease sore muscles or muscle spasm associated with tendinitis conditions.

Stretching and Flexibility Techniques for the Musculotendinous Unit

- Gentle stretching of forearm and wrist musculature if tolerated without an increase in symptoms

Other Therapeutic Exercises

- Continue as Phase I
- May begin elliptical or treadmill as tolerated.
- Begin trunk/core strengthening with emphasis on requirements for activities of sports or vocation
- Continued cardiovascular conditioning
- Continued total arm strength as tolerated through use of shoulder and elbow exercise including rotator cuff and scapular control exercises.

Activation of Primary Muscles Involved

- Concentric submaximal isometric followed by submaximal isotonic progressive resistive exercises with light weight or bands. Start exercises such as wrist extensor muscles by initiating strengthening with isometrics, which if tolerated can be followed by isotonic movements through a safe range of motion for wrist extension.
- Exercises done in cardinal planes. For example, starting isotonic exercises in frontal plane only versus using total arm movements that might incorporate multiple planes of movement of the forearm.

TIMELINE14-1: **Nonoperative Rehabilitation of Forearm Tendinitis** (Continued)

PHASE III (weeks 4 to 6)	PHASE IV (weeks 6 to 12)
• D/C sling, splint or brace • PT modalities as needed • AROM, AAROM, PROM—full • Mobilizations as needed • Trunk and core exercises as tolerated • TBS/TAS activities as recommended and tolerated • Rotator cuff exercises—PREs • Scapular exercises—PREs • "Plyometric-like" exercises • Light weight, bilateral progressing to unilateral • Functional exercises (90/90 shoulder) for throwers • Putty exercises • Gripping exercises • Rice bucket exercises • Pushing and pulling-type exercises • Wrist flexion/extension, and pronation and supination PREs	• AROM, AAROM, PROM full • TBS/TAS/TLS activities as recommended and tolerated • Mobilizations as needed • Trunk and core exercise as tolerated • Rotator cuff exercises—PREs • Scapular exercises—PREs • Plyometric exercises • Functional exercises • PNF exercises • Progress CKC exercises • Sports progression as tolerated

- Putty exercises
- Gripping (ball squeeze)
- Rice bucket exercises

Open and Closed Kinetic Chain Exercises

- Place hand wrist on table top and slowly and gently load in various weight-bearing directions.

Techniques to Increase Muscle Strength, Power, and Endurance

- Continue to progress total arm strength by working proximal musculature. Ensure proper proximal muscle control by working elbow flexors, extensors, glenohumeral, and scapular shoulder muscles.
- Mild symptoms may occur and be alright as long as they do not persist or worsen.

Neuromuscular Dynamic Stability Exercises

- Increase exercise intensity, working on enhancing control during tendon loading.
- Gradually control intensity and duration of exercises.

Functional Exercises

- Grasping, pushing, and pulling motions
- Holding sports/vocational equipment for short durations in effort to build endurance

Milestones for Progression to the Next Phase

- No swelling
- No pain
- Full range of motion
- No loss of sensation
- 4/5 manual muscle test of affected muscles
- Prepare elbow for advanced activity

Phase III (weeks 4 to 6)

Management of Pain and Swelling

- As described previously if pain/swelling continues

Techniques for Progressive Increase in Range of Motion

Manual Therapy Techniques

- As described previously if needed
- If limitations of motion are capsular (joint restrictions) in nature, can begin joint mobilization techniques to restore normal joint arthrokinematics

Soft Tissue Techniques

- As described previously if needed
- Continue deep tissue massage as needed for muscle spasm.

Stretching and Flexibility Techniques for the Musculotendinous Unit

- As described previously if needed
- Should be able to tolerate gentle stretching now without re-exacerbation.

Other Therapeutic Exercises

- Continue trunk/core strengthening with emphasis on requirements for activities of sports or vocation
- Continued cardiovascular conditioning
- Continued total arm strength as tolerated

Activation of Primary Muscles Involved

- Submaximal isotonic progressive resistive exercises with light weight or bands. Concentric or eccentric wrist extension exercises with 3-lb weights or red resistance band, three sets of 20 repetitions.
- Begin eccentric strengthening to promote higher load tolerance to tendon. Progressing to eccentric only exercises with 4-lb weights or green resistance band three sets of 20 repetitions.

Open and Closed Kinetic Chain Exercises

- Progressively load upper extremity in more provocative patterns.
- Start leaning on wall, to bilateral upper extremity in quadruped, to unilateral extremity in tripod.

Techniques to Increase Muscle Strength, Power, and Endurance

- Increase strength and endurance as tolerated by modulating dosage of exercises as appropriate for activities of daily living and sports. Depending on specific needs, patient may require more of a strengthening training load, including increased resistance and higher repetitions, but others may need more endurance by manipulating to lower resistance but higher repetitions.

Plyometrics

- Gentle plyometric "type" exercises with light weights, bilaterally progressing to unilaterally
- Bilateral chest pass into PlyoBack device, throwing and catching chest height with two hands, light weight. When this becomes easier, athlete can progress to unilateral pass to PlyoBack device.

Functional Exercises

- Incorporation of more functional movement–specific tasks (D2 flexion/extension patterns for shoulder while gripping band for forearm exercise; swinging hammer without full-weight hammer head)

Sport-Specific Exercises

- Incorporation of more functional movement–specific tasks (D2 flexion/extension patterns for shoulder while

gripping band for forearm exercise); swinging sport-specific instruments
- Light swinging of tennis racquet
- Assess racquet weight, size, fit, length, structure
- Gentle throwing/hitting motions
- Motions starting may be initially done without ball (baseball, softball) or racquet (tennis), progressing to motions with equipment.
- Gentle golfing motions can be started with swinging 50% effort progressing to 75% over several visits or weeks.
- Use of elastic tubing around tennis racquet while moving into positions of cocking for forehand and backhand tennis strokes.

Milestones for Progression to the Next Phase

- No swelling
- No pain
- Full range of motion
- No loss of sensation
- 5/5 strength of affected muscles
- Prepare for full return of activities

Phase IV (weeks 6 to 12)

Management of Pain and Swelling

- As described previously if pain/swelling continues

Techniques for Progressive Increase in Range of Motion

Manual Therapy Techniques

- As described previously if needed
- If limitation of motion are capsular (joint restrictions) in nature, can begin joint mobilization

Soft Tissue Techniques

- As described previously if needed

Stretching and Flexibility Techniques for the Musculotendinous Unit

- As described previously if needed
- Should be able to tolerate more progressive stretching now without re-exacerbation

Other Therapeutic Exercises

- Continue trunk/core strengthening with emphasis on requirements for activities of sports or vocation
- Continued cardiovascular conditioning
- Continued total arm strength as tolerated using larger movements and proximal musculature such as during upper body ergometer or pushup progression

Activation of Primary Muscles Involved

- Maximal isotonic progressive resistive exercises with light weight or bands. This is done through the use of heavier resistance with use of weights or bands for decreased number of repetitions in order to gain physical strength.
- Continuance of program to maintain or increase strength and or endurance as needed for full, unrestricted return to activity. The program should be continued until the patient has full, unrestricted strength and the ability to return to previous activity.

Open and Closed Kinetic Chain Exercises

- Progression as described previously
- Increased resistance from heavier dumbbells, thicker resistance bands, or more provocative position such as overhead movements or movements away from body. Can also add loaded exercises such as pushups with feet elevated 12 inches or pushups with clap between.

Techniques to Increase Muscle Strength, Power, and Endurance

- Increase strength and endurance as tolerated by modulating dosage of exercises as appropriate for activities of daily living and sports.
- Increase speed and or resistance with exercises where appropriate to allow increased power during activities. Use of light tubing while swinging bat or racquet in simulated game type situations.

Neuromuscular Dynamic Stability Exercises

Progressive increase in dynamic stability drills for entire upper extremity.

Plyometrics

- If tolerated "gentle plyometric-type" exercises in previous stage can progress to heavier weights and to unilateral exercises
- Increase weight of Plyoball to add resistance and overload. Additionally Plyoball can be done in more provocative positions such as overhead motions.

Functional Exercises

- Incorporation of more functional movement–specific tasks (e.g., use of actual hammer or saw)
- All done in slow progression from 50% to 75% to 100% effort
- One set of 25 repetitions progressing to up to three sets of 25 repetitions at each intensity level

Sport-Specific Exercises

- Incorporation of more functional movement-specific tasks (e.g., use of throwing baseball, football, swinging racquet or bat)
- All done in slow progression from 50% to 75% to 100% effort
- One set of 25 repetitions progressing to up to three sets of 25 repetitions at each intensity level

Milestones for Progression to Advanced Sport-Specific Training and Conditioning

- No swelling
- No pain
- Full range of motion
- No loss of sensation
- 5/5 Strength of affected muscles

Criteria for Abandoning Nonoperative Treatment and Proceeding to Surgery or More Intensive Intervention

- Continued pain
- Continued swelling
- Continued numbness and tingling
- No return of strength
- Progression of symptoms

Tips and Guidelines for Transitioning to Performance Enhancement

- Ensure that symptoms do not return.
- Gradual slow progression is always more reliable than a rushed approach to return to function without creating setbacks.

Performance Enhancement and Beyond Rehabilitation: Training/Trainer and Optimization of Athletic Performance

- Gradual progression to full return of functional activities involving total body movement patterns with no return of symptoms
- Hitting or serving progressions. Use of weight equipment or bands or cables to challenge muscular control of trunk and full body

Specific Criteria for Return to Sports Participation: Tests and Measurements

- No swelling
- No pain
- Full range of motion
- No loss of sensation
- 5/5 strength of affected muscles

Evidence

Batteson R, Hammond A, Burke F, et al: The de Quervain's screening tool: Validity and reliability of a measure to support clinical diagnosis and management. *Musculoskeletal Care* 6(3):168–180, 2008.

This study was performed in an outpatient hand unit of a district hospital. The study was done to provide evidence for content and construct validity and test-retest reliability and interrater reliability of a de Quervain's syndrome screening tool (DQST). Sample of convenience of 59 patients with de Quervain's were recruited. Additionally, 16 with osteoarthritis of the carpometacarpal joint and 18 with carpal tunnel syndrome were recruited. Diagnostic criteria were initially generated from literature review and content validity was established by seven expert doctors with interest in upper limb. The DQST was tested on those with de Quervain's syndrome. Construct validity was tested with all patients. The median score was five out of a possible seven diagnostic criteria. Interrater reliability was excellent. Test-retest reliability was good. Sensitivity and specificity demonstrated that the DQST discriminated between pathologies. (Level IV evidence)

Blanchette MA, Normand MC: Augmented soft tissue mobilization vs natural history in the treatment of lateral epicondylitis: A pilot study. *J Manipulative Physiol Ther* 34(2):123–130, 2011.

Randomized clinical trial of 27 subjects with lateral epicondylitis. Subjects were randomly placed into one of two groups. The experimental group (n = 15) received augmented soft tissue mobilization (ASTYM) twice a week for 5 weeks. Control group received advice on the natural evolution of pathology, ergonomics and stretching exercises. Outcomes were assessed at baseline and after 6 weeks and 3 months using visual analog scale (VAS). Function was tested with pain-free grip strength at baseline and after 6 weeks. Both groups improved in pain-free grip strength, VAS, and patient-reported outcomes. (Level II evidence)

Kaneko S, Takasaki H: Forearm pain, diagnosed as intersection syndrome managed by taping: A case series. *J Orthop Sports Phys Ther* 41(7):514–519, 2011.

Case series of five patients who were treated for intersection syndrome by the use of taping. Therapist used nonstretch sports tape with ulnarly directed tension across dorsal aspect of forearm. Crepitus was completely eliminated. Disability identified by disability/symptom subscale of DASH decreased at 3-week follow-up, and reduction was maintained at 4-week and 1-year follow-ups. (Level IV evidence)

Tagliafico AS, Ameri P, Michaud J, et al: Wrist injuries in nonprofessional tennis players: Relationships with different grips. *Am J Sports Med* 37(4):760–767, 2009.

A cross-sectional study that evaluated 370 nonprofessional division III and IV tennis players to determine if the use of different grips determined a pattern of wrist injuries. Screening of players consisted of a questionnaire to investigate wrist injuries. Medical records of players who reported a wrist injury were reviewed. Fifty participants incurred injuries. Ulnar-sided wrist injuries were more common. These were associated with Western or semi-Western grips, whereas the radial side injuries were associated with the Eastern grip. No differences were observed regarding body mass index, years of practice, weekly hours of training, racket weight, and strings. (Level III evidence)

Tyler T, Thomas GC, Nicholas SJ, et al: Addition of isolated wrist extensor eccentric exercise to standard treatment of chronic lateral epicondylosis: A prospective randomized trial. *J Shoulder Elbow Surg* 19:917–922, 2010.

Twenty-one patients with chronic unilateral epicondylosis were randomly placed into either an eccentric training

group (n = 11) or a standard treatment group (n = 10). Outcomes were the Disability of Arm Shoulder and Hand Questionnaire, visual analog scale, tenderness, and wrist and middle finger extension. Measurements were taken at baseline and end of treatment. Improvements in all variables were greater for the eccentric training group. (Level II evidence)

Multiple Choice Questions

QUESTION 1. In which phase may forearm muscle submaximal isotonic strengthening begin following a conservative approach to lateral epicondylitis?

A. Phase I
B. Phase II
C. Phase III
D. Phase IV

QUESTION 2. During late phases of rehabilitation for tendinitis, what percentage of full effort should the patient use while swinging a tennis racquet during a gradual progression or return to activity phase of rehabilitation?

A. 25
B. 50
C. 75
D. 100

QUESTION 3. Which of the following rehabilitation concepts would apply to a 22-year-old college pitcher with chronic ulnar nerve compression caused by attenuation of the medial collateral ligament of the elbow?

A. Cardiovascular conditioning
B. Total arm strengthening
C. Total body strengthening
D. All of the above

QUESTION 4. A 15-year-old male golfer is being seen for medial epicondylitis. He has been slowly improving to the point where he wants to start swinging his golf club again. What criteria should be met before he begins a return to golfing program?

A. 80% return of flexibility
B. Less than 4/10 complaint of pain
C. 5/5 strength of affected muscles
D. Minimal forearm swelling after therapy

QUESTION 5. When treating a patient with a limitation of passive motion of elbow extension, when would it be appropriate to use a contract and relax technique versus a joint mobilization technique to the elbow?

A. Motion limitation is from contractile tissue.
B. Stretching is extremely painful.
C. No response to passive overpressure
D. Motion limitation is inert tissue.

Answer Key

QUESTION 1. Correct answer: **B** (see Phase II)

QUESTION 2. Correct answer: **A** Almost all progressions start with a slow and easy progression at minimal levels to ensure success at lower levels before progression to higher levels. (see Phase IV)

QUESTION 3. Correct answer: **D** (see all phases of rehabilitation)

QUESTION 4. Correct answer: **C** He should have return of full strength. (see Phase IV)

QUESTION 5. Correct answer: **A** Motion limitation is contractile tissue. Using a joint mobilization technique would be better for someone with a capsular limitation (inert tissue) to motion.

Chapter 15

Triangular Fibrocartilage Complex Injuries

INTRODUCTION

Sidney M. Jacoby, MD, Paul A. Sibley, DO, and Leo T. Kroonen, MD

Epidemiology

Age

- Acute tears are most common in the active individual during the second and third decades of life.
- Degenerative tears begin in the third decade of life, with increasing frequency and severity with each passing decade.
- No completely normal triangular fibrocartilage complex (TFCC) after seventh decade, based on a cadaveric study

Sex

- Predominantly males but is most often sport specific, with a preponderance in athletic individuals

Sport/Position

- Most common in athletes who grip bats, clubs, sticks, etc. In particular, baseball players, golfers, racquet sports, hockey, gymnastics, boxing, pole-vaulting
- No position-specific factors; however, tears commonly occur in dominant wrist

Pathophysiology

Intrinsic Factors

- TFCC composed of a confluence of soft-tissue elements that surround and stabilize the distal radioulnar joint (DRUJ)
- Wedge-shaped disc of fibrocartilage with thick cartilaginous attachments to sigmoid notch of radius
- Very little stability provided by bony elements
- Anatomy (Figures 15-1 and 15-2)
  - Dorsal and volar radioulnar ligament (main stabilizers of DRUJ)
    - Superficial attachment to mid-point of styloid
    - Deep attachment to the fovea
  - Central articular disc
    - Extends from sigmoid notch of radius to its insertion at the base of the ulnar styloid

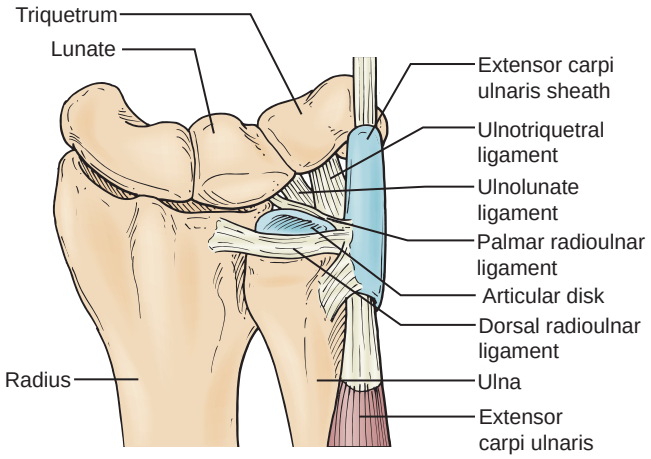

FIGURE 15-1. Schematic components of the triangular fibrocartilage complex. R, radius; U, ulna; ECU, extensor carpi ulnaris; DRUL, dorsal radioulnar ligament; PRUL, palmar radioulnar ligament; L, lunate; T, triquetrum; UL, ulnolunate ligament; UT, ulnotriquetral ligament.

FIGURE 15-2. Meniscus homologue is an irregularly shaped soft tissue structure that variably fills the space between the ulnar capsule, disk, and proximal aspect of the triquetrum. L, lunate; R, radius; Tq, triquetrum; U, ulna; 1, articular disk of triangular fibrocartilage; 2, meniscus homologue. *(From Adams BD: Distal radioulnar joint instability. In Wolfe SW, Pederson WC, Hotchkiss RN, Kozin SH, editors: Green's operative hand surgery, 6th ed, Philadelphia, 2010, Elsevier, Figure 16-7.)*

- Meniscus homologue
  - Function is ill-defined
  - Vascularized tissue between the ulnar capsule, TFCC, and triquetrum
- Ulnar collateral ligament
- Extensor carpi ulnaris (ECU) subsheath
  - TFCC acts as a pulley for the ECU tendon
- Ulnocarpal ligament complex
  - Lunocapitate (LC), ulnolunate (UL) and ulnotriquetral (UT) ligaments
- Blood supply (Figure 15-3)
  - Peripheral 10% to 40% is well vascularized (ulnar more than radial aspect)
    - Dorsal and palmar branches of anterior interosseous artery
    - Dorsal and palmar radiocarpal branches of ulnar artery
  - Central portion is avascular
- Ulnar positivity (positive ulnar variance)
  - Normal axial loading has 20% of load through ulna, with 80% through radius
  - +2.5 mm ulnar positivity can increase load through the ulna to 40%
  - Positivity increases with pronation and grip

Extrinsic Factors

- Power drills, whereby the drill rotates the wrist instead of the drill-bit
- Rotational torque such as those that occur with athletics or a fall on outstretched wrist
- Sports activities that involve high level of grip activities

Traumatic Factors

- Palmer Type I (traumatic)
  - Mechanism
  - Sudden, rotational traumatic event
  - Racquet sports with sudden, abrupt supination
  - Most common is fall on extended wrist with forearm pronation
  - Traction injury to ulnar side of wrist
  - Distal radius fractures
- Palmer Type II (degenerative)
  - Associated with positive ulnar variance

Classic Pathological Findings

- Palmer Classification (Figure 15-4), Type I (traumatic)
  - IA: isolated central perforation or tear, no instability
    - Pain, mechanical clicking
  - IB: peripheral tear at base of ulnar styloid (with or without ulnar styloid fracture), mild DRUJ instability, may have ECU instability
    - Painful forearm rotation

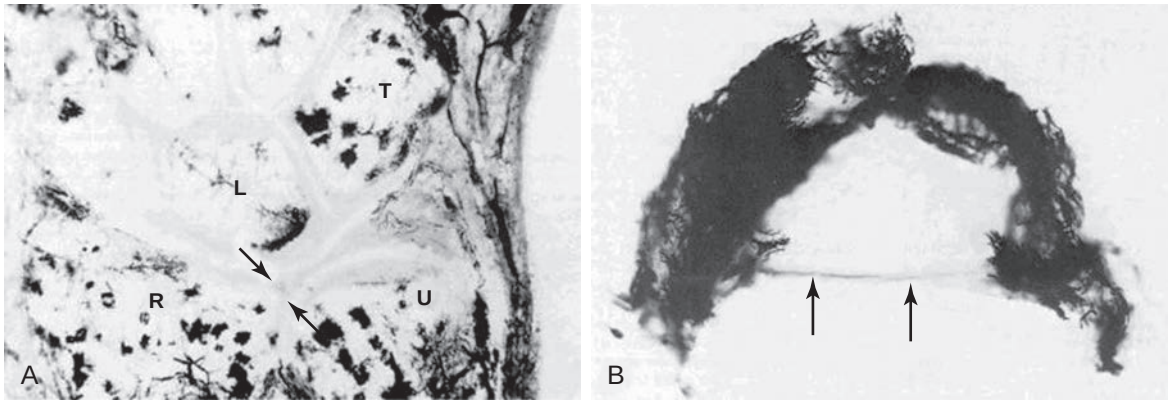

FIGURE 15-3. TFCC is well vascularized in its periphery, whereas only the outer 15% of the disk has vascular penetration. *Arrows* in **A** and **B** identify avascular regions of TFCC at its attachment to radius. **A,** Coronal section through wrist. **B,** Axial view of TFCC. L, lunate; R, radius; T, triquetrum; U, ulna. *(From Adams BD: Distal radioulnar joint instability. In Wolfe SW, Pederson WC, Hotchkiss RN, Kozin SH, editors: Green's operative hand surgery, 6th ed, Philadelphia, 2010, Elsevier, Figure 16-8.)*

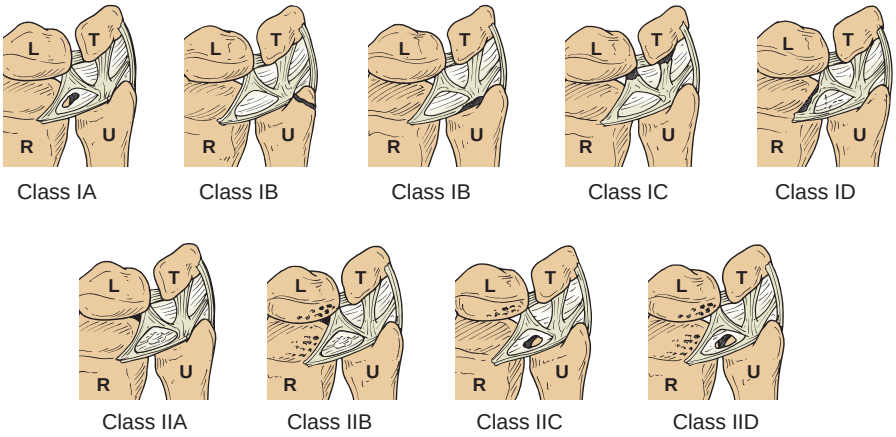

FIGURE 15-4. Palmer's classification separates TFCC lesions into two broad categories: traumatic (class IA-D) and degenerative (class IIA-E). See text for descriptions. *(Redrawn from Palmer AK: Triangular fibrocartilage complex lesions: a classification, J Hand Surg [Am] 14:594–606, 1989.)*

- IC: distal avulsion of origin of ulnar extrinsic ligaments (UL and LT ligaments)
  - Least common
  - Painful rotation
  - May be associated with IB tear
- ID: radial detachment of the TFCC from the sigmoid notch of the distal radius
  - May be associated with distal radius fracture
  - May include both radioulnar ligaments
  - Often in the avascular zone
- Palmer Type II (degenerative [developmental or acquired] with ulnar impaction)
  - IIA: TFCC wear and thinning without perforation, tear, or chondromalacia
  - IIB: TFCC wear with lunate and/or ulnar head chondromalacia
  - IIC: TFCC perforation with lunate chondromalacia
  - IID: TFCC perforation with ulna and/or lunate chondromalacia and LT ligament injury but without carpal instability
    - No volar intercalated segment instability (VISI)
  - IIE: TFCC perforation with arthritic changes involving ulnocarpal and DRUJ (Figure 15-5)
    - LT ligament injury

Clinical Presentation

History

- Traumatic
  - Fall on outstretched, pronated hand
  - Acute or chronic rotational wrist injury
  - Forced ulnar deviation
  - Radial deviation traction injury
  - Ulnar-sided wrist pain often accompanied with clicking
  - Baseball players, golfers have pain during hitting
- Nontraumatic
  - Pain with activities that require forearm pronation
    - Gripping and twisting doorknobs, trying to open jars, or turning a door key is often painful.
    - Deep, aching discomfort
    - May be associated with mechanical elements of locking, clicking, or catching
    - Firm gripping activities are painful, especially in patients with dynamic ulnar impaction.

Physical Examination

Abnormal Findings

- Examine patient where she or he can rest both elbows on a flat surface with hands toward ceiling
  - Enables examiner to access forearm rotation with the wrist in any position and compare to uninvolved wrist

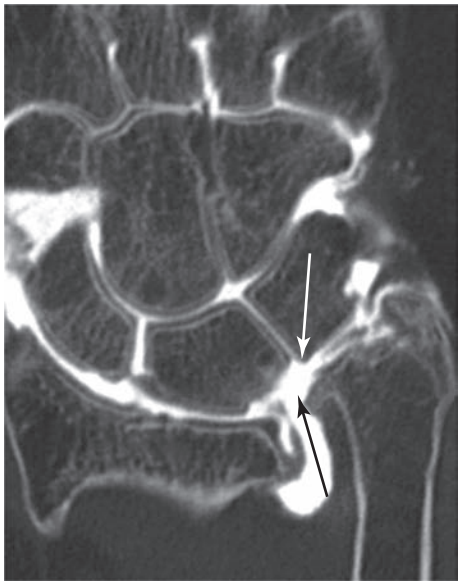

FIGURE 15-5. Palmer class IIE lesion (ulnocarpal osteoarthritis). Ulnocarpal impaction with positive ulnar variance. The TFCC is completely absent, and large communication between ulnocarpal and distal radioulnar joints is seen in this Multidetector CT arthrography coronal view obtained after single- compartment injection (black arrow). The lunotriquetral ligament is completely disrupted (*white arrow*), and communication between the midcarpal and ulnocarpal joints is also seen. No articular cartilage is observed at the ulnar aspect of lunate or at the radial aspects of the ulnar head and triquetrum. Subchondral bone attrition is visible at ulnar aspect of lunate, and a large osteophyte is seen at ulnar head. *(From Crema MD, Marra MD, Guermazi A, et al: MDCT arthrography features of ulnocarpal impaction syndrome. AJR Am J Roentgenol 193(5):1376–1381, 2009.)*

FIGURE 15-6. Tenderness at the ulnar fovea. *(Courtesy of Sidney Jacoby, MD.)*

FIGURE 15-8. TFCC grind test. *(Courtesy of Sidney Jacoby, MD.)*

- Inspect
  - Usually no visible deformity
  - Subtle fullness or swelling of ulnar wrist
  - Visible swelling may be evident in patients with synovitis of ulnocarpal joint
- Palpate (most important)
  - Localize area of maximal tenderness
  - Also palpate pisotriquetral articulation, lunotriquetral articulation, soft tissue elements (ECU, dorsal sensory branch of ulnar nerve)
  - Point foveal tenderness located at base of ulnar snuffbox between triquetrum and ulnar styloid (Figure 15-6)
    - Most common finding
    - Soft spot on ulnar side between FCU and ECU
    - Palpate dorsal TFCC with pronation, volar portion with supination
- Provocative maneuvers
  - Assess volar/dorsal stability of DRUJ with shuck test (Figure 15-7)
    - Compare to uninvolved side
    - Piano key sign
      - Prominent dorsal distal ulna with full pronation
  - Ulnocarpal stress test (rotation with ulnar deviation) (Figure 15-8)
    - Pain suggests ulnocarpal impaction
  - "Press test"
    - Pushing up on chair rails from a seated to a standing position elicits pain (Figure 15-9)
  - Rule out coexisting pisotriquetral or lunotriquetral abnormalities
  - ECU subluxation
    - Tendon should be stable within its groove
    - Forearm rotation with wrist flexion will elicit instability
  - Pain elicited with ulnar deviation (TFCC compression) or radial deviation (TFCC tension)
  - Decreased range of motion

Pertinent Normal Findings

- Radial snuffbox and radial wrist often nontender

Imaging

- Radiographs—initial screening tool
  - Neutral rotation PA is usually best
  - Usually negative
    - DRUJ
    - Ulnar variance (Figure 15-10)
      - Beware of ulnar positivity (high incidence of ulnar impaction and TFCC tears)

FIGURE 15-7. Shuck test. *(Courtesy of Sidney Jacoby, MD.)*

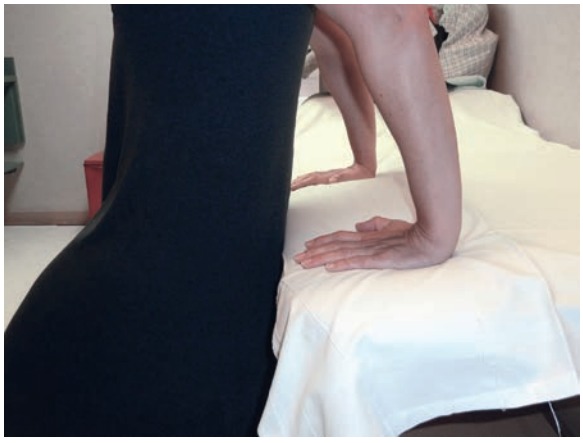

FIGURE 15-9. Press test. *(Courtesy of Sidney Jacoby, MD.)*

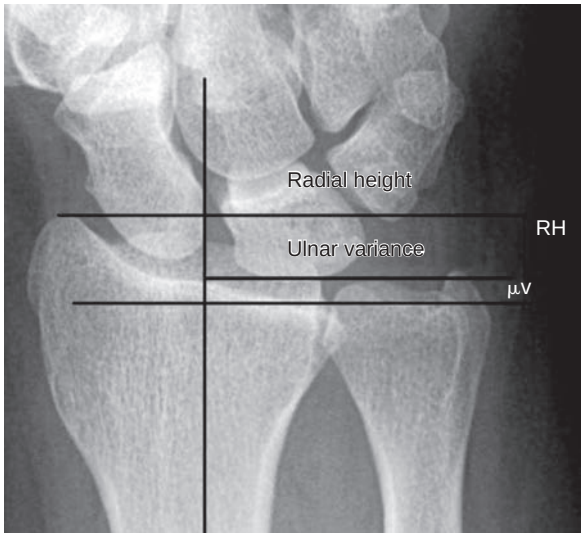

FIGURE 15-10. AP radiograph demonstrating measurement of ulnar variance. *(Courtesy of Sidney Jacoby, MD.)*

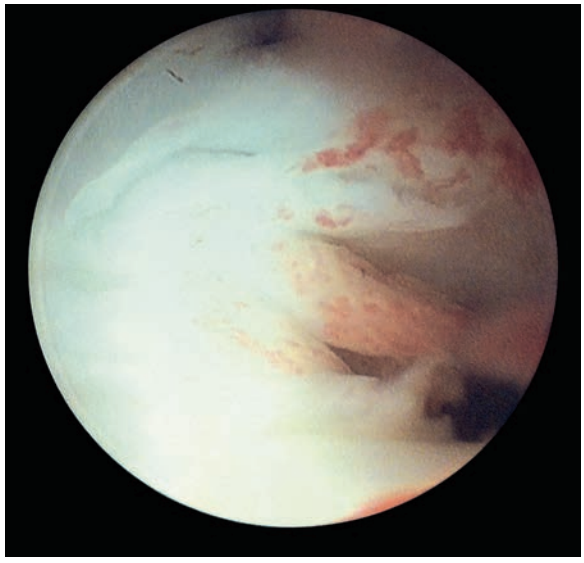

FIGURE 15-12. View of peripheral TFCC tear with ulnar-sided synovitis. *(Courtesy of Sidney Jacoby, MD.)*

  - Dynamic PA grip view with forearm pronation also helpful to assess dynamic ulnar impaction
  - Assess volar ulnar portion of lunate for lucency often seen in those with chronic ulnar impaction

- If diagnosis still unclear order advanced imaging
  - MRI with or without gadolinium-enhanced arthrogram—has largely replaced plain arthrography (Figure 15-11)
    - Tears and signal changes in the ulnar aspect of the lunate
    - Consistent with ulnocarpal impaction
    - Asymptomatic patients may have pathology, so correlate with history and physical exam
    - Helps distinguish impaction lesions from osteonecrosis
  - Plain arthrography—joint injection shows extravasation
    - Sensitivity 74% to 100%
  - Other studies: three-compartment cinearthrography, plain tomography, CT, CT arthrogram
    - Less diagnostic compared with MR arthrogram
  - Arthroscopy—gold standard for visualizing size and stability of tear (Figures 15-12 and 15-13)
    - Diagnostic and therapeutic
    - Detects concomitant ligament or chondral injuries
    - Detects peripheral vs. central tears
    - Identification and treatment of loose bodies
    - Types of treatment:
      - Repair, debridement, and tissue ablation

FIGURE 15-11. MRI of an ulnar-sided peripheral tear of the TFCC demonstrated by a high intensity signal on a T_2-weighted image (*red arrow*). *(Courtesy of Sidney Jacoby, MD.)*

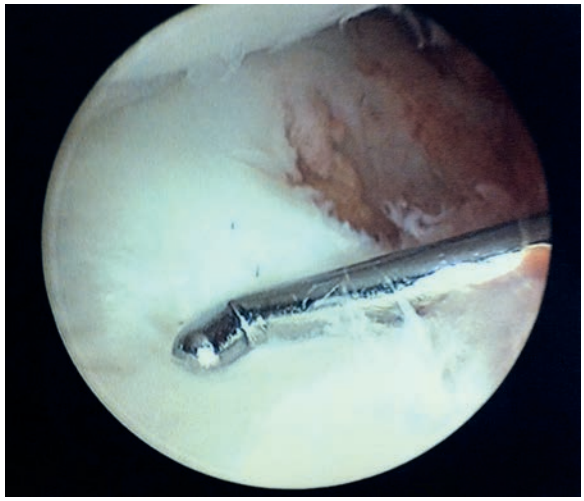

FIGURE 15-13. Probe entering from 6R portal revealing TFCC tear and lack of normal "trampoline" effect. *(Courtesy of Sidney Jacoby, MD.)*

Differential Diagnosis

- Extraarticular
  - ECU tendonitis
  - ECU instability
  - Neuritis of dorsal sensory branch of ulnar nerve ("cyclist's palsy")
  - Ulnar nerve entrapment at Guyon's canal
  - Hypothenar hammer syndrome
  - Osseous
    - Hamate fracture
    - Pisiform fracture
    - Ulnar styloid fracture
    - Fracture of base of fifth metacarpal
- Periarticular
  - TFCC tears
  - Ulnocarpal impaction
  - Impingement
  - ECU subsheath
  - Disc-carpal ligament injuries
  - LT ligament injuries
  - Synovitis
- Articular
  - DRUJ arthrosis
  - DRUJ instability
  - LT arthrosis
  - CMC arthrosis
  - PT arthrosis
  - Midcarpal instability
  - Loose bodies
  - Ulnar chondrosis
  - Lunate chondrosis
  - Kienbock's disease

Treatment

Nonoperative Management

- Type I with no instability
  - Long arm immobilization with forearm in a semi-supinated position, slight flexion, and slight ulnar deviation (Figure 15-14)
  - NSAID's, ice
  - Repeat exam in 4 to 6 weeks
- Type I with instability and concentric reduction of DRUJ and ulnocarpal relationship
  - Long arm cast in full supination for 6 weeks followed by long arm splinting for 6 weeks

FIGURE 15-14. Muenster splint which prevents forearm rotation. *(Courtesy of Sidney Jacoby, MD.)*

- Type II (initial)
  - Activity modification and elimination of offending activities
  - Long arm splinting to control rotation
  - NSAIDs
  - Elastic compression strap in those who work and may find the long arm splint cumbersome and impractical
  - Steroid injections (diagnostic and therapeutic)
    - Usually temporary relief
    - Useful when associated with synovitis

Guidelines for Choosing Among Nonoperative Treatments

- Start with activity modification and NSAIDs
- Steroid injections if continued pain
- Monitor pain while immobilized to continue nonsurgical treatment vs. pursuing surgery
  - Be more aggressive with high-level athletes

Surgical Indications

- Absolute
  - Failure of nonoperative treatment (several months of wrist splinting and activity modification)
    - Can be more aggressive with higher-level athletes (waiting as soon as 2 to 3 weeks if conservative measures fail)
  - TFCC instability with malreduced DRUJ and ulnocarpal joint
  - Congruent reduction, but with dorsal instability with 30° supination
- Relative
  - TFCC instability with reduced DRUJ and ulnocarpal joint
- Palmer classification grade: see below

Aspects of History, Demographics, or Exam Findings that Affect Choice of Treatment

- Based primarily on the severity of ulnar sided wrist pain and stability of the TFCC
- Age
- Activity level/level of competition
- Occupation
- Time since injury

Aspects of Clinical Decision Making When Surgery Is Indicated

- After trying several months of wrist splinting and activity modification without a significant result
- Type IA
  - Arthroscopic debridement of unstable portion
    - Leave at least 2 mm peripherally to avoid instability
- Type IB (Figure 15-15)
  - Arthroscopic repair of TFCC tear (all inside vs. outside-in); if ulnar styloid non-united with tear, need open procedure
    - Pathognomonic finding is loss of "trampoline" tension effect as determined with a probe

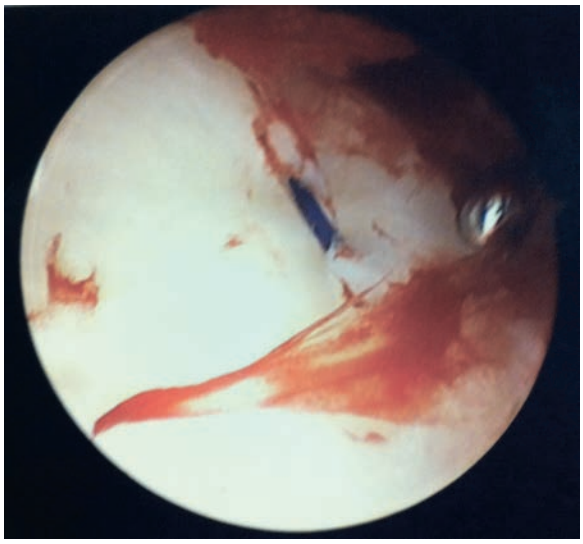

FIGURE 15-15. TFCC repair with restoration of normal "trampoline" effect and healthy bleeding after debridement of peripheral rim and repair of large tear following release of tourniquet. *(Courtesy of Sidney Jacoby, MD.)*

- Type IC
  - Arthroscopic reefing or tenodesis procedure
  - Open repair for large defect
    - Can augment with a strip of FCU
- Type ID
  - Open radial-sided TFCC repair with Munster cast for 4 weeks
- Type II
  - Decompression of ulnocarpal articulation
  - Correction of concomitant positive ulnar variance recommended
  - IIA/IIB
    - Arthroscopic evaluation and synovectomy
    - Open ulnar diaphyseal shortening
      - Indicated if ulnar positive variance greater than 2 mm
      - Advantage of effectively tightening the ulnocarpal ligaments and is favored with LT instability is present
  - IIC
    - Debridement of central tear
    - Arthroscopic wafer procedure (can be performed through a central tear) vs. open ulnar shortening osteotomy
      - Only if ulnar positive variance less than 2 mm
  - IID
    - Debridement and arthroscopic wafer
    - Open ulnar shortening if LT ligament unstable
    - Limited open ulnar head resection (Bowers' hemiarthroplasty)
      - Leads to creation of proximal pseudoarthrosis at the level of the ulnar neck
      - TFCC needs to be intact or reconstructable
  - IIE
    - Ulnar shortening osteotomy with LT debridement
    - LT pinning if unstable after ulnar shortening
    - Sauve-Kapandji procedure (DRUJ fusion with proximal ulnar pseudoarthrosis)
    - Darrach procedure (distal ulna resection)
      - Avoided because of problems with distal ulnar stump instability and radio-ulnar impingement (convergence)

Evidence

Anderson ML, Larson AN, Moran SL, et al: Clinical comparison of arthroscopic versus open repair of triangular fibrocartilage complex tears. *J Hand Surg [Am]* 33(5):675–682, 2008.

In a study of 75 patients with TFCC repair by arthroscopic or open technique between 1997 and 2006, Anderson et al. found that there was no statistical difference in clinical outcome for arthroscopic and open techniques for TFCC repair. They did note an increased rate of postoperative superficial ulnar pain in patients who underwent open repair (14 of 39 patients with open technique versus 8 of 36 patients with arthroscopy). Females had a statistically significant higher rate of reoperation. (Level III evidence)

Chen AC, Hsu KY, Chang CH, et al: Arthroscopic suture repair of peripheral tears of triangular fibrocartilage complex using a volar portal. *Arthroscopy* 21(11):1406, 2005.

Surgical repair of a Palmer type IB TFCC tear can be difficult using conventional dorsal portals and it may need special repair kits. The authors describe an arthroscopic technique using an additional volar portal that allows quick access and a secure purchase of peripheral TFCC tears as well as a distinct approach to dorsal wrist structures. (Level V evidence)

Hulsizer D, Weiss AP, Akelman E: Ulna-shortening osteotomy after failed arthroscopic debridement of the triangular fibrocartilage complex. *J Hand Surg [Am]* 22(4):694–698, 1997.

Over a 4-year period, 160 wrist arthroscopies were performed at 1 institution. Ninety-seven patients had central or nondetached ulnar peripheral tears of the TFCC and underwent arthroscopic debridement. Thirteen of the 97 had persistent pain in the TFCC region for more than 3 months after surgery. At an average of 8 months after failed arthroscopic debridement of the TFCC, all 13 patients underwent a 2-mm ulna-shortening osteotomy with fixation by a 3.5-mm 6-hole dynamic compression plate. At follow-up examination (average 2.3 years), 12 of the 13 had complete relief of pain at the ulnar side of the wrist. There was no statistically significant difference between the arthroscopic debridement alone cohort and the arthroscopy/ulna-shortening subgroup relative to ulnar variance or incidence of associated LT ligament tears. On the basis of these findings the authors recommend a 2-mm ulna-shortening osteotomy for patients whose previous arthroscopic debridement for central or nondetached peripheral TFCC was unsuccessful in eliminating ulnar-sided wrist pain. (Level IV evidence)

McAdams TR, Swan J, Yao J: Arthroscopic treatment of triangular fibrocartilage wrist injuries in the athlete. *Am J Sports Med* 37(2):291–297, 2009.

This case series looked at 16 athletes (mean age 23) with TFC injuries treated arthroscopically. Repair was performed for unstable tears, whereas all others underwent debridement alone. Pre and postsurgery mini-DASH scores and clinical evaluation demonstrated that arthroscopic debridement or repair provides predictable pain relief and return to play in competitive athletes. Return to play may be delayed in athletes with other concomitant ulnar-sided wrist injuries. (Level IV evidence)

Osterman AL, Terrill RG: Arthroscopic treatment of TFCC lesions. *Hand Clin* 7(2):277–281, 1991.

This review followed 133 patients looked at the natural history of symptomatic tears. Traumatic tears with neutral ulnar variance did not worsen over time, and one third of patients were asymptomatic at 9.5 years of follow-up. In persons with traumatic tears with ulnar positive variance, two thirds of patients worsened over time both symptomatically and radiologically. (Level IV evidence)

Papapetropoulos PA, Wartinbee DA, Richard MJ, et al: Management of peripheral fibrocartilage complex tears in the ulnar positive patient: Arthroscopic repair versus ulnar shortening osteotomy. *J Hand Surg [Am]* 35(10):1607–1613, 2010.

This retrospective review of prospectively collected data of 51 patients with Palmer 1B tears and ulnar positivity compared arthroscopic repair to ulnar shortening osteotomy (USO). At final follow-up, they found no statistically significant difference between the repair and USO groups with regard to range of motion. Likewise, there was no significant difference in grip strength, DASH scores, or visual analog scores. When analyzing each cohort individually, both groups improved significantly after surgery with regard to DASH score, visual analog scores, and wrist extension. There was also a trend toward improved motion in all other directions except for an insignificant decrease in postoperative pronation in the repair group. (Level III evidence)

Reiter A, Wolf MB, Schmid U, et al: Arthroscopic repair of Palmer 1B triangular fibrocartilage complex tears. *Arthroscopy* 24(11):1244–1250, 2008.

This was a retrospective study of 46 patients who underwent arthroscopic repair of Palmer class IB tears to determine patients' functional and subjective outcomes, as well as whether clinical outcomes were related to ulnar length. Good to excellent results were achieved in 63% of the patients, including increased range of motion and grip strength and pain relief. Ulnar neutral or positive variance was not a contraindication for repair and did not necessitate simultaneous ulnar shortening. (Level IV evidence)

Slade JF, III, Gillon TJ: Osteochondral shortening osteotomy for the treatment of ulnar impaction syndrome: A new technique. *Tech Hand Upper Ext Surg* 11(1):74–82, 2007.

A new technique for ulnar shortening osteotomy is described that preserves the articular surface of the distal ulnar. The osteotomy is secured with headless compression screws and therefore complications associated with plating are avoided. (Level V evidence)

Yao J: All-arthroscopic triangular fibrocartilage complex repair: Safety and biomechanical comparison with a traditional outside-in technique in cadavers. *J Hand Surg [Am]* 34(4):671–676, 2009.

This cadaveric study compared an all-arthroscopic TFCC repair technique with an outside-in technique in 10 matched pairs of fresh-frozen cadaveric wrists and found that the all-arthroscopic technique resulted in decreased operative time, reduced postoperative immobilization, and decreased irritation from suture knots below the skin. (Level V evidence)

Multiple-Choice Questions

QUESTION 1. Which of the following is NOT considered part of the TFCC?

A. Meniscus homologue
B. Volar radioulnar ligament
C. FCU tendon sheath
D. Central articular disc

QUESTION 2. A 22-year-old soccer player presents to your office after a fall. He has pain and ulnar-sided catching. He has no tenderness over the ECU tendon. X-rays, including a carpal tunnel view, are normal. The most likely mechanism for his fall is

A. Forearm supination, wrist flexion
B. Forearm supination, wrist extension
C. Forearm pronation, wrist flexion
D. Forearm pronation, wrist extension

QUESTION 3. Which of the following is the gold standard for diagnosing stability of a TFCC tear?

A. Zero rotation PA radiograph
B. MR arthrogram
C. Three compartment cinearthrography
D. Arthroscopy

QUESTION 4. Which of the following should be on your differential for periarticular ulnar-sided wrist pain (besides a TFCC tear)?

A. Ulnar impaction
B. Neuritis of dorsal sensory branch of ulnar nerve
C. Kienbock's disease
D. DRUJ instability

QUESTION 5. Which of the following is an appropriate treatment in a 27-year-old professional athlete who has been diagnosed with a peripheral TFCC tear at the base of the ulnar styloid and an associated ulnar styloid fracture with normal ulnar variance?

A. Debridement alone
B. Arthroscopic versus open outside-in repair
C. Ulnar shortening osteotomy
D. Short arm splint

Answer Key

QUESTION 1. Correct answer: **C** (see Pathophysiology)

QUESTION 2. Correct answer: **D** (see Pathophysiology)

QUESTION 3. Correct answer: **D** (see Clinical Presentation)

QUESTION 4. Correct answer: **A** (see Differential Diagnosis)

QUESTION 5. Correct answer: **B** (see Treatment)

NONOPERATIVE REHABILITATION OF WRIST SPRAINS AND TRIANGULAR FIBROCARTILAGE COMPLEX INJURIES

Roisin T. Dolan, MA, MD, MRCSI, Joseph S. Butler, MA, PhD, MRCSI, Joanne Finn, Grad. Dip. Phys. MCSP, Darragh E. Hynes, MCh FRCSI, and Alexander Y. Shin, MD

GUIDING PRINCIPLES OF NONOPERATIVE REHABILITATION

- In a suspected triangular fibrocartilage complex (TFCC) injury presenting with ulnar-sided wrist pain and normal radiographs, a period of rest, activity modification, ice, splint immobilization for 3 to 6 weeks, nonsteroidal antiinflammatory medications and/or corticosteroid joint injections followed by therapy aimed at restoring normal range, power, endurance, and function may be effective.
- Specific to TFCC injuries, rehabilitation consists of four key phases:
  - The first phase aims to limit further injury, decrease pain, and minimize inflammation and edema.
  - The strength and flexibility of relevant structures are improved throughout the second phase.
  - The third phase targets an improvement in strength, flexibility, proprioception, and endurance until normal activities of daily living can be performed relatively pain free.
  - The final phase focuses on return to sport and prevention of injury with an increase in sport-specific skill, co-ordination and flexibility. This final phase targets the individual needs of the athlete with emphasis on their specific sport.

Phase I (weeks 1–4)

Goals

- To limit further injury through education and activity modification, decrease pain and minimize inflammation and edema, and last, optimize healing through splint immobilization

Protection

- Reduces pain by limiting movements that exacerbate the injury and second, places the wrist in a protective position to aid restoration and maintenance of normal anatomical alignment
- Gripping activities, ulnar deviation, and pronation may be limited, where appropriate, by use of splints.
  - Ulnar gutter orthosis is sufficient to alleviate pain.
  - Some patients will require a splint limiting forearm rotation.
  - Custom made or prefabricated splints (sugar-tong or Muenster type) are frequently used (Figure 15-16). Both allow for midrange elbow flexion and extension. The sugar-tong splint provides greater limitation in pronation and can be adjusted to allow for changes in edema.
- Duration of immobilization
  - For TFCC tears of degenerative etiology a period of 4 weeks of immunization is required. If the tear is of a traumatic etiology, immobilization ranging from 4 to 6 weeks may be required.
  - When distal radioulnar joint instability is observed on physical examination and the patient opts for a trial of nonsurgical management, the forearm should be immobilized in a position that reduces the instability (typically supination) for at least 4 weeks. Afterward, the wrist alone should be immobilized for an additional 2 weeks before initiating therapy.

Management of Pain and Swelling

- Pain and swelling must be adequately optimized with simple oral analgesics, with quantities tailored in response to the individual athlete's pain scores.
- Use of NSAIDs (e.g., ibuprofen, diclofenac) can limit this acute phase inflammatory response and optimize pain management.

TIMELINE 15-1: **Nonoperative Rehabilitation of Wrist Sprains/Triangular Fibrocartilage Complex Injuries**

PHASE I (weeks 1 to 4)	PHASE II (weeks 4 to 8)
• Education • Analgesia/NSAIDs • Activity modification • Immobilization: splint (gutter or forearm) • Cryotherapy • AROM exercises for joints not immobilized • Consider unilateral training of free limb	• Education • Soft splint for nighttime support • Tapering of analgesia/ NSAIDs • AROM or AAROM exercises all joints • Passive accessory movements or MWMs • Tendon gliding exercises • Functional exercises or light ADLs • Early proprioception exercises • Soft tissue techniques

FIGURE 15-16. Types of forearm splints. **A,** Sugar-tong splint. **B,** Muenster splint.

- Intraarticular corticosteroid injections may be of benefit in the setting of severe symptoms.
- Cryotherapy (e.g., application of cold packs, crushed ice over the site of injury) may optimize pain control and limit the symptomatic effects of tissue edema.

Patient Education and Advice

- Essential to ensure the patient understands the injury and the rationale behind the treatments selected

Patient Engagement

- Patient participation and compliance are essential to achieving timely progress through each phase and prevention of future injury.

Activity Modification and Identification of Targets

- Removes the inciting force of injury and prevents future injury recurrence
- Realistic milestones are outlined and agreed between athlete and therapist.
- Several factors are important to consider when treatment is initiated for a TFCC injury:
  - The athlete's specific sport
  - His/her desires regarding return to play
  - The impact of injury management on the athlete's future participation in his/her sport

Specific Therapeutic Exercises

Maintenance Exercises

- Full active range of movement of fingers and thumb should be encouraged within the splint to prevent small joint stiffness and muscle atrophy and to assist in the resolution of soft tissue edema.

Free Limb Strength Training

- Total arm strength training the free limb may attenuate the strength loss acquired in unilateral immobilization while also maintaining muscle bulk.
- Cross-education effect may provide another tactic in the management of the patient during this phase of immobilization.

Early Intervention

- For high-level (elite high school, collegiate, or professional) athletes who have negative initial imaging yet persistent symptoms limiting participation, diagnostic (and potentially therapeutic) arthroscopy may be indicated after as little as 2 to 3 weeks of splinting.

Milestones for Progression to the Next Phase

- Significant alleviation of pain as demonstrated by decreased requirements for analgesics and antiinflammatory medications
- Splint independence: Adequate pain control and minimal edema when splint is removed

Phase II (weeks 4–8)

Goals

- This phase aims to ameliorate residual stiffness and edema from phase I immobilization; to restore range

TIMELINE 15-1: Nonoperative Rehabilitation of Wrist Sprains/Triangular Fibrocartilage Complex Injuries (Continued)

PHASE III (weeks 8 to 12)	PHASE IV (weeks 12+)
• Static progressive or dynamic splinting as needed • Progress PROM to full • MWMs in weightbearing • Isokinetic exercises • Isometric exercises • Eccentric/concentric exercises • Grip strengthening exercises • Proprioception: conscious and unconscious neuromuscular rehabilitation • Early low level plyometrics—gravity eliminated/reduced • Progression of functional exercises	• Activity modification • Wrist protection • Maintain full AROM/PROM • Good flexibility • TAS or TBS activities as recommended • Progression of plyometrics—"single arm bounce back" • Sport-specific exercises • OKC rhythmic stabilization exercises • CKC exercises in weightbearing position • Simulation of game or competition needs • Use of periodization training model

of motion, flexibility, co-ordination, and function of the wrist joint; and commence early muscle strengthening work.

Protection

- Therapists should strongly advocate the use of removal splints to protect the injury in this early phase of rehabilitation and prevention of reinjury.
- The use of night splinting is crucial.

Management of Pain and Swelling

- Patient feedback during passive assessment is essential to prevent irritation of recently healed structures.
- It may be suitable to defer measurement of resisted activities to a later phase.
- Use of analgesics and NSAIDs should be tailored to allow maximal pain-free participation in the exercise program.

Establishment of Functional Losses

- Once the splint is removed, physiotherapy is the key determinant of post-rehabilitation functional outcome.
- A comprehensive assessment of the wrist and the joints above and below determines baseline measurements and is vital in developing an individualized exercise program that will form the core of the athlete's rehabilitation to competitive sport.
- Active range of motion (AROM), assisted AROM, and passive range of motion (PROM) of the wrist joint, stiffness and swelling, muscle strength, forearm length, and painful movements are determined.

Patient Education

- Protection of joints during demanding activities or vocational duties should be highlighted by therapists to prevent reinjury.
- Pamphlets should be provided with schematic/photographic representation and instructions of the exercises to be performed.

Techniques for Progressive Increase in Range of Motion

- The following techniques aim to achieve the two main goals of initial physiotherapy rehabilitation: increased range of motion and decreased swelling. These exercises should be prescribed in sets of 3 to 5 per day, with the amount of repetitions and sets adjusted to meet the individual athlete's desired level of function.

Active and Assisted Active Range of Motion Exercises

- Most activities of daily living (ADLs) are performed within a range that utilizes midcarpal rather than radiocarpal joint motion, known as *dart-thrower's motion*. Joint range is typically from 40° wrist extension, 20° radial and ulnar deviation, and 0° flexion.
- AROM exercises should initially target these goals to allow for increased pain-free function before advancing to the next level.
- AROM and assisted AROM exercises include wrist (flexion/extension, ulnar/radial deviation), fingers/thumb (flexion/extension), forearm (pronation/supination), and elbow (flexion/extension).

Tendon Glide Exercises

- Prolonged periods of immobilization can cause tightness within the musculotendinous unit.
- This can be overcome by using tendon glide exercises directed at both wrist and finger flexor and extensor tendons. Differential glides should be included to allow progressive increase in range of motion (Figure 15-17).

Functional Exercises

- Functional exercises, to include fist formation, opposition, and grip, are essential in increasing strength, endurance, and dexterity.
- Assessment of the management of carpal instability by Australian hand therapists[1] revealed grip strength to be 67% of the contralateral uninjured side. Basic ADLs should therefore be encouraged to aid strength and restore patient confidence. The use of a soft splint may help facilitate this process.

Mobilizations with Movement/Passive Accessory Movement Glides

- Mobilizations with movement (MWM) that apply a sustained force or accessory glides while performing a previously painful movement may be of use in achieving end-range movements. Initially performed with the wrist non–weight-bearing and progressed as tolerated.
- Passive accessory movement glides, particularly of the wrist (AP, PA, and medial/lateral) and distal radioulnar joint (AP/PA), can help restore joint range but care must be taken with healing tissue and appropriate grades of movement used.

Soft Tissue Techniques

- Lymphatic massage and gentle cross-friction massage can be applied at the site of the lesion to increase mobility of collagen fibers without longitudinally stressing the ligament and to promote lymphatic drainage.
- Application of nonthermal ultrasound promotes increased tissue perfusion, thereby reducing inflammation and swelling at the site of injury. Thermal ultrasound therapy can also be employed to decrease localized pain stimuli.

Other Therapeutic Exercises

Sensorimotor Exercises

- Early proprioception exercises address joint position sense and kinesthesia, controlling range and protecting healing structures. These include mirror therapy,

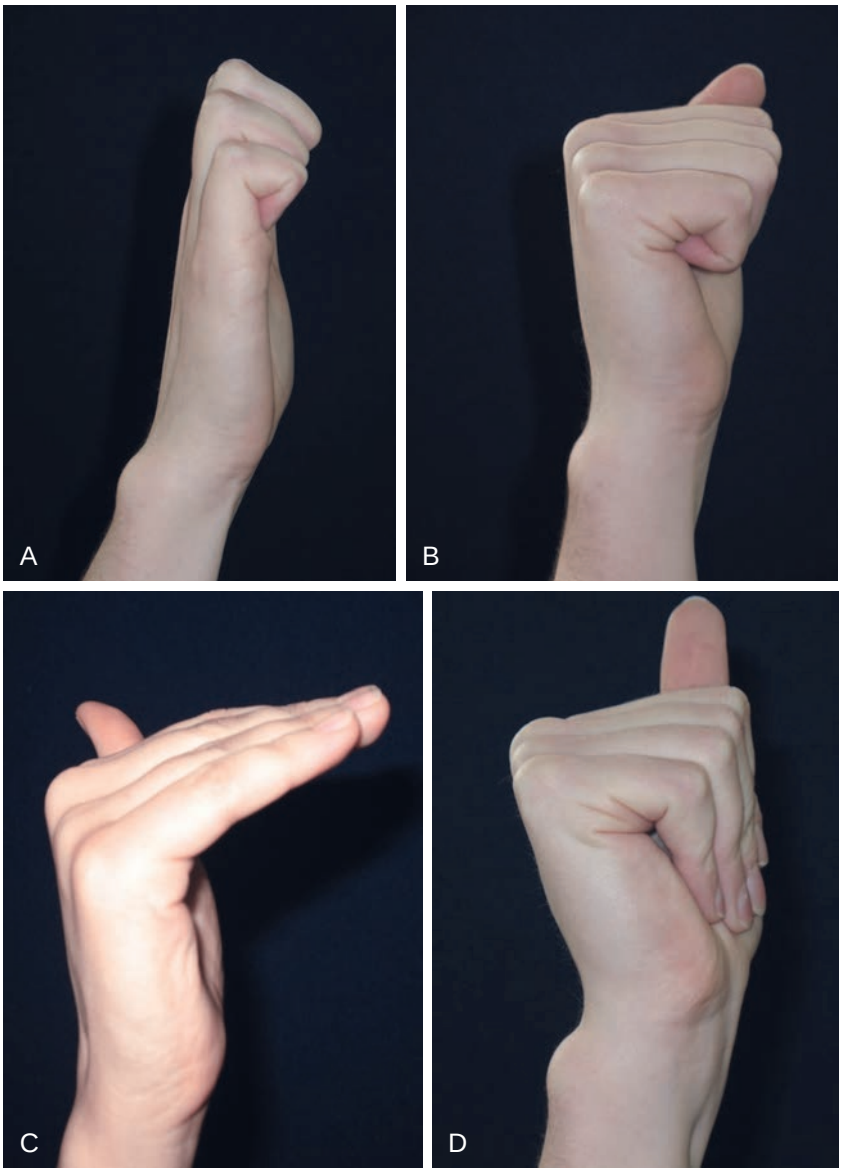

FIGURE 15-17. Differential tendon glide exercises. Progress in sequence from right to left, top to bottom. **A,** Hook grip. **B,** Full fist. **C,** Table top. **D,** Straight fist.

blinded passive and active reproduction of joint angle, and motion detection.
- These can be achieved using an exercise machine, such as an upper limb exerciser or manual passive motion.
- They may be an appropriate addition to the rehabilitation of gymnasts who specifically require a high level of proprioceptive function in their wrists.

Milestones for Progression to the Next Phase

- Improvement in comfort: Significant reduction in pain and decreased swelling at the site of injury with simple ADLs
- Increased ROM: Displays good tolerance through progressive range of exercises along a spectrum of gentle AROM to beginning strengthening exercises

Phase III (weeks 8–12)

Goals

- This phase aims to achieve a progressive improvement in strength, flexibility, proprioception, and endurance of the injured structures until near-normal function is achieved. This can only be initiated when a significant improvement in wrist ROM, has been consistently demonstrated.

Protection

- Static/dynamic splinting
  - If ROM improvement has plateaued before reaching functional ROM, incorporation of a static or dynamic progressive splint is recommended.
  - This additional support promotes increases in movements in desired directions by placing the targeted

joint(s) in a gentle stretch. Typically such splints are applied in a forearm supination or wrist extension position.
- Removal splints
  - The use of removal splints is strongly recommended, encouraged specifically during sleeping and ADLs that may reinjure the TFCC.
  - In addition to injury protection, removal splints facilitate heading by promoting rest of the arm and forearm.

Guidelines for Strengthening, Proprioception, and Endurance Rehabilitation

Mobilizations with Movement

- MWM can now be performed in a weight-bearing position to gain full pain-free end range movements at the wrist.
- Once this full ROM target has been reached, strengthening prescription should begin with progression onto more resistance-based exercises as tolerated.

Isometric Exercises

- Strengthening exercises should focus on the wrist, forearm, hand, elbow, and shoulder. In particular, grip strength exercises are of critical functional value in most daily activities and occupational duties.
- Isometric exercises (strength training in which the joint angle and muscle length do not change during contraction) against the therapist can be instituted initially.
- Isometric exercise promotes early neuromuscular control and prevents excessive joint motion. Unilateral isometric exercises of the wrist have been shown to increase voluntary muscle activation bilaterally.
- A TFCC injury with concomitant distal radioulnar joint instability can be treated with isometric exercise designed to target pronator quadratus in supinated and neutral wrist positions. Hence, the isometric exercises appear to have a key role in early wrist proprioception reeducation.

Eccentric/Concentric Exercises

- Eccentric and concentric exercises with progressive resistance can be introduced to improve muscle bulk, endurance, and joint stability. Generally higher repetitions with low load are effective. Prescription of such exercises should be based on initially building muscle mass, using moderate repetitions (6 to 10 reps) and eccentric loading (3 seconds down and 1 second up phase) for initially 3 to 5 sets per day.
- To improve endurance, the athlete should be performing high repetitions (greater than 10 reps) of a low weight, pain permitting, in between or after strength exercise sets.
- Pronation/supination exercises may be performed both concentrically and eccentrically using a hammer, held in the hand, as a lever.
- Progressive gripping activities from a supinated position, through neutral and finally in a pronated position has been recommended to prevent irritation of the TFCC.
- Wrist flexion/extension exercises should be performed with a small dumbbell (or resistive bands) starting at 500g and progressing to higher masses as tolerated.
- Elbow and shoulder strengthening should be addressed.
- Eccentric exercises of wrist extensors influence the coactivation pattern of wrist flexors, enhancing the stability of the wrist.
- Coactivation exercises demand the use of concentric, eccentric, and isometric exercises. This can be reproduced by performing balance exercises with both hands on a ball. Slow and controlled motion of the ball on a table will allow the patient to simultaneously exercise flexors and extensors to produce a balanced wrist position in early proprioceptive training.

Isokinetic Dynamometry

- Isokinetic training involves optimal loading of muscles in dynamic conditions and consistent preselected velocity of movement. This is an ideal treatment option for those individuals who put extreme demands on their wrists.
- Exercises should start with submaximal contraction intensity and slow speed movement and progressively intensify (increase in intensity contraction and speed movement).
- Program effectiveness can be assessed through pain score evaluation, muscle strength measurement, and ultrasonographic examination.

Proprioceptive Rehabilitation

- For athletes such as gymnasts in whom wrist "balance" is vital, more complex proprioceptive rehabilitation is required to maximize wrist functional outcome.
- Human proprioception comprises three major senses: kinesthesia, joint position sense (JPS), and unconscious neuromuscular control.
- Kinesthesia constitutes the ability to sense motion of a joint and is measured as the smallest change in joint angle needed to elicit a conscious awareness of joint motion. The joint is placed at a certain angle and then moved passively and slowly at a speed of 0.5° to 2° per second, until the patient signals that joint motion occurs. This is referred to as *threshold to detection of passive movement* (TTDPM).
- Accurate control of the degree and speed of motion can be achieved using professional training devices such as an Upper Limb Exerciser (Biometrics Ltd, Ladysmith, VA) or Biodex Dynamometer (Biodex Medical Systems Inc., Shirley, NY). Joint position sense is defined as the ability to accurately reproduce a specific joint angle.
- JPS training can be performed passively or actively, with visual cues or blinded. Passive JPS is when the therapist moves the wrist and the patient signals when the target position is reached. Active JPS is when the patient moves the wrist to the predetermined target position.
- Unconscious proprioceptive sense is the feed-forward anticipatory control of muscles around a joint, the ability to unconsciously maintain an adequate posture, joint stability, and equilibrium. Reactive muscle activation (RMA) therapy aims to restore the neuromuscular reflex patterns that exist in a normal joint.

- Suggested strategies to stimulate RMA include use of gyroscopic tools such as Powerball (NSD Powerball, RPM Sports, Tipperary, Ireland). The multidirectional motion generated by the gyroscope, demands a reflex activation of the wrist muscles and an unconscious activation of both the agonist and antagonist muscles, to increase muscle endurance.

Plyometric Exercise

- The identifying feature of plyometric exercise is lengthening of the muscle-tendon unit followed directly by shortening (stretch-shortening cycle) (Figure 15-18). This enhances the ability of the muscle tendon unit to produce maximal force in the shortest amount of time, prompting the use of plyometric exercise as a bridge between pure strength and sports-related speed.
- Clinical milestones such as pain-free moderate loading during traditional strengthening exercise and functional movement patterns with proper form should be achieved before safe implementation.
- The progression of low- to higher-intensity plyometric exercise will prepare the musculoskeletal system for rapid movements and high forces that may equate to the demands imposed during sport participation, thus assisting the athlete with return to full function.

Incorporation of Functional Activities

- These activities will progress rehabilitation to a level of pain-free function, enabling integration back into independent living. Such functional activities include folding, washing, using cutlery, using tools such as screwdrivers, and incorporation of other occupational/sport-specific tasks.
- Use of computerized work simulators, such as the Baltimore Therapeutic Equipment Work Simulator, may allow stepwise task-based rehabilitation in a safe manner.

Milestones for Progression to Phase IV

- At the end of phase III, patients should have normal joint range, power, and endurance compared to the noninjured side and be able to perform all ADLs without pain. They should be fit to return to work and progress to phase IV sport-specific training.

Phase IV (12 weeks onward)

Goals

- The final phase (Phase IV) of rehabilitation involves progression toward functional independence and focus on sport-specific training and conditioning. Athlete education and development of injury prevention measures are key factors to successful rehabilitation.

Activity Modification

- As sport-specific skill and functional demands are reintroduced in this final phase of rehabilitation, it is imperative that a comprehensive reassessment of wrist function is performed.
- Athletes should continue to perform both AROM and PROM exercises for isolated upper extremity strengthening, with close attention to tissue reaction.

Patient Education and Protection

- Injury prevention, education, and application of wrist protection principles are important features of this phase.
- Daily protection of the wrist during demanding ADLs or vocational duties should be highlighted to include

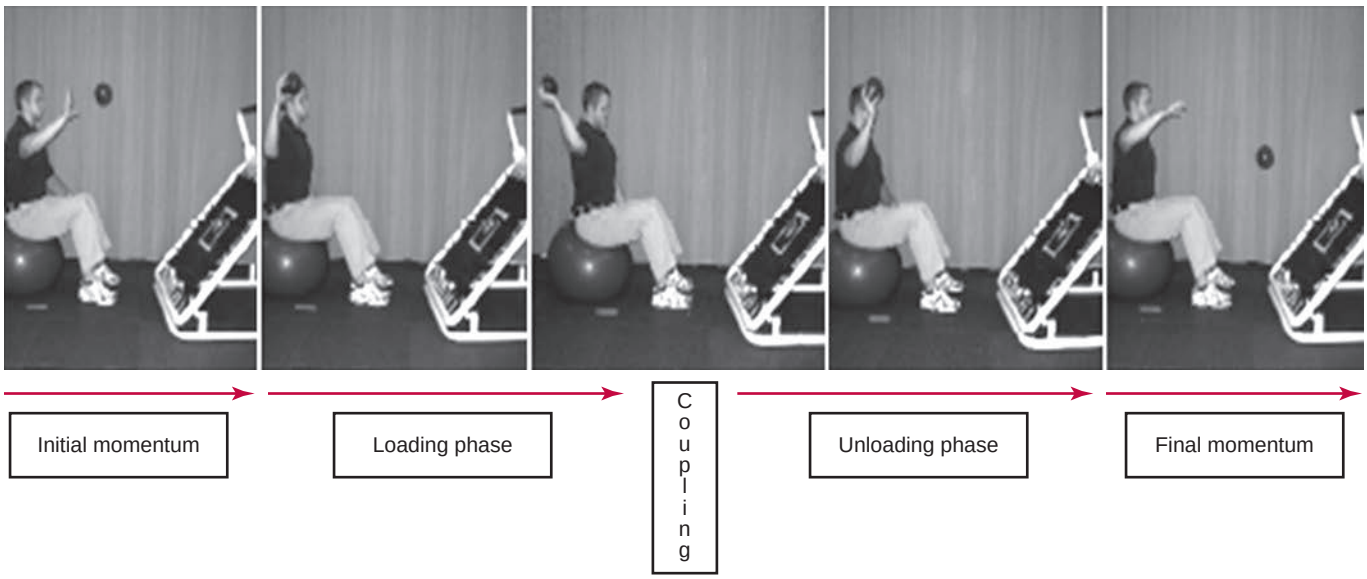

FIGURE 15-18. Upper extremity plyometric exercise. The three phases of plyometric activity include loading, coupling and unloading. The loading phase involves stretch on the muscle-tendon unit, which initiates the stretch-shortening cycle. The coupling phase is the transition between loading and unloading and is characterized by quasi-isometric muscle activity. The unloading phase involves shortening of the muscle-tendon unit and capitalizes on the mechanisms of the stretch-shortening cycle. *(From Chmielewski TL, Myer GD, Kauffman D, Tillman SM: Plyometric exercise in the rehabilitation of athletes: Physiological responses and clinical application. J Orthop Sports Phys Ther 36(5):308–319, 2006.)*

use of the strongest joint available for noncompetitive activities, use of each joint in its most stable anatomical and functional plane, and maintenance of muscle balance and correct patterns of motion.
- Although avoidance of static positioning of joints is encouraged, wrist supports may be used to facilitate training but only temporarily and under the strict guidance of the coach/rehabilitation team.

Periodization Training

- Decisions regarding return to competition should be agreed upon by the multidisciplinary rehabilitation team and optimal strength training and conditioning achieved through a sport-specific training program.
- *Periodized strength training* refers to varying the training program at regular time intervals in an attempt to bring about optimal resistance gains in strength, power, motor performance, and/or muscle hypertrophy. It is conceptualized by programmed variation in the training stimuli (i.e., volume, intensity, frequency) with the use of planned rest periods to augment recovery and restoration of an athlete's potential.
- Periodization training programs are designed according to two different models: the linear model and the nonlinear model.
- The undulating (nonlinear) model enables variation in intensity and volume within each 7- to 10-day cycle and is deemed superior to linear training (volume decrease, intensity increase with program progression).
- Implementation of undulating periodization requires an initial adaptation phase. Thus the athlete performs a base program for 4 to 6 weeks using lighter weights, allowing climitization to the resistance training program, before an undulating progression of varying intensities.
- An active rest or recovery period (halt resistance training and remain active with other sporting activities) of 2 to 3 weeks commences after the 16-week cycle. The most common undulating periodization model is shown in Table 15-1.

Sport-Specific Rehabilitation

- Strengthening exercises should be further developed throughout phase IV to include overhead, torqueing, and weightbearing activities. These activities will effectively assess the impact of additional strain on the TFCC, thus providing key prognostic information on readiness to return to competitive sport.
- It is imperative that proprioceptive rehabilitation is maintained throughout this phase of reconditioning to achieve maximal wrist function and injury prevention for athletes placing high demands on their wrists. This is exemplified by gymnastics, wherein a high level of wrist flexibility and strength is required.
- Handstands against the wall allow for some support to aid strength and flexibility before moving to supporting full body weight against gravity. Nonprofessional tennis players have been shown to stress radial or ulnar aspects of the wrist depending on the individual's racket grip. Activity modification and wrist supports should therefore compliment initial return to sport.
- Simulation training or positive imagery representative of game or competition conditions can help prepare the athlete for return to the sport.

Table 15-1 Sample Protocol of Undulating Periodization in a 16-Week Mesocycle*

Monday	**Monday**
4 sets of 12 to 15 RM	4 or 5 sets of 1 to 3 RM
Wednesday	**Wednesday**
4 sets of 8 to 10 RM	Power day
Friday	**Friday**
3 or 4 sets of 4 to 6 RM	2 sets of 12 to 15 RM

From Kraemer WJ, Fleck S: *Optimizing strength training, Champaign,* Illinois, 2007, *Human Kinetics.*
*This protocol uses a 6-day rotation. Active rest for 2 to 3 weeks after the 16-week mesocycle is completed.

Plyometric Exercise

- Ongoing progression of plyometrics can encourage total body engagement, enhancing stability around the wrist with motion generated in the whole upper limb.
- Activities such as the single arm bounce back (throwing a weighted ball against a screen, catching the ball as it bounces back, and throwing it immediately) are effective. These are particularly useful if the sport requires explosive power and control.
- An upper extremity stretch shortening drill has been described consisting of warmup, throwing, trunk flexion/extension exercises, and medicine ball wall exercises.

Open-/Closed-Chain Kinetic Exercises

- Athletes who are unable to perform plyometric exercise usually struggle to attain preinjury level of functioning.
- Closed-chain exercises incur compressive forces and are typically weight bearing (e.g., pushups for gymnasts and wrestlers).
- Open-chain rhythmic stabilization exercises incur shearing forces (e.g., biceps curl, lateral raise) and work well for baseball athletes, particularly pitchers. The act of throwing a baseball is itself an open-chain movement in which the pitching arm rotates extremely quickly around the glenohumeral joint and the ball is released at high velocities.

Criteria for Abandoning Nonoperative Treatment and Proceeding to Surgery or More Intensive Intervention

- Persistent symptoms
  - Several factors are key determinants of rehabilitation outcomes post-TFCC injury, including the extent of the TFCC injury, the athlete's motivation and

adherence to program milestones, and the presence of medical comorbidities.
  - Failure of symptom (pain, edema) resolution 4 to 6 weeks post injury despite optimization with immobilization, and analgesic and antiinflammatory medications warrants prompt surgical intervention.
- High-level athletes
  - Professional athletes who have negative initial imaging yet persistent symptoms limiting participation despite compliance require surgical intervention after as little as 2 to 3 weeks of immobilization.

Guidelines for Progression to Sport-Specific Training and Conditioning

- Each athlete will have different goals, varying skill levels, and different levels of competition. This may influence progression in an individualized rehabilitation model. The following criteria should be fulfilled before commencement of reconditioning.
  - Normal joint range, power and endurance
  - Pain-free moderate loading during traditional strengthening exercise and functional movement patterns with proper form
  - Normal pain-free activities of daily living
  - Fulfillment of basic plyometric activity
  - Incorporation of routine functional activities into standard exercise prescription
  - Integration into independent living: return to work/vocational activities

Performance Enhancement and Beyond Rehabilitation: Optimization of Athletic Performance

- Optimization of athletic performance following strength training and reconditioning is multifactorial. It is imperative that performance goals and methodology are agreed upon by the rehabilitation team to prevent reinjury. Means of achieving maximal athletic performance include:
  - Maintenance of cardiovascular fitness and agility skills to help prepare the athlete for advanced conditioning
  - Progression from muscle conditioning, flexibility, functional exercises to sport-specific skills and incorporation into the standard periodization program
  - Maintenance of proprioceptive training to increase wrist stability and thus injury prevention
  - Upper limb assessment: A comprehensive upper limb assessment is required. This will identify abnormal biomechanics (e.g., shoulder instability). In such cases motor reeducation with focus on scapular stability improves overall upper limb function.
  - Sports psychology: Use of simulation and imagery promotes sports motivation and performance enhancement.
  - Visual cues: Video analysis to assess biomechanical problems and implement corrective strategies

Criteria for Return to Sport

- Complete resolution of pain and edema with return to full range of movement
- Strength, flexibility, and endurance at preinjury status with plyometrics
- Good proprioception: normal kinesthesia, joint position sense, and unconscious control
- Stepwise completion of training program without reinjury/symptom exacerbation
- Maintenance of cardiovascular fitness throughout the rehabilitation period
- Psychological preparedness for return to competitive status

Evidence

Ahn A, Chang D, Plate AM: Triangular fibrocartilage complex tears: A review. *Bull NYU Hosp Jt Dis* 64(3–4):114–118, 2006.

A comprehensive review of the etiology, biomechanics, and treatment options available following triangular fibrocartilage tears. (Level IV evidence).

Chmielewski TL, Myer GD, Kauffman D, et al: Plyometric exercise in the rehabilitation of athletes: Physiological responses and clinical application. *J Orthop Sports Phys Ther* 36(5):308–319, 2006.

A review of the mechanisms involved in plyometric exercise, considerations for implementing plyometric exercise into rehabilitation protocols. Evidence supporting the use of plyometric exercises and recommendations for future research are discussed. (Level IV evidence).

Hagert E: Proprioception of the wrist joint: A review of current concepts and possible Implications on the Rehabilitation of the Wrist. *J Hand Ther* 23:2–17, 2010.

Narrative review of novel research findings on the subject of wrist joint proprioception. The concept of proprioception is explored as it relates to neuromuscular control, joint stability, and therapeutic application in the context of wrist rehabilitation. (Level IV evidence).

Henry MH: Management of acute triangular fibrocartilage complex injury of the wrist. *Am Acad Orthop Surg* 16(6):320–329, 2008.

A comprehensive systematic review of the management of triangular fibrocartilage complex injuries in the acute setting. Anatomy, biomechanics, imaging, and conservative and operative strategies are thoroughly explored. (Level IV evidence).

Hendy AM, et al: Cross education and immobilization: Mechanisms and implications for injury rehabilitation. *J Sci Med Sport* 15(2):94–101, 2012.

This review examines the impact of immobilization on muscle tissue and the central nervous system, the possible mechanisms that may contribute to cross-education strength transfer, and the practical application of unilateral training to maintain strength during immobilization. (Level IV evidence).

Parmelee-Peters K, et al: The wrist: Common injuries and management. *Prim Care* 32(1):35–70, 2005.

A review of the epidemiology of wrist injuries in the active population and appropriate management options for each type of injury. (Level IV evidence).

Rhea MR, Ball SD, Phillips WT, et al: A comparison of linear and daily undulating periodized programs with equated volume and intensity for strength. *J Strength Cond Res* 16(2):250–255, 2002.

A randomized control trial comparing strength gains following linear periodization and daily undulating periodization training. Daily program alterations were more effective in eliciting strength gains than monthly alterations, supporting the use of daily undulating periodized programs as the superior method of strength training. (Level II evidence).

Slaughter A, Miles L, Fleming J, et al: A comparative study of splint effectiveness in limiting forearm rotation. *J Hand Ther* 23:241–248, 2010.

A case series exploring the effectiveness of Muenster, sugar-tong, antipronation distal radioulnar joint, and standard wrist splints in restricting forearm pronation. The sugar-tong splint is recommended for maximal restriction in pronation, but individual patient characteristics require consideration in splint choice. (Level IV evidence).

Watanabe A, Souza F, Vezeridis PS, et al: Ulnar-sided wrist pain. II. Clinical imaging and treatment. *Skeletal Radiol* 39(9):837–857, 2010.

A review of the etiology, mechanisms, imaging, and treatment options available for the common diseases that cause ulnar-sided wrist pain. (Level IV evidence).

Multiple-Choice Questions

QUESTION 1. Phase I rehabilitation following a TFCC injury does not involve

A. Immobilization
B. Analgesia and antiinflammatory medications
C. Active range of motion exercises
D. Education
E. Activity modification

QUESTION 2. Milestones for progression to phase IV rehabilitation include:

A. Return to work/vocational activities
B. Removal of forearm splints
C. Commencement of soft tissue techniques
D. Progression to eccentric/concentric exercise
E. Progression to isokinetic exercise

Answer Key

QUESTION 1. Correct Answer: **C** (see Phase I)

QUESTION 2. Correct Answer: **A** (see Milestones for progression to Phase IV)

POSTOPERATIVE REHABILITATION AFTER TRIANGULAR FIBROCARTILAGE COMPLEX REPAIR/DEBRIDEMENT AND WRIST LIGAMENT REPAIR/WRIST ARTHROSCOPY

Dominic Gomez-Leonardelli, MD, Jack Browne, OT, CHT, and Leo T. Kroonen, MD

Indications for Surgical Treatment

Triangular Fibrocartilage Complex Injuries

- Patients with traumatic injuries (Type I) or degenerative pathology (Type II) to the Triangular Fibrocartilage Complex (TFCC) who do not respond to nonoperative treatment (see Box 15-1 below and Figure 15-4 in the Introduction for a description of the Palmer classification of TFCC abnormalities)
- Peripheral or ulnar-sided repairs may benefit from early arthroscopic repair.
- Arthroscopic repair of acute (within 3 months) radial and peripheral tears gives the best prognosis.
- An aggressive approach can be considered in elite athletes with distinct distal radial ulnar joint instability.

Scapholunate Ligament (SL) Injuries

- Acute ligament disruption as indicated by mechanism of injury, clinical examination, and radiographic evidence of complete or partial rupture
- Subacute and chronic ligament disruption with persistent pain unresponsive to nonoperative treatment attempts

Lunotriquetral Ligament Injuries

- Arthroscopy is indicated for staging and treatment of acute lunotriquetral (LT) ligamentous injuries with dynamic or static instability, with improved healing potential seen with early intervention.
- Suspected lunotriquetral ligamentous injuries with persistent painful symptoms unresponsive to nonoperative treatment

BOX 15-1 The Palmer Classification of TFCC Abnormalities

Class I: Traumatic

A. Central perforation
B. Ulnar avulsion
   With distal ulnar fracture
   Without distal ulnar fracture
C. Distal avulsion
D. Radial avulsion
   With sigmoid notch fracture
   Without sigmoid notch fracture

Class II: Degenerative (ulnocarpal abutment syndrome)

A. TFCC wear
B. TFCC wear
   + Lunate and /or ulnar chondromalacia
C. TFCC perforation
   + Lunate and/or ulnar chondromalacia
D. TFCC perforation
   + Lunate and/or ulnar chondromalacia
   + L-T ligament perforation
E. TFCC perforation
   + Lunate and/or ulnar chondromalacia
   + L-T ligament perforation
   + Ulnocarpal arthritis

- Chronic, symptomatic lunotriquetral ligamentous injuries are appropriate candidates for arthroscopic debridement, and possible ulnar shortening osteotomy

Brief Summary of Surgical Treatment

Major Surgical Steps

Treatment of TFCC Injuries

- With the wrist in an arthroscopy tower under 12 to 15 lbs of traction, standard wrist arthroscopy portals are used (we prefer 3 to 4 and 6R portals for the radiocarpal joint and both radial and ulnar midcarpal portals for evaluation of the midcarpal joint).
- Standard of care includes a midcarpal arthroscopy in all wrist arthroscopy cases.
- Decision to debride or repair is based upon the location and stability of the TFCC tear based on the Palmer classification (see Box 15-1)
- Debridement is considered adequate when no loose edges or a smooth rim of TFCC has been fashioned.
- IA injuries' (central tears) accepted surgical treatment involves removal of unstable tissue via arthroscopic portals and debridement.
- IB injuries (ulnar sided peripheral tears) may be repaired arthroscopically via outside-in or inside-out techniques employing vertical or longitudinal sutures tied over the capsule.
- IC injuries (distal tear away from the carpus) may be repaired arthroscopically or via open technique. Arthroscopic repair utilizes looped 2-0 PDS sutures through ulnocarpal ligaments then tied over the capsule.
- ID injuries (radial tears) surgical debridement includes debridement or repair with reported similar clinical outcomes. Arthroscopic repair techniques involve drilling suture tunnels via the sigmoid notch through the distal radius metaphysis for suture repair of the radial edge of the TFCC.
- Patients who present with a traumatic TFCC injury and ulnar positive variance should receive consideration for combined arthroscopic TFC repair and ulnar shortening osteotomy.

Treatment of Scapholunate Ligament Injuries

- Partial ligament injury in acute phase wherein inherent healing potential of ligamentous structures is the favorable treatment includes percutaneous or arthroscopic debridement or electrothermal shrinkage followed by guided percutaneous fixation of the scapholunate joint after reduction with Kirschner wire or compression screw fixation.
- Complete ligament injury with a repairable ligament may be repaired after reduction of the scapholunate joint via transosseous sutures or suture anchor fixation, potentially augmented with dorsal capsulodesis. Repair is protected with K wire fixation of the scapholunate and scaphocapitate joints, or with screw fixation across the scapholunate interval.
- Complete ligament injury with nonrepairable ligamentous structures and normal carpal alignment may be treated by various approaches:
  - Reconstruction of the SL ligament with locally harvested portions of the dorsal intercarpal ligament or the dorsal radiocarpal ligament
  - Reconstruction of the SL ligament with locally harvested half of the flexor carpi radialis (triligament tenodesis)
  - Bone ligament bone grafts involving transferring bone-retinaculum-bone autograft harvested from the carpus of the foot
  - Dorsal capsulodesis: tightening radioscaphoid capsule in which a dorsal capsular flap is created and imbricated after reduction of the SL joint
- Complete ligament injury with nonrepairable ligamentous structures and reducible subluxation of the scaphoid may be treated with various SL ligament reconstruction techniques utilizing slips of the ECRB, ECRL, and FCR and various bone tunnels.
- Complete ligament injury with nonrepairable ligamentous structures and irreducible carpal alignment and normal cartilage may be treated with various arthrodesis techniques:
  - Scaphoid-trapezium-trapezoid
  - Scaphoid-capitate
  - Scaphoid excision and midcarpal fusion (four-corner fusion)
- Complete ligament injury with nonrepairable ligamentous structures, irreducible carpal alignment and advanced cartilage degeneration may be treated by various approaches, depending on the extent of the arthrosis:
  - Radial styloidectomy
  - Scaphoidectomy with midcarpal fusion
  - Proximal row carpectomy

- Total wrist arthrodesis
- Total wrist arthroplasty

Treatment of Lunotriquetral Ligament Injuries

- Partial lunotriquetral ligament injuries (LTIL) may be treated with arthroscopic debridement with excellent reported resolution of pain.
- Ulnar shortening osteotomy results in tightening of secondary restraints and theoretic stabilization of the lunotriquetral joint.
- Lunotriquetral arthrodesis has been described as a treatment option with an anticipated loss of 20° to 30° range of motion.
- Complete LTIL tears may be treated with arthroscopic reduction and pinning of the lunotriquetral joint, arthroscopic extrinsic ligament plication, or reconstruction with locally harvested extensor carpi ulnaris.

Factors That May Affect Rehabilitation

TFCC

- Debridement: Motion may begin immediately with use of splinting as needed for pain.
- Repair: typically 6 weeks of immobilization

Scapholunate Ligament and Lunotriquetral Ligament Injuries

- Debridement: Motion may begin immediately with use of splinting as needed for pain.
- Repair or reconstruction: Motion should not commence until 6 weeks postoperative. If pins are in place, motion should not commence until removal at 12 weeks postoperative. Our preference is to use screw fixation, which will allow for gentle early motion at 6 weeks postoperative, while still providing mechanical support to prevent early diastasis of the affected joint

Other Surgical Techniques and Options

Other TFCC Injuries/Treatments

- IB injuries more chronic in nature as well as those directly involving TFCC anatomic insertion to the fovea; consider open repair techniques
- ID injuries with large displaced radial avulsion fractures involving the sigmoid notch indicate an open repair via a dorsal approach.

Overview of Goals, Milestones, and Guidelines[1]

GUIDING PRINCIPLES OF POSTOPERATIVE REHABILITATION

- Understand the anatomy and wrist kinematics in order to appreciate how particular wrist movements may exacerbate existing pathology or challenge areas of repair.
- Respect ROM and strengthening limitations to allow appropriate healing and minimize postoperative inflammatory responses.

Goals Before Surgery

- Avoid exacerbation of initial injury.
- Immobilization for soft tissue rest and pain control—may include formal short arm cast or soft splint.
- Gentle range of motion to avoid stiffness

Goals After Surgery

TFCC Repair

- Immobilization in Munster or sugar-tong splint for 6 weeks with forearm in supination, wrist in 15° extension, and the finger MCP joints free.
- Begin AROM for the wrist and forearm at 6 weeks postoperative. Short arm wrist splint between exercise sessions for pain if needed
- Begin strengthening at 8 weeks postoperative.
- Return to full activity is anticipated at 12 weeks.
- Return to sports at 14 to 18 weeks
- Early return to activity may result in exacerbation of postoperative synovitis.

Debridement

- Splinting and immobilization as needed for pain
- Immediate ROM
- Return to sports unprotected 2 to 6 weeks

Scapholunate Ligament Injury

- Partial injury, SL joint with screw fixation: immobilization in below elbow cast with finger ROM immediately, screw removal at 12 weeks postoperative with protection in removable splint, ROM, and grip exercises beginning at 6 weeks postoperative.
- Complete injuries with repairable SL ligament: immobilization in below elbow cast for 6 weeks, immediate finger ROM, wrist ROM at 6 weeks, screw removal 5 to 6 months, additional protection in removable splint as needed beginning at 6 weeks
- Complete injuries with nonrepairable SL ligaments and reducible scaphoid subluxation: immobilization in below elbow thumb spica splint/cast for 6 weeks, screw removal at 5 to 6 months. Gentle wrist ROM can commence at 6 weeks, contact sports resumed at 6 months postoperative with protection, 10 months unprotected.

Phase I (days 0 to 14): Immediate Postoperative Period

Clinical Pearls

Hourly active tendon gliding exercises for the fingers help to maintain finger mobility and to control edema. Encourage very light functional use of the injured extremity while lifting no more than one pound.

[1]*Prehabilitation, if appropriate, is described in the Nonoperative Rehabilitation section of this chapter.*

Goals

- Maintain finger, elbow, and shoulder mobility.
- Manage edema using elevation, compression, and active motion.
- Avoid painful posturing or sustained static positioning of the extremity.

Protection

- Munster or sugar-tong splint for repair or reconstruction, short arm removable splint for debridement procedures

Management of Pain and Swelling

- Narcotic or nonsteroidal antiinflammatory pain medications are appropriate as needed.
- Compressive tubular dressing for forearm, wrist, and fingers
- Active motion of the fingers, elbow, and shoulder
- Elevation at heart level or higher

Techniques for Progressive Increase in Range of Motion

Manual Therapy Techniques

- Low grade distraction for finger MCP, PIP, and DIP joints if fingers are stiff and swollen

Soft Tissue Techniques

- May use edema mobilization techniques

Other Therapeutic Exercises

- TBS/TAS/TLS that do not require use of the involved upper extremity

Open and Closed Kinetic Chain Exercises

- OKC Exercises
  - Hourly tendon gliding as follows
    - Straight position (fingers fully extended) (Figure 15-19*A*)
    - Table top position (MCPs fully flexed with PIPs, and DIPs in full extension) (Figure 15-19*B*)
    - Hook position (MCPs in full extension with PIPs and DIPs in full flexion) (Fig 15-19*C*)
    - Fist position (MCPs, PIPs, and DIPs in full flexion) (Fig 15-19*D*)
    - AROM for thumb IP joint and thumb MCP joint as allowed by splint

Phase II (postoperative weeks 2 to 6)

Goals

- See Phase I

Protection

- See Phase I

Management of Pain and Swelling

- Wean from narcotic pain medications if possible.
- Nonsteroidal antiinflammatories are appropriate as necessary.
- Decrease swelling per Phase I recommendations.

Techniques for Progressive Increase in Range of Motion

Manual Therapy and Soft Tissue Techniques

- See Phase I

Other Therapeutic Exercises

- See Phase I

Open and Closed Kinetic Chain Exercises

- See Phase I

Phase III (postoperative weeks 6 to 10)

Goals

- 80% of normal active range of motion
- Near pain-free for available active range of motion
- Normal use of involved extremity for light ADLs

Protection

- Wrist splint for 4 weeks, or until asymptomatic

Management of Pain and Swelling

- Cryotherapy
- Frequent active range of motion for the hand, wrist, and upper extremity
- Compression sleeve and/or edema glove if needed
- Elevation

Techniques for Progressive Increase in Range of Motion

- Active and active-assistive range of motion in flexion, extension, ulnar deviation, dart thrower's pattern, and forearm pronation/supination
- Consider static-progressive or dynamic mobilization splinting if not showing weekly progress with ROM.

Other Therapeutic Exercises

- Gentle Theraputty exercises for hand intrinsic and extrinsic muscles, or use of soft foam exerciser if near pain free

Open and Closed Kinetic Chain Exercises

- Continue tendon gliding if fingers remain stiff.

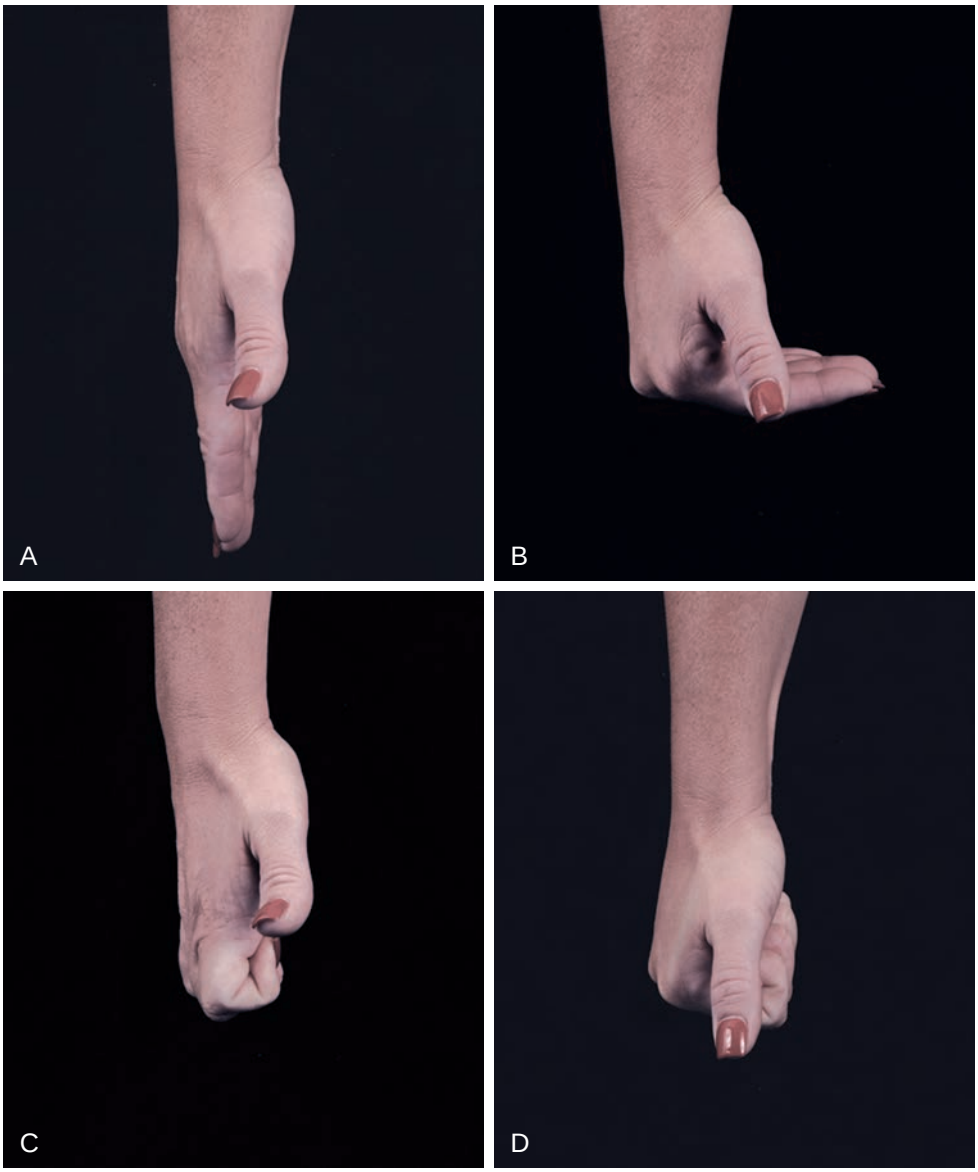

FIGURE 15-19. Tendon gliding exercise. **A,** Straight hand position**. B,** Hand in tabletop position. **C,** Hand in hook position. **D,** Hand in fist position.

TIMELINE 15-2: **Postoperative Rehabilitation after Open or Arthroscopic TFCC and Carpal Ligament Repair**

PHASE I (weeks 1 to 2 postop)	PHASE II (weeks 3 to 6 postop)	PHASE III (weeks 6 to 10 postop)

• Nonremovable splint for reconstructive; removable for debridement
• Compressive dressing to relieve swelling
• Active motion of fingers, elbow, and shoulder
• Elevation at heart or higher
• TFCC debridement: immediate active range of motion
• S-L ligament (partial): immobilization below elbow; finger ROM immediately
• TBS/TAS/TLS activities as tolerated, not involving affected extremity
	• TFCC repair: continue immobilization for 6 weeks
	• TFCC debridement:
	  • Discontinue splint
	  • Continued ROM, strengthening
	  • Return to sport unprotected week 2 to 6
	• SL ligament
	  • Immobilization 6 weeks then gentle finger ROM
	  • Grip strength exercises week 6
		• TFCC repair:
		  • Begin active range of motion for wrist and forearm week 6
		  • Begin strengthening exercises week 8
		• S-L ligament: finger and wrist ROM starting week 6
		• Active and active assist for goal 80% normal active ROM TBS/TAS/TLS activities tolerated
		• Gentle strengthening exercises for hand intrinsics and extrinsics

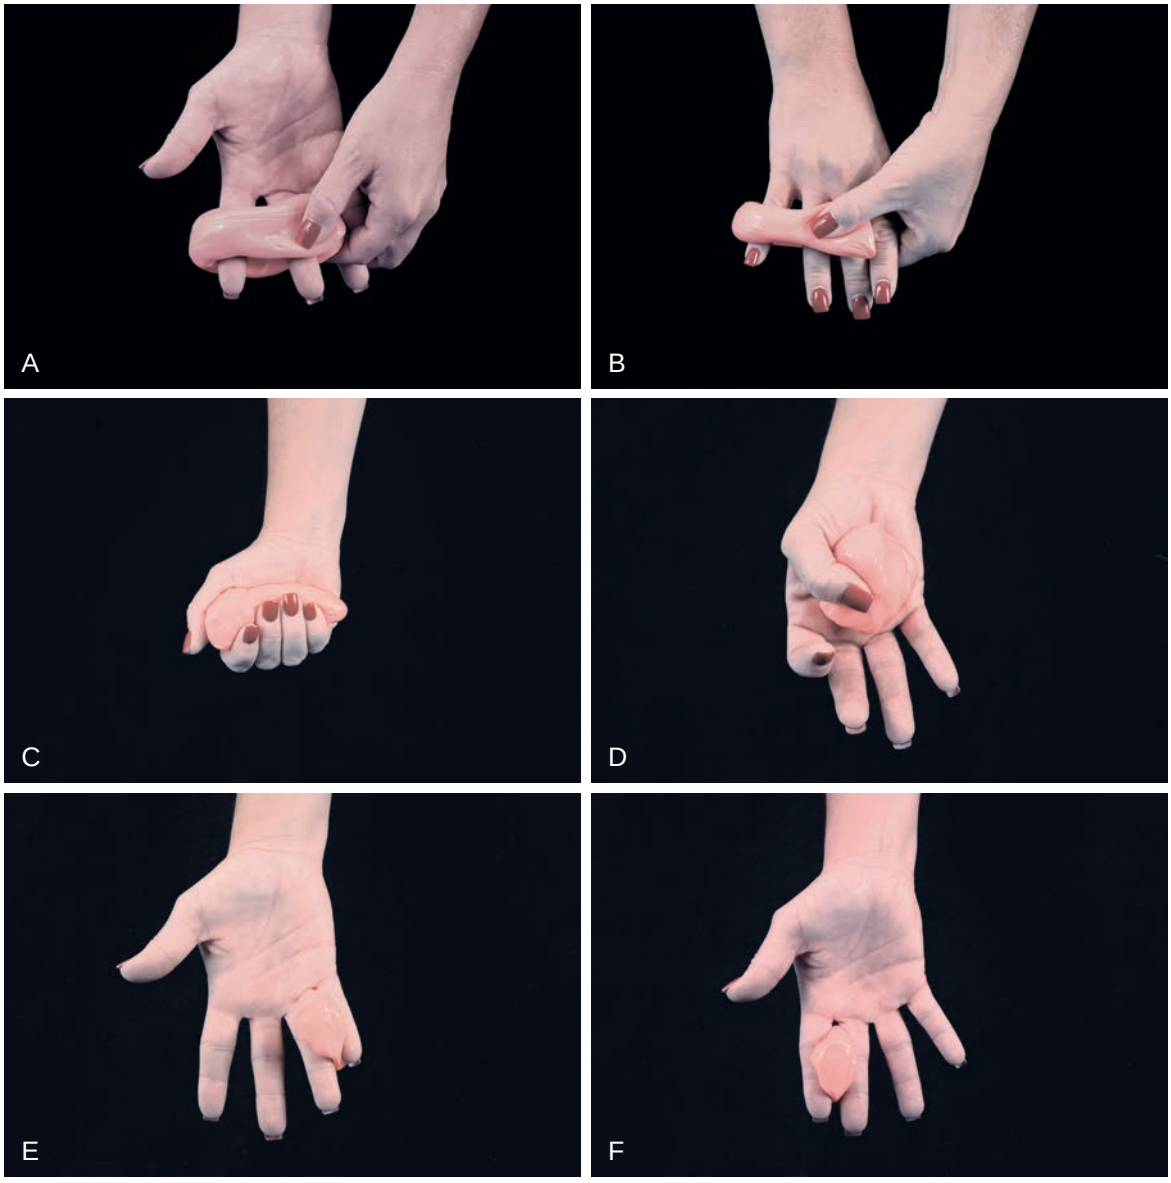

FIGURE 15-20. Interosseus Theraputty exercise. **A,** Volar view. **B,** Dorsal view. **C,** Grip Theraputty exercise. **D,** Thumb to fifth digit Theraputty exercise. **E,** Volar interosseus index finger Theraputty exercise. **F,** Volar interosseus small finger Theraputty exercise.

TIMELINE 15-2: **Postoperative Rehabilitation after Open or Arthroscopic TFCC and Carpal Ligament Repair** (Continued)

PHASE IV (weeks 10 to 14 postop)	PHASE V (weeks 14 to 24 postop)	PHASE VI (weeks 24 to 52 postop)

• TFCC repair:
  • Anticipate return to full activity week 12
  • Return to sport unprotected beginning week 14
• SL ligament (partial tear): screw/pin removal week 12, postoperative (screw removal) protect in removable splint
	• Active finger, grip, wrist and forearm strength
	• TBS/TAS/TLS activities as tolerated
		• SL ligament (complete): screw removal 5 to 6 months
		• SL ligament reconstruction:
		  • Screw removal 6 months
		  • Resume contact sports 6 months (protected)
		  • Resume contact sports 10 months (unprotected)

Techniques to Increase Muscle Strength, Power, and Endurance

- Theraputty exercises for hand intrinsic and extrinsic muscles if near pain free (Figure 15-20*A-F*)

Functional Exercises

- To be done only if near pain free
- Lifting and placing pegs or cones with forearm stabilized
- Dart thrower's motion (wrist extension + radial deviation to wrist flexion and ulnar deviation) while holding a small bottle or ball (Figure 15-21*A-C*).

Milestones for Progression to the Next Phase

- Pain-free AROM within available range of motion

Phase IV (postoperative weeks 10 to 14)

Goals

- Maintain a near pain free wrist
- 50% or better of normal grip strength
- 80% or better of normal active range of motion

Management of Pain and Swelling

- Cryotherapy ad lib
- Compressive tubular dressing for forearm, wrist, and fingers
- Active motion of the fingers, elbow, and shoulder

Techniques for Progressive Increase in Range of Motion

Manual Therapy Techniques

- Mobilization as needed

Other Therapeutic Exercises

- TBS/TAS/TLS as tolerated

Techniques to Increase Muscle Strength, Power, and Endurance

- Grip PREs

Milestones for Progression to the Next Phase

- 50% of normal grip

Phase V (postoperative weeks 14 to 24)

Goals

- 80% of normal grip strength or better
- 80% of normal wrist and forearm AROM

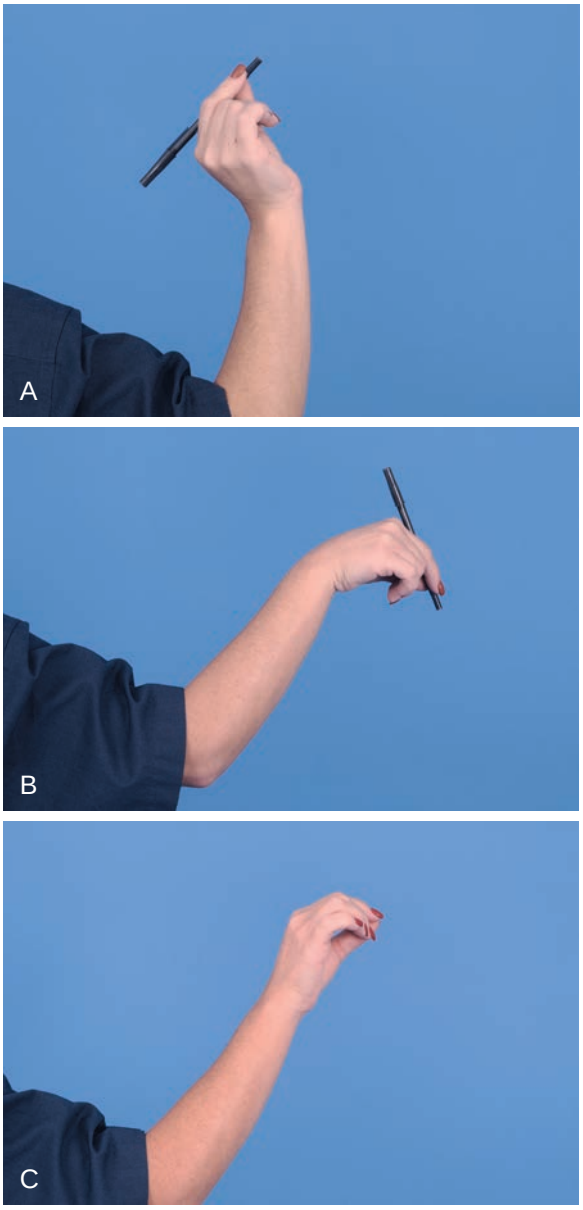

FIGURE 15-21. Dart thrower exercise. **A,** Initial phase. **B,** Midphase. **C,** End phase.

- Able to perform pain-free gentle conditioning for the upper extremity

Management of Pain and Swelling

- Cryotherapy ad lib

Techniques for Progressive Increase in Range of Motion

Manual Therapy Techniques

- Mobilization as needed

Stretching and Flexibility Techniques for the Musculotendinous Unit

- Stretching with gentle distraction for the wrist in all planes of motion

Other Therapeutic Exercises

- TBS/TAS/TLS as tolerated

Techniques to Increase Muscle Strength, Power, and Endurance

- Pain-free, light resistance/high repetition upper extremity conditioning using dumbbells with the wrist maintained in neutral

Plyometrics

- Medicine ball thrown against trampoline, starting with two hands and progressing to one hand
- Dart thrower's motion using ball with elastic band attached

Functional Exercises

- General pain free upper extremity conditioning using dumbbells with wrist in neutral, and with very low resistance and high repetitions

Milestones for Progression to the Next Phase

- Grip strength is 80% of normal

Phase VI (postoperative weeks 24 to 52)

Goals

- Full functional use of the hand, wrist, and upper extremity
- Able to return sport or work activity
- Near pain free with all activities

Management of Pain and Swelling

- Cryotherapy as needed

Techniques for Progressive Increase in Range of Motion

Manual Therapy Techniques

- Mobilization as needed

Other Therapeutic Exercises

- TBS/TAS/TLS as tolerated

Techniques to Increase Muscle Strength, Power, and Endurance

- Grip strengthening, TAS PREs

Plyometrics

- Medicine ball thrown against trampoline, starting with two hands and progressing to one hand

Milestones for Progression to the Next Phase

- Full return to sport or activity

Criteria for Return to Sport

- Involved wrist and upper extremity is near pain free with current exercise program
- 80% of normal AROM of the wrist and forearm
- 80% of normal grip strength of the involved upper extremity

After Return to Sport

Continuing Fitness or Rehabilitation Exercises

- Stretching and range of motion exercises as demonstrated in therapy to maintain supple joint and reduce chance of subsequent injury

Exercises and Other Techniques for Prevention of Recurrent Injury

- Minimize overpressure into extremes of wrist motion

Evidence

Anderson M, Moran S, Cooney W, et al: Clinical comparison of arthroscopic versus open repair of triangular fibrocartilage complex tears. *J Hand Surg* 33A:675–682, 2008.

This is a retrospective review of outcomes for surgical repair of traumatic, peripheral TFCC comparing open versus arthroscopic techniques performed within 4 months of injury. This series assessed the results of treatment for 76 patients, 37 treated with arthroscopic management and 39 treated with open surgical management, with an average age of 32. Mean follow-up of 43 months demonstrated no significant difference in outcomes. Mayo Modified Wrist Score, DASH, VAS, and Patient Reported Wrist Evaluation score between open and arthroscopic surgical techniques with improvement in these outcomes noted for both approaches. Less postoperative loss of wrist motion noted after arthroscopic treatment.

Darlis N, Weiser R, Sotereanos D: Partial scapholunate ligament injuries treated with arthroscopic debridement and thermal shrinkage. *J Hand Surg* 30A(5):908–914, 2005.

This is a retrospective review of 16 patients treated with arthroscopic debridement and thermal shrinkage of the scapholunate ligament for Griessler grade 1 or 2 instability. Patients, average age 34 years old, were treated at mean interval of 5.4 months from injury to surgery after an unsuccessful trial of conservative treatments. At 19 months postoperative 87% of patients reported substantial pain relief. Marginal improvement in wrist flexion and significant improvement in grip strength was noted. There was no evidence of radiographic instability and 90% of patients reporting excellent or good outcomes at 19 months with no complications reported.

McAdams T, Swan J, Yao J: Arthroscopic treatment of triangular fibrocartilage wrist injuries in the athlete. *Am J Sports Med* 37(2):291–297, 2009.

This is a case series reviewing the arthroscopic repair or debridement of sixteen athletes between the years of 2001 and 2005, with an average follow-up of 32.8 months. Mean mini-DASH scores improved from 47.3 to 0 and mini-DASH sports module improved from 79.9 to 1.95. Return to play averaged 3.3 months.

Rettig A: Athletic injuries of the wrist and hand: Part I: traumatic injuries of the wrist. *Am J Sports Med* 31:1031, 2003.

This is a review of hand and wrist injuries associated with sports reviewing the cause of such injuries as well as the biomechanical findings with respect to the range of motion required in different sports. Emphasis is placed on problematic traumatic injuries such as carpal scaphoid fractures and hook of the hamate fractures as well as ligament injuries to the wrist with regard to diagnosis, treatment, and return to athletic competition.

Steinberg B: Acute wrist injuries in the athlete. *Orthop Clin North Am* 33:535–545, 2002.

This is a review of common wrist injuries encountered in the athlete, including a review of pertinent anatomy, diagnosis, and treatment of injuries including scaphoid, carpal, and distal radius fractures. The diagnosis and treatment of various ligamentous injuries are also reviewed.

Whipple T, Geissler W: Arthroscopic management of wrist triangular fibrocartilage complex injuries in the athlete. *Orthopedics* 16(9):1061–1067, 1993.

This is a review of Triangular Fibrocartilage Complex injuries, biomechanics of injury, diagnosis, and classification of these injuries. A review of surgical techniques including equipment and techniques for the debridement and repair of TFCC injuries, as well as the expected results of treatment.

Multiple-Choice Questions

QUESTION 1. When should range of motion begin after debridement of TFCC injuries?

A. Immediately as tolerated
B. 4 weeks postoperatively
C. 6 weeks postoperatively
D. 12 weeks postoperatively

QUESTION 2. When should grip strength and ROM training commence after arthroscopic treatment of partial scapholunate ligamentous injuries?

A. Immediately as tolerated
B. 6 weeks postoperatively
C. 12 weeks postoperatively
D. 20 weeks postoperatively

QUESTION 3. When should return to contact sports (unprotected) be allowed in patients undergoing SL ligament reconstruction?

A. As soon as patient obtains pain-free range of motion
B. 6 weeks postoperative
C. 12 weeks postoperative
D. 6 months postoperative

Answer Key

QUESTION 1. Correct answer: **A** (see Postoperative Rehabilitation Protocol week 0 to 2)

QUESTION 2. Correct answer: **B** (see week 4 to 6)

QUESTION 3. Correct answer: **D** (see After Surgery-Postoperative Rehabilitation: Overview of goals, important milestones and guidelines.)

Chapter 16

Jersey Finger and Mallet Finger

INTRODUCTION

A. Lee Osterman MD, Abdo Bachoura MD, Sidney M. Jacoby MD,
Terri M. Skirven OTR/L, CHT, and Jason A. Suda MOTR/L

Epidemiology

Age/Sex

- Age: Predominantly in young, active individuals involved in contact sports
- Mallet finger
  - Definition: a finger injury that involves damage to the terminal extensor tendon insertion on the dorsal aspect of the distal phalanx, resulting in inability to actively extend the distal interphalangeal joint (Fig. 16-1)
  - Predominantly in young active males involved in contact sports
  - Males 1.5 times more affected than females in the general population
    - In a study by Simpson et al.[1] 851 patients presented with acute sport injuries. 18 presented with Mallet injuries, and 17 of these were men.
    - Incidence 10 to 19 year old males 1.2/10,000 per year
    - Incidence 10 to 19 year old females 0.5/10,000 per year
    - Incidence 20 to 29 year old males 1.5/10,000 per year
    - Incidence 20 to 29 year old females 0.4/10,000 per year
    - Incidence 30 to 39 year old males 1.3/10,000 per year
    - Incidence 30 to 39 year old females 0.5/10,000 per year
- Jersey finger
  - Definition: a finger injury that involves damage to the flexor digitorum profundus tendon, resulting in inability to actively flex the distal interphalangeal joint (Fig. 16-2)
  - Sex: predominantly in males, although female involvement has also been reported

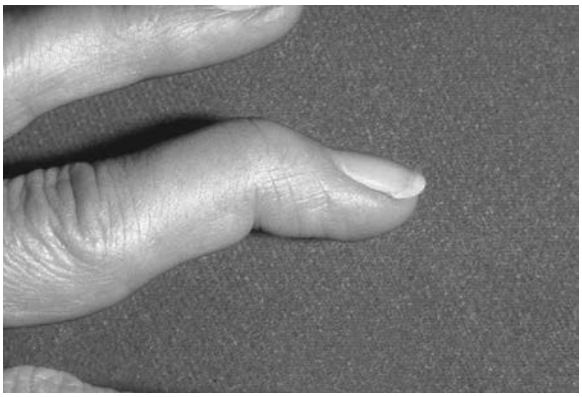

FIGURE 16-1. Small finger mallet injury characterized by loss of active extension at the DIP joint with resting posture of the DIP joint in flexion. *(Reprinted with permission from Hart RG, Kleinert HE, Lyons K: The Kleinert modified dorsal finger splint for mallet finger fracture. Am J Emerg Med 23:145–148, 2005.)*

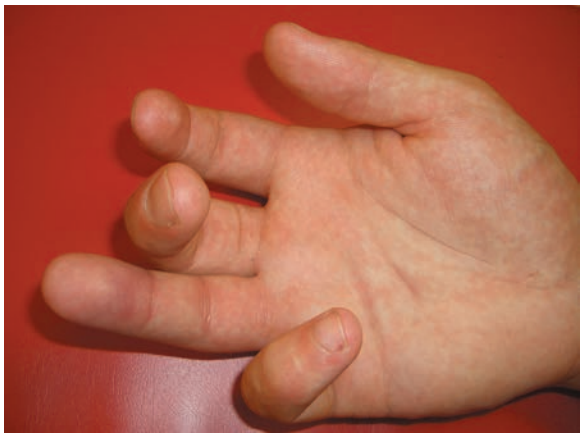

FIGURE 16-2. Jersey finger injury seen in the ring digit, causing inability to flex the DIP joint and make a full fist. *(Courtesy of Mr. Michael Hayton, MB.ChB, FRCS.)*

Sport

- Mallet finger
  - Any contact sport such as softball, baseball, football, basketball, or soccer in which the hand is subjected to force from a ball or another player
  - In most instances, the player's distal phalanx is subjected to some type of crush injury (often resulting in a distal phalanx fracture) or the distal interphalangeal joint (DIP) is forced into flexion (often resulting in a rupture of the terminal extensor tendon with or without a chip of bone).
- Jersey Finger
  - Mainly football and rugby
  - Any contact sport in which the athlete's hand is subjected to blunt forces from a ball or other player. It is seen in sports wherein an athlete's finger is forced into extension while trying to maintain a flexed position (i.e., rock climbing or when an athlete grabs another player's jersey who then quickly breaks away)
- Injury is common in any full contact sports, but mallet and jersey fingers represent a small number of traumatic injuries that occur in these sports.
- Rugby is still growing in popularity in the United States. As such, research is still lacking in the area. However, in high school students "rugby appears to have a lower injury rate than ice hockey, higher injury rates than basketball and soccer, and similar injury rates to football and wrestling."[2]

Position

- Mallet finger
  - Fielders in baseball and softball, receivers in football, goalkeeper in soccer
- Jersey finger
  - Defensive players involved in tackling
- Because of the nature of rugby, all playing positions require tackling. As such, it does not appear that any playing position results in a higher incidence of jersey or mallet finger injuries. The authors do not know of any literature that reports the predominance of these injuries with any specific position in rugby.

Pathophysiology

Intrinsic Factors

- Mallet finger
  - Extensor tendon insertion as the terminal tendon on the base of the dorsal aspect of the distal phalanx
- Jersey finger
  - The ring finger is the most frequently involved because it has the least independent motion, has a weaker flexor tendon insertion than the long finger, and absorbs most of the force during grip.

Extrinsic Factors

- Mallet Finger
  - The distal location of the finger tip
  - Catching a ball flying at a high velocity
  - Poor catching form or a lack of concentration during catching may contribute to this form of injury
- Jersey Finger
  - The player gets his or her finger caught in a jersey of a strong fabric worn by another player.
- Quarrie et al.[3] studied risk factors for injury in rugby players. They found the following factors to be associated with injury rate or time lost to injury: being in a higher grade, cigarette smoking, a history of prior injury, and a body mass index greater than 26.5. This study focused on general injuries of rugby players; it is speculated that similar factors would contribute to flexor or mallet finger in rugby players.

Traumatic Factors

- Mallet Finger
  - Can often occur when any type of force pushes the extended DIP joint into flexion. As the player extends his/her fingers to catch an incoming ball, the ball strikes the fingertips, forcing sudden flexion of the DIP joint.
  - Sudden flexion will lead to avulsion of the extensor tendon off the dorsal surface of the distal phalanx.
  - Can also occur when an athlete hits the distal end of his finger against another player, ground, or any other solid object.
- Jersey Finger
  - Forced hyperextension of the DIP joint while the finger is actively flexing.
  - The flexor digitorum profundus (FDP) tendon is avulsed off the volar surface of the distal phalanx
  - Often associated with an eccentric load on the flexed DIP joint. This is often seen when a player grabs another player's jersey who quickly pulls away, hence the name "Jersey Finger."

Classic Pathological Findings

- Mallet finger
  - Doyle[4] classified mallet finger into four types:
    - Type I: Closed trauma with loss of tendon continuity with or without avulsion fracture
    - Type II: Laceration at distal interphalangeal joint with loss of tendon continuity
    - Type III: Deep abrasion with loss of skin, subcutaneous tissue and tendon substance
    - Type IVA: Transepiphyseal fracture in children
    - Type IVB: Fracture fragment of the articular surface involving 20% to 50% of the distal phalanx
    - Type IVC: Hyperextension injury with articular fracture >50% the distal phalanx joint surface
  - Avulsion of the extensor tendon off its insertion on the base of the dorsal distal phalanx (also known as a soft tissue mallet)
  - An intraarticular bony fragment may or may not be avulsed at the insertion of the extensor mechanism (also known as a bony mallet).
  - As a result, a patient with mallet finger will have no active extension of the DIP joint and will have a significant extensor lag (see Fig. 16-1).

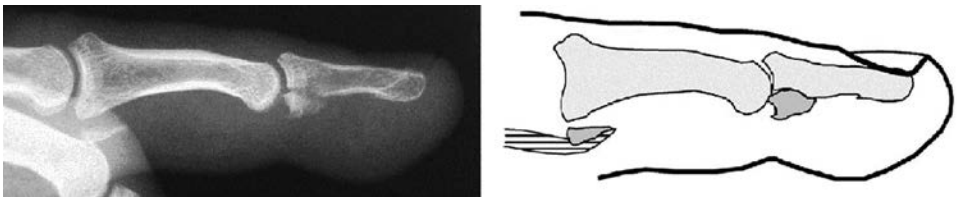

FIGURE 16-3. Type 3 Jersey finger: The avulsed tendon has a large bony fragment attached and is at the level of the A4 pulley. *(Reprinted with permission from Kang N, Pratt A, Burr N: Miniplate fixation for avulsion injuries of the flexor digitorum profundus insertion. J Hand Surg Br 28:363–368, 2003).*

- Jersey finger
  - Avulsed FDP with or without a bone fragment
  - Retraction of the FDP to a various degree
  - Ruptured vincula disrupts nutrition to the tendon
  - Muscle contraction occurs within ten days, making it difficult, if not impossible to regain original tendon length
  - Tendon sheath scarring occurs within 7 to 10 days of injury
  - There are five types of jersey finger:
    - Type I: The avulsed tendon retracts to the level of the palm. With this, the vinculum blood supply is often disrupted.
    - Type II: The avulsed tendon retracts to the proximal interphalangeal (PIP) joint. The vinculum blood supply stays intact.
    - Type III: The avulsed tendon has a large bony fragment attached and is at the level of the A4 pulley (Fig. 16-3).
    - Type IV: A combination of bone avulsion and a separate tendon avulsion. The FDP can then retract to flexor sheath or to the palm.
    - Type V: A combination of bony avulsion and a comminuted distal phalangeal fracture
  - A patient with jersey finger will have weakened grip strength and will show no active DIP motion with manual muscle testing of the FDP of the involved finger.

Clinical Presentation

History

- Mallet finger
  - Patient unable to straighten the DIP joint of the involved finger (see Fig. 16-1)
  - Pain over the DIP joint is usually present.
  - May be painless
  - Finger swelling
- Jersey finger
  - The patient often feels a pop in the finger.
  - Pain over the DIP joint may or may not be present.
  - Finger bruising may or may not be present.
  - Patients are unable to flex the DIP joint and cannot make a complete fist because the injured finger cannot flex to the palm.
- In both of the injuries, the patient often reports feeling a "pop" in the finger.
- Both injuries can result from blunt trauma to the hand. This can be the athlete's hand hitting the ball or while tackling or grappling with another player.
- Most players will continue to play the game despite the injury reporting "I just thought I jammed my hand."

Physical Examination

Abnormal Findings

- Mallet Finger
  - Loss of active DIP joint extension
  - Swelling, tenderness, and ecchymosis over the dorsal aspect of the DIP joint
  - Resting posture of DIP joint in flexion
  - Proximal interphalangeal PIP joint hyperextension can appear with attempts to extend the DIP joint, particularly in individuals with joint laxity
  - May observe a subungual hematoma in the nail of the involved finger
- Jersey finger
  - Inability to actively flex the DIP joint (see Fig. 16-2)
  - Swelling and ecchymosis over the DIP joint can be observed.
  - Tenderness can be elicited over the DIP joint.
  - Jersey Finger can sometimes involve hyperextension of the DIP joint owing to lack of balance between the flexor and extensor.
  - Limited PIP flexion can also be seen if the FDP retracts to the PIP joint. If the FDP retracts even further to the palm the athlete may then report tenderness in the palm.
  - Inability to make a fist

Pertinent Normal Findings

- Mallet Finger
  - Active flexion of the DIPJ is maintained.
  - Usually a closed injury with no break in the skin
  - Capillary refill should be normal.
  - Sensation in the fingertip should be intact.
- Jersey Finger
  - Active extension of the DIP joint is maintained.
  - Usually a closed injury without a break in the skin
  - Capillary refill should be normal, less than 2 seconds.
  - Sensation in the tip of the finger should be intact.

Imaging

- Mallet finger
  - Standard posteroanterior, oblique, and lateral x-rays of the involved finger should be sufficient to determine whether bone avulsion has occurred.
- Jersey finger
  - Standard posteroanterior, oblique, and lateral x-rays of the involved finger should be sufficient to determine whether bone avulsion has occurred.

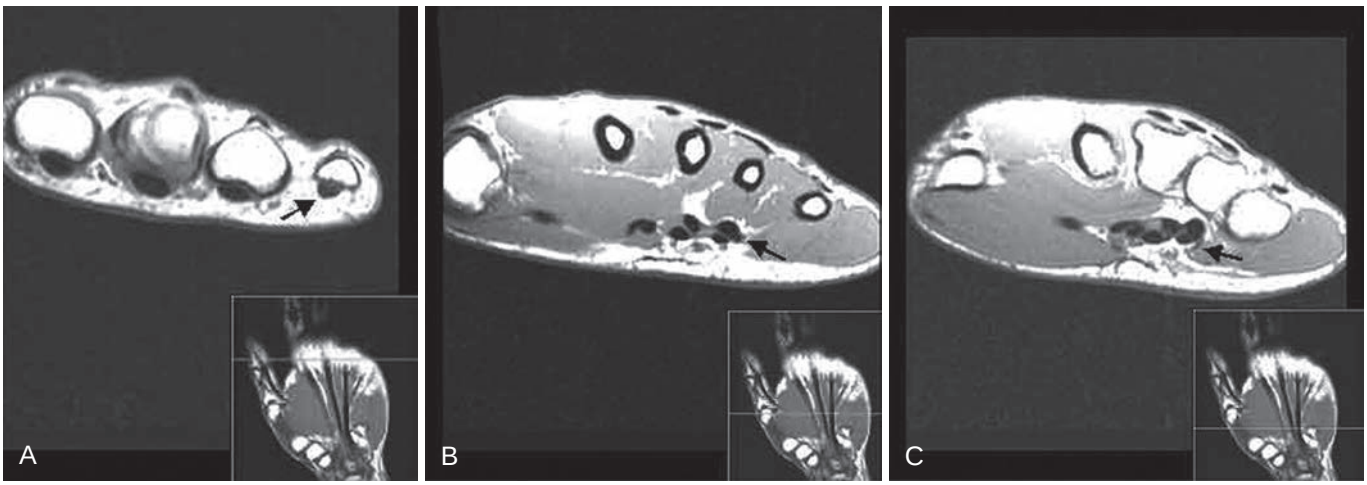

FIGURE 16-4. MRI and ultrasound of chronic jersey finger helping to determine the level of tendon retraction. *(Reprinted with permission from Masaki F, Isao T, Aya Y, Ryuuji I, Yohjiroh M: Spontaneous flexor tendon rupture of the flexor digitorum profundus secondary to an anatomic variant. J Hand Surg Am 32:1195–1199, 2007).*

- For chronic jersey finger injuries ultrasound or MRI can be useful because they can help determine the level of tendon retraction (Fig. 16-4).

Differential Diagnosis

- Mallet finger
  - Transverse distal phalangeal fracture: Radiographic findings can determine the type and nature of the distal phalangeal fracture.
  - Seymour's fracture: Open fracture through the nail bed especially in children with active growth plates. Careful physical exam and radiographs can rule out this type of frequently missed injury (Fig. 16-5).

FIGURE 16-5. Pediatric Seymour's fracture. *(Reprinted with permission from Al-Qattan MM: Extra-articular transverse fractures of the base of the distal phalanx (Seymour's fracture) in children and adults. J Hand Surg Br 26:201–6, 2001).*

  - PIP joint volar injury and/or laxity resulting in Swan neck deformity with hyperextension of the PIP joint and flexed posture of the DIP joint (Fig. 16-6)
- Jersey Finger
  - Transverse distal phalangeal fracture: Radiographic finding can determine the type and nature of the distal phalangeal fracture.

Treatment

Nonoperative Management

- Mallet finger
  - Volar or dorsal orthotic positioning of the DIP joint in full extension for 2 to 6 months, depending on the extent of injury and patient progress (Fig. 16-7).
  - Most mallet injuries can be treated with orthoses.
  - Insufficient evidence to support superiority of a specific type of orthosis.
- Jersey finger
  - Jersey finger cannot be corrected without surgery, but an athlete can still have a high level of functioning

FIGURE 16-6. PIP joint volar injury and/or laxity resulting in Swan neck deformity with hyperextension of the PIP joint and flexed posture of the DIP joint (see Fig. 16-5).

FIGURE 16-7. Mallet finger orthosis positioning the DIP joint in extension.

without active flexion of the DIP joint. However, the long-term consequences must be weighed before making this decision.
- Nonsurgical management after injury includes early mobilization emphasizing range of motion exercises.

Guidelines for Nonoperative Treatment

- Mallet Finger
  - Closed injury
  - No bony avulsion
  - Bony avulsion that is minimally displaced and is less than 30% of the articular surface of the distal phalanx
  - Patient's ability to understand and comply with the orthotic use protocol
- Jersey finger
  - Nonsurgical treatment is reserved for chronic injuries or in those individuals who are either unwilling or unable to comply with a vigorous postoperative therapy protocol.
  - Nonsurgical management requires the patient's understanding of the permanent loss of active DIP joint flexion.

Surgical Indications

- In general, jersey finger is treated surgically when diagnosed without delay.

Absolute

- Mallet finger
  - Open injuries
  - Closed fracture with more than 30% of the articular surface displaced (Fig. 16-8)
- Jersey finger
  - Open Injuries
  - Diagnosis is made early and surgery can be performed within 7 to 10 days of injury, although there are reports of successful repair in injuries outside this window of injuries.
  - Types 1 to 5 injuries

Relative

- Mallet finger
  - Chronic injuries, more than 6 months old that have failed conservative treatment
  - Demand for faster recovery and earlier return to function
  - Cosmetic preferences
  - Poor patient compliance
- Jersey finger
  - Chronic injuries

Aspects of History, Demographics, or Exam Findings that Affect Choice of Treatment

- Mallet finger
  - Patient age
  - Hand dominance
  - Patient occupational demands
  - Cosmetic preferences: Surgical treatment may lead to an improved cosmetic appearance.
  - Recovery period: Surgical treatment often leads to a faster recovery and less daily impedance as a result of no splint wear.
- Jersey finger
  - The time elapsed since injury
  - Within 7 to 10 days of injury the injured tendon retracts and scars, rendering surgical treatment less effective.
  - Size of bony fragment
  - Extent of proximal retraction of the tendon
  - Age
  - Patient demand

Aspects of Clinical Decision Making When Surgery is Indicated

- Mallet finger
  - Degree of bony displacement
  - Acuity or chronicity of the injury
  - Patient age and growth plate status
- Jersey finger
  - Type of jersey finger seen (Pathophysiology section)

FIGURE 16-8. Mallet fracture: bony avulsion that is minimally displaced and is less than 30% of the articular surface of the distal phalanx. *(Reprinted with permission from Zhang X, Meng H, Shao X, Wen S, Zhu H, Mi X: Pull-out wire fixation for acute mallet finger fractures with k-wire stabilization of the distal interphalangeal joint. J Hand Surg Am 35:1864–1869, 2010.)*

Evidence

Mallet Finger

Al-Qattan MM: Extra-articular transverse fractures of the base of the distal phalanx (Seymour's fracture) in children and adults. *J Hand Surg Br* 26(3):201–206, 2001.

This case series looked at 25 adult and pediatric patients who sustained a Seymour open fracture, which presents clinically as a mallet injury and a nail plate injury and must be ruled out. (Level IV evidence)

Clayton RA, Court-Brown CM: The epidemiology of musculoskeletal tendinous and ligamentous injuries. *Injury* 39(12):1338–1344, 2008.

This study, set in the UK, describes the epidemiology of a range of adult musculoskeletal soft tissue injuries in a well-defined catchment population of about 535,000. Demographic details over 5 years were recorded prospectively. Eighteen ligamentous injury types were studied including mallet finger and data was stratified according to age group and sex. (Level IV evidence)

Handoll HH, Vaghela MV: Interventions for treating mallet finger injuries. *Cochrane Database Syst Rev* (3):CD004574, 2004.

This review looked at randomized or quasi-randomized clinical trials evaluating different interventions, including no intervention for treating mallet finger injuries, and included four trials that involved 283 mallet finger injuries. The authors concluded that there was insufficient evidence to establish the relative effectiveness of different, either custom-made or off-the-shelf, finger splints used for treating mallet finger injury. (Review)

Pike J, Mulpuri K, Metzger M, et al: Blinded, prospective, randomized clinical trial comparing volar, dorsal, and custom thermoplastic splinting in treatment of acute mallet finger. *J Hand Surg Am* 35(4):580–588, 2010.

This prospective, randomized study of 87 with Type I mallet finger injuries randomized the patients to three conservative treatment groups: volar padded aluminum splint, dorsal padded aluminum splint, and custom thermoplastic. No lag differences were demonstrated radiographically after 12 weeks (Therapeutic Level II evidence).

Simpson D, Queen MM, Kumar P: Mallet deformity in sport. *J Hand Surg Br* 26B(1):32–33, 2001.

This article describes cases of acute sporting injuries that were treated at an orthopedic trauma unit, in a 4-month time period. Mallet finger made up a small amount of cases seen and did have excellent functional outcomes. (Level IV evidence)

Wehbe MA, Schneider LH: Mallet fractures. *J Bone Joint Surg Am* 66A(5):658–669, 1984.

In this retrospective study, 21 patients who had bone-involved mallet finger injuries were treated either conservatively or surgically. Mean follow up was 3.25 years. Radiographic assessment revealed that bone remodeling and reconstitution of the articular surface and preservation of the joint space in all digits. In addition, there was a near-normal range of painless motion in all but one finger. Surgical treatment offered no advantage over splinting and introduced more morbidity. The authors subsequently concluded that "most mallet fractures can be treated conservatively, ignoring joint subluxation and the size and amount of displacement of the bone fragment." (Level IV evidence)

Zhang X, Meng H, Shao X, et al: Pull-Out Wire Fixation for Acute Mallet Finger Fractures With K-Wire Stabilization of the Distal Interphalangeal Joint. *J Hand Surg Am* 35A(11):1864–1869, 2010.

The aim of this study was to describe and assess a surgical technique for the treatment of mallet finger fractures using a pull-out wire with K-wire stabilization of the distal interphalangeal (DIP) joint in extension. (Level IV evidence)

Jersey Finger

Evans RB: A study of the zone 1 flexor tendon injury and implications for the treatment. *J Hand Ther* 3(3):133–148, 1990.

This article describes early motion protocol for patients who have had surgical repair of Zone 1 Flexor tendon injuries then reviews the clinical results. (Level IV evidence)

Evans RB: Zone I flexor tendon rehabilitation with limited extension and active flexion. *J Hand Ther* 18(2):128–140, 2005.

This study looks at the outcomes for 41 patients who had surgical repairs of Zone 1 FDP tendon injuries. Surgery was followed by therapy in which the patient performed an early active flexion protocol with limited extension. These patients were followed for 10 years and showed a mean total active range of motion that was 81% of their normal motion. (Level IV evidence)

Kang N, Pratt A, Burr N: Miniplate fixation for avulsion injuries of the flexor digitorum. *J Hand Surg Br* 28B(4):363–368, 2003.

This article describes the use of a miniplate and cortical screws in the treatment of five cases of flexor digitorum profundus (FDP) tendon avulsion. One case was type II, three cases were type III, and one case was type IV. Near normal joint congruity was restored together with bony union in all cases. Six months after surgery four cases had near normal range of motion at the distal interphalangeal joint compared with the contralateral uninjured finger. These four patients were to return to their previous activities without restriction by 3 months. One repair of a type III avulsion ruptured but the distal interphalangeal joint was pain free and stable and the patient declined further surgery. Miniplate fixation offers some advantages over existing methods of repair and adds to the range of techniques available for reattachment of the FDP tendon in these injuries. (Level IV evidence)

Leddy JP, Packer JW: Avulsion of the profundus tendon insertion in athletes. *J Hand Surg Am* 2A(1):66–69, 1977.

This article looked at 36 jersey fingers retrospectively and developed the early classification system for flexor tendon avulsion injuries (Types 1, 2, and 3). The authors found that Type 1 injuries should be repaired within 7 days, whereas Type 2 injuries can be repaired within a few months. They suggested that prompt diagnosis and surgical repair within 1 week result in the best outcomes. (Level IV evidence)

Lunn PG, Lamb DW: "Rugby finger"—avulsion of profundus of ring finger. *J Hand Surg Br* 9B(1):69–71, 1984.

This is a study of nine patients who sustained an isolated avulsion injury of the FDP tendon, all to the ring finger while playing rugby. The patients all presented later than 4 weeks and were treated surgically with palmaris tendon grafting, followed by 6 to 9 weeks of physiotherapy. The mean follow up was 4.3 years and hand function improved in all cases. The authors subsequently recommended that experienced surgeons should use this technique for the treatment of young and motivated patients. (Level IV evidence)

Masaki F, Tasaki I, Aya Y, et al: Spontaneous flexor tendon rupture of the flexor digitorum profundus secondary to an anatomic variant. *J Hand Surg Am* 32A(8):1195–1199, 2007.

This is a case report of flexor digitorum profundus tendon rupture of the little finger, which was predisposed by an anatomic variation of the tendon. Intraoperative findings and magnetic resonance imaging of the opposite hand suggested that the flexor digitorum profundus tendons of the ring and the little finger bifurcated. The patient had tendon reconstruction and regained function. (Level of evidence: Case report)

Sawaya ET, Choughri H, Pelissier P: One-stage treatment of delayed 'jersey finger' by z-step lengthening of the flexor digitorum profundus tendon at the wrist. *J Plast Reconstr Aesthet Surg* 65(2):264–266, 2012.

This is one of a few case reports on FDP tendon avulsions in females. The authors presented a case of a 19 year old female who had acquired a Type 2 injury 6 weeks prior to presentation. She was successfully treated surgically by z-step lengthening of the FDP at the wrist. (Level of evidence: Case report).

Tuttle HG, Olvey SP, Stern PJ: Tendon avulsion injuries of the distal phalanx. *Clin Orthop Relat Res* 445:157–168, 2006.

This is one of the latest review articles about jersey finger. The authors concisely summarized the current FDP tendon avulsion classification system (Types 1 to 5). (Review)

Wenger DR: Avulsion of the profundus tendon insertion in football players. *Arch Surg* 106:145–149, 1973.

This case series looked at four teenage American football players that acquired FDP avulsion injuries to the ring finger; three of the four injuries were in defensive players. One of the players did not experience any pain. The author warned that the diagnosis may be delayed if physicians that deal with athletes are not aware of FDP avulsion injuries. (Level IV evidence)

Rugby Injuries

Collins CL, Micheli LJ, Yard EE, et al: Injuries Sustained by high school rugby players in the United States, 2005-2006. *Arch Pediatr Adolesc Med* 162(1):49–54, 2008.

This article describes the incidence and characteristics of injuries among US high school rugby players and identifies possible injury risk factors. (Level 4 evidence)

Quarrie KL, Alsop JC, Waller AE, et al: The New Zeland Rugby injury and performance project. VI. A prospective cohort study of risk factors for injury in rugby union football. *Br J Sports Med* 35(3):157–166, 2001.

This article examines the association between potential risk factors and injury risk. Using a multiple regression model to study a prospective cohort of 258 male rugby players, the authors concluded that previous injury is a predictor of injury incidence and of missing play. (Level 2 evidence)

Multiple-Choice Questions

Mallet Finger

QUESTION 1. What kind of fingertip injury clinically presents similar to a mallet finger and should be ruled out immediately because of its potential for causing complications?

A. Transverse fracture of the distal phalanx
B. Jersey finger
C. Seymour's fracture
D. Subungual hematoma

QUESTION 2. Most mallet injuries can be treated with

A. open reduction and internal fixation.
B. splinting.
C. percutaneous pinning.
D. observation.

QUESTION 3. A surgeon may perform surgery to treat a mallet injury if

A. the injury occurred 1 month prior to presentation.
B. the injury occurred 6 months prior to presentation.
C. the patient demands surgery because he/she has read that surgery results in better cosmetic outcomes.
D. the injury involves 35% of the articular surface of the distal phalanx and was displaced.

QUESTION 4. Mallet finger injures are characterized by

A. loss of passive DIP joint extension.
B. resting posture of PIP joint hyperextension.
C. loss of active DIP joint extension.
D. inability to flex the DIP joint.

QUESTION 5. Mallet finger injuries are most often treated with

A. 3 weeks of nighttime splinting.
B. DIP joint ROM exercises and taping.
C. 6 to 8 weeks of uninterrupted DIP joint extension splinting.
D. splinting of the DIP and PIP joints for 1 month during the day.

Jersey Finger

QUESTION 6. Acute flexor digitorum profundus avulsion injuries should be treated surgically as early as possible because

A. tendon sheath scarring tends to occur within 7 to 10 days of injury.
B. tendon retraction and myostatic contraction can permanently shorten the tendon.
C. rupture of the vincula disrupts the transport of nutrition to the tendon.
D. All of the above

QUESTION 7. The Ring finger is the most frequently involved digit in jersey finger because

A. the ring finger has the least independent motion.
B. the ring finger has a weaker FDP insertion compared to the long finger.
C. the ring finger absorbs most of the force during grip.
D. All the above

QUESTION 8. What factor is the least important when planning a surgery for jersey finger?

A. Hand dominance
B. The duration since injury
C. The level of tendon retraction
D. The size of the bony fragment

Answer Key

QUESTION 1. Correct answer: **C** (see Differential Diagnosis)

QUESTION 2. Correct answer: **B** (see Treatment)

QUESTION 3. Correct answer: **D** (see Surgical Indications)

QUESTION 4. Correct answer: **C** (see Classic Pathological Findings)

QUESTION 5. Correct answer: **C** (see Treatment.)

QUESTION 6. Correct answer: **D** (see Aspects of History, Demographics, or Exam Findings that Affect Choice of Treatment)

QUESTION 7. Correct answer: **D** (see Pathophysiology: Intrinsic Factors)

QUESTION 8. Correct answer: **A** (see Aspects of History, Demographics, or Exam Findings that Affect Choice of Treatment)

NONOPERATIVE REHABILITATION FOR MALLET FINGER

A. Lee Osterman, MD, Abdo Bachoura MD, Sidney M. Jacoby, MD, Terri M. Skirven, OTR/L, CHT, and Jason A. Suda, MOTR/L

GUIDING PRINCIPLES OF NONOPERATIVE REHABILITATION

JERSEY FINGER

- Surgery is required to restore active DIP joint flexion
- Nonoperative management addresses:
  - Postinjury swelling
  - Limitations in range of motion of the adjacent joints and digits
  - Loss of full grip function

MALLET FINGER

- Late management does not preclude successful outcome of nonoperative management. People treated 4 months after injury did as well as an early-treatment group (2 months out).[1]
- Type of mallet injury (i.e., bony versus soft)
- Doyle's classification of mallet injury
  - Type I: Closed trauma with loss of tendon continuity with or without avulsion fracture
  - Type II: Laceration at distal interphalangeal joint with loss of tendon continuity
  - Type III: Deep abrasion with loss of skin, subcutaneous tissue, and tendon substance
  - Type IVA: Transepiphyseal fracture in children
  - Type IVB: Fracture of articular surface of 20% to 50% hyperflexion injury
  - Type IVC: Hyperextension injury with articular fracture
  - Condition of proximal joints (i.e., hyperextension of PIP joint or secondary swan neck deformity)
  - Patient compliance
  - Open or closed injury
  - Associated injuries

Phase I (weeks 0 to 6 ± 2): Bony Mallet Injuries Will Heal Faster than Soft Tissue Mallet Injuries

Protection

- Custom fabricated DIP joint extension orthosis (Fig. 16-9)
  - Can include a PIP joint hyperextension block when mallet injury is accompanied by a swan neck deformity (Fig. 16-10)
- Additional Coban wrap to secure splint as needed

Management of Pain and Swelling

- Can include if needed 2 to 4 days after injury:
  - Compressive wraps
  - Ice

FIGURE 16-9. Orthosis for mallet finger supports the DIP joint in full extension to mild hyperextension.

FIGURE 16-10. Orthosis for a mallet finger with secondary swan neck deformity. The orthosis blocks the PIP joint from full extension and maintains the DIP joint in full extension to slight hyperextension.

Techniques for Progressive Increase in Range of Motion

- PIP and MP ROM of the involved digit with DIP splint in place
- No DIP ROM during phase I
- ROM of all uninvolved digits
- Isometric extension of DIP joint while in the splint
- Some players return immediately to play; however, they play with the mallet splint taped to secure it to the finger.
  - Players are reminded that if the splint falls off they will have to start the immobilization process all over.
- With splint in place the patient may continue total body strengthening, core stability, total arm/leg strengthening, any cardiovascular activity
- No participation in contact drills
- The patient may resume all practice activities as long as splint stays in place; however, the athlete is encouraged to avoid contact drills in which the hand may be grabbed and the splint pulled off. Because the injury is only at the level of the distal end of the finger a rugby player will find he or she can participate in most noncontact drills and activities the player was involved with prior to their injury.

Milestones for Progression to the Next Phase

- Adherence to continuous splinting program in phase I
- Absence of extensor lag or droop with splint off by week 6 to 8
- Ability to actively extend or maintain DIP extension with the splint off by week 6 to 8

TIMELINE 16-1: Nonoperative Rehabilitation of Mallet Finger

PHASE I (weeks 1 to 6 to 8)	PHASE II	
	(weeks 6 to 8 to 10)	(weeks 10 to 12)
• Use of custom fabricated DIP joint orthosis with DIP joint in full extension to slight hyperextension • Patient education regarding importance of uninterrupted orthosis use/splint use • Patent education regarding skin care and hygiene while maintaining the DIP joint in extension • AROM exercise of the PIP joint and the MCP joint • Stabilization of the MCP joint during PIP joint exercises (blocking) • Isometric extension of the DIP joint within the orthosis/splint • Reinforce splint security using tape or Coban when sleeping and during activities as needed. • Regular follow-up visit to therapist for monitoring of orthosis fit, skin condition, ROM of the uninvolved joints and protocol compliance • Can engage in noncontact sports with additional tapping to secure splint.	• If no extensor lag, begin active DIP joint ROM out of the splint. • Controlled rate of recovery of DIP joint flexion to avoid over stress to the extensor tendon caused by overzealous flexion and fisting • Emphasize DIP joint extension while introducing DIP joint flexion exercises to avoid development of DIP joint extensor lag. • Reduce use of mallet splint/orthosis in increasing increments of time over the next 2 weeks while continuing mallet splint at night. Adjust rate of weaning based on extensor lag: i.e., if lag develops increase use of splint; if no lag is present, increase intervals of no splint use during the day. • While the splint is off kinesiotape can be applied dorsally to provide additional support for DIP extension. • Begin ADL involving finger flexion without resistance. • Avoid repetitive gripping exercises. • Continue with sport activities with splint in place and secured with tape.	• Continue splint use at night based on need (presence of development of extensor lag when splint is not on). • Light strengthening exercise using therapy putty, alternating flexion and extension exercises • Gradually resume ADL and other activities while monitoring for extensor lag. • Engage in sport activities with splint and or taping.

Phase II (weeks 8 to 10)

Protection

- Begin to wean from splint. Splint is worn in public, at night, or during activities in which the finger may be exposed to stress for another 2 to 4 weeks.

Management of Pain and Swelling

- Can continue ice and Coban wraps as needed

Techniques for Progressive Increase in Range of Motion

- If the patient is compliant and the extensor lag is minimal (about 10°) the patient may be weaned from the splint and gentle DIP range of motion can begin (i.e., gentle fisting or tendon glides).
- Emphasis is also placed on DIP active extension. Flexion/extension exercises should be done in the favor of DIP extension to reduce the likelihood of a DIP lag. The athlete is instructed to resume use of the splint if the extensor lag worsens.
- The athlete is weaned from the splint but encouraged to wear the splint in public, when sleeping at night, and in any activities in which a forceful grip may be used
  - When performing light activities the splint can be off but kinesiotape can be used over the dorsal aspect of the finger to offer support for DIP extension.
- At 9 weeks the athlete is progressed to DIP blocking exercises if the lag does not increase with gentle ROM activities. Again active extension of the DIP joint is emphasized over flexion of the DIP joint.
- At 10 weeks the patient can resume strengthening and full contact sports if the lag does not worsen with DIP blocking exercises. However, during these activities the patient can be encouraged to tape or continue to use the splint for DIP extension if a mild lag still persists. A slight lag is not uncommon (about 10 to 15° even after operative treatment)
  - Kinesotaping (Fig. 16-11) can provide flexible support for DIPJ extension. Can be used as the patient resumes sports or resistive activities of daily living (ADLs)

Other Therapeutic Exercises

- The athlete may return to practice and sports activities as long as these activities do not increase or cause an extensor lag of the DIP joint.
  - It is recommended that the athlete first start with weight lifting or plyometrics, progress to tackling and contact drills, and then full contact rugby games, monitoring for extensor lag throughout this time period.
  - If the extensor lag begins to increase the athlete then returns to splint use until extensor lag improves. Once lag improves the athlete may try to progress with activities again.
  - It is possible to have some noncompliant athletes wear the mallet splint for 20 weeks before weaning from a splint.

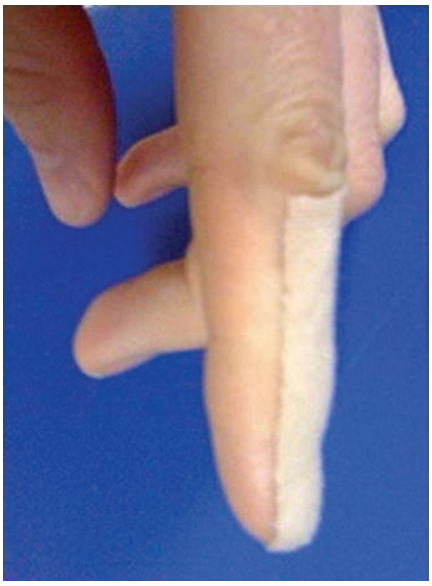

FIGURE 16-11. Kinesiotape used to provide support for DIP joint extension during the phase of weaning from the mallet splint.

  - It is important to note that with a nonoperative or operative treatment, it is possible for an extensor lag to remain (of about 10°) after healing but this lag will not limit function. Only if the extensor lag increases with activity should the patient return to splint use. It is recommended that a therapist follow the athlete while he or she returns to sport activities for the first 1 to 2 weeks in order to monitor for the development of extensor lag.

Milestones for Progression to Advanced Sport-Specific Training and Conditioning

- There are no additional stages of rehabilitation for nonoperative mallet finger treatment.

Evidence

Al-Qattan MM: Extra-articular transverse fractures of the base of the distal phalanx (Seymour's fracture) in children and adults. *J Hand Surg Br* 26(3):201–206, 2001.

This case series looked at 25 adult and pediatric patients who sustained a Seymour open fracture, which presents clinically as a mallet injury and a nail plate injury and must be ruled out. (Level IV evidence)

Handoll HH, Vaghela MV: Interventions for treating mallet finger injuries. *Cochrane Database Syst Rev* (3):CD004574, 2004.

This review looked at randomized or quasi-randomized clinical trials evaluating different interventions, including no intervention for treating mallet finger injuries, and included four trials that involved 283 mallet finger injuries. The authors concluded that there was insufficient evidence to establish the relative effectiveness of different, either custom-made or off-the-shelf, finger splints used for treating mallet finger injury. (Review)

Kalaninov DM, Hoepfner PE, Hartigan BJ, et al: Nonsurgical treatment of closed mallet finger fractures. *J Hand Surg* 30A:580–586, 2005.

In this study 22 closed bony mallet injuries were treated nonsurgically with DIP extension splints. With a mean splinting time of 5.5 weeks patients expressed negligible pain, minimal difficulties with activities of daily living, and showed high satisfaction with finger function but were marginally satisfied with the appearance of the finger. (Level IV evidence)

O'Brien LJ, Bailey MJ: Single blind, prospective, randomized controlled trial comparing dorsal aluminum and custom thermoplastic splints to stack splints for acute mallet finger. *Arch Phys Med Rehabil* 92(2):191–198, 2011.

In this study 64 people were treated with prefabricated stack splints, dorsal padded aluminum splints, or custom-made thermoplastic splints. All were worn for 8 weeks continuously, with a 4 week graduated withdrawal and exercise program. There was no difference in primary outcomes between the groups. The Stack and dorsal splint groups had a significant rate of treatment failure. (Level I evidence)

Okafor B, Mbubaegbu C, Munshi I, et al: Mallet Deformity of the finger: Five-year follow-up of conservative treatment. *J Bone Joint Surg* [Br] 79-B:544–547, 1997.

This article looked at 31 patients that were treated with stack splinting for a mean time of 7.2 weeks. 48% had osteoarthritic changes, 29% had a swan-neck deformity; extensor lag greater than 10° for 35% but patient satisfaction was generally high with little functional impairment. (Level IV evidence)

Pike J, Mulpuri K, Metzger M, et al: Blinded, prospective, randomized clinical trial comparing volar, dorsal, and custom thermoplastic splinting in treatment of acute mallet finger. *J Hand Surg Am* 35(4):580–588, 2010.

This prospective, randomized study of 87people with Type I mallet finger injuries randomized the patients to three conservative treatment groups: volar padded aluminum splint, dorsal padded aluminum splint, and custom thermoplastic. No lag differences were demonstrated radiographically after 12 weeks. (Level II evidence)

Simpson D, Queen MM, Kumar P: Mallet deformity in sport. *J Hand Surg* (British and European Volume). 26B(1):32–33, 2001.

This article describes cases of acute sporting injuries that were treated at an orthopedic trauma unit in a 4-month time period. Mallet finger made up a small amount of cases seen in did have excellent functional outcomes.

Wehbe MA, Schneider LH: Mallet fractures. *J Bone Joint Surg Am* 66(5):658–669, 1984.

In this retrospective study, 21 patients who had bone-involved mallet finger injuries were treated either conservatively or surgically. Mean follow up was 3.25 years. Radiographic assessment revealed bone remodeling and reconstitution of the articular surface and preservation of the joint space in all digits. In addition, there was a near-normal range of painless motion in all but one finger. Surgical treatment offered no advantage over splinting and introduced more morbidity. The authors subsequently concluded that "most mallet fractures can be treated conservatively, ignoring joint subluxation and the size and amount of displacement of the bone fragment." (Level IV evidence)

Multiple-Choice Questions

QUESTION 1. What is a potential problem that may occur during Phase I of mallet finger rehabilitation?

A. Skin breakdown
B. Loss of PIP ROM
C. Inadequate position of DIP within splint
D. All of the above

QUESTION 2. What indications are used to determine when to initiate DIP ROM after six weeks in the non-operative treatment of mallet finger?

A. DIP joint extensor lag
B. PIP joint hyperextension
C. Inability to flex the DIP joint
D. Skin breakdown

QUESTION 3. The most significant risk of nonoperative management of jersey finger is

A. loss of grip strength.
B. loss of tenodesis activity of the involved finger.
C. hyperextension of the PIP joint.
D. DIP joint flexion contracture.

QUESTION 4. When a mallet finger injury is accompanied by a swan neck deformity, what modification should be made to the orthosis/splint?

A. DIP joint should be positioned in slight flexion.
B. PIP joint should be blocked from full extension with DIP joint supported in slight hyperextension.
C. PIP joint should be blocked from full extension but the DIP should be allowed to flex.
D. None of the above

QUESTION 5. A rugby player with a mallet finger injury can return to play

A. immediately as long as the finger is taped.
B. with the mallet splint on and taped to secure it.
C. after 3 months of splinting.
D. as soon as the pain and swelling subside.

Answer Key

QUESTION 1. Correct answer: **D** (see Phase I)

QUESTION 2. Correct answer: **A** (see Phase II)

QUESTION 3. Correct answer: **A** (see Guiding Principles of Nonoperative Rehabilitation box)

QUESTION 4. Correct answer: **B** (see Phase I)

QUESTION 5. Correct answer: **B** (see Phase I)

POSTOPERATIVE REHABILITATION FOR MALLET FINGER AND JERSEY FINGER

A. Lee Osterman MD, Abdo Bachoura MD, Sidney M. Jacoby, MD,
Terri M. Skirven, OTR/L, CHT, and Jason A. Suda, MOTR/L

Indications for Surgical Treatment

- Failure or noncompliance of non-operative treatment for mallet finger
- If the patient finds the lack of active DIP flexion with Jersey finger, or DIP joint extension with mallet finger prohibitive of work tasks, participation in sport activities, or other activities of daily living

Brief Summary of Surgical Treatment

Major Surgical Steps

Jersey Finger

- Under either regional, general, or local anesthesia a well-padded pneumatic tourniquet is placed about the affected limb and set to 250 mm Hg.
- Preoperative antibiotics are typically delivered.
- Either a volar-based Bruner incision or a midlateral incision is utilized to visualize the flexor tendon sheath; hemostasis is achieved with bipolar cautery.
- Critical pulleys, including A2 and A4, are preserved during surgical dissection.
- Proximal and distal stumps of the avulsed tendon are identified (Fig. 16-12*A*); frequently a "milking maneuver" is performed to reveal the proximal stump of the avulsed flexor tendon.
- If the proximal stump has retracted far proximal, either a Swanson suture passer or other thin device such as a pediatric feeding tube or red rubber catheter may be placed retrograde through the flexor tendon sheath; the proximal stump is then provisionally fixed to this device and passed through the flexor tendon tunnel with great care to avoid injury to the intact FDS attachments and critical A2 and A4 pulleys, as well as neurovascular structures nearby (Fig. 16-12*B*).

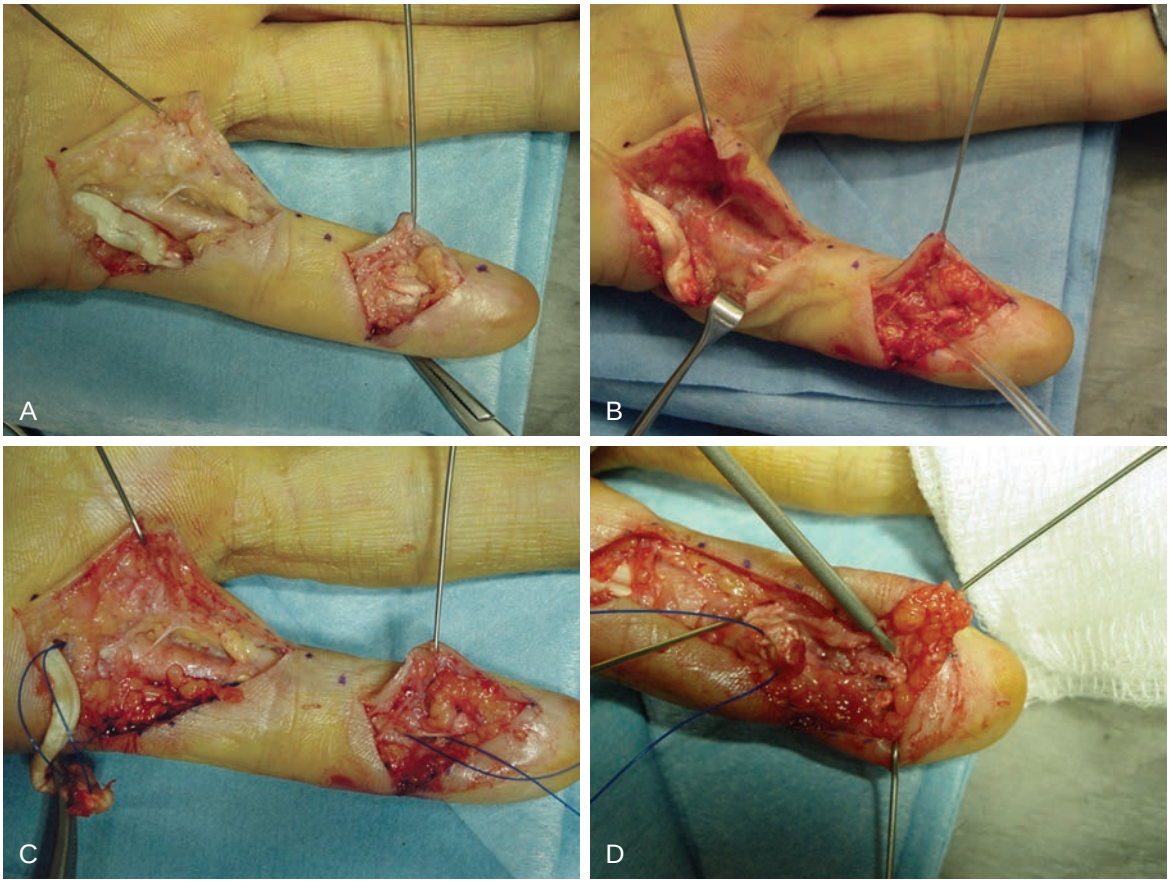

FIGURE 16-12. A, The ruptured flexor digitorum profundus tendon of the small finger is identified at the level of carpometacarpal joint level. **B,** Drain tubing has been passed through the A2 and A4 pulleys to ensure their preservation. **C,** A Prolene stitch is used to pull the proximal stump of the tendon through the annular pulleys to the distal phalanx. **D,** A suture anchor is used to fix the stump to the anatomic footprint of the FDP insertion. *(Courtesy of Mr. Michael Hayton, MB.ChB, FRCS.)*

- Tendon repair is performed either with direct suture repair to the residual stump (if there is enough tendon substance to suture) or via a pull-through technique in which the proximal stump is sutured with a 3-0 Prolene stitch that is passed through Keith needles and ultimately drilled through the distal phalanx and fixed to a dorsal button (Fig. 16-12*C,D*). Some authors utilize either a mini or micro suture anchor placed in the distal phalanx at the anatomic footprint of FDP insertion. Finally, some authors propose passing Keith needles containing the limbs of the 3-0 Prolene around the distal phalanx and tied down to the nail plate without a button.

Mallet Finger

- Affected finger is placed in a neutral to slightly extended posture and either a 0.035 or 0.042 inch K-wire is driven retrograde through the DIP joint to the base of the middle phalanx. Wire is often cut just beneath the skin surface.
- For bony mallet injuries, a dorsal block pin (0.045 inch K-wire) may be placed at the distal aspect of the middle phalanx in a retrograde fashion to help maintain reduction and prevent subluxation of the fracture fragment. A second pin is then driven retrograde as indicated above.

Factors that May Affect Rehabilitation

- Nonsurgical treatment is reserved for chronic injuries or for those individuals who are either unwilling or unable to comply with an intensive postoperative therapy protocol. Otherwise, surgical patients are rehabilitated as will be discussed below.

GUIDING PRINCIPLES OF POSTOPERATIVE REHABILITATION

MALLET FINGER

- Understanding the type of surgical repair performed
- Understanding of the anatomic structures and their rate of healing
- Understanding positions and activities that stress the healing structure
- Proper selection of manual therapy intervention applied at the appropriate phase of healing
- Surgery for mallet finger involves pinning the DIP joint in full extension for 6 to 8 weeks.
  - The patient is instructed to clean the pin with a 50:50 mixture of hydrogen peroxide and sterile water if a crust begins to develop at the pin area.
  - The patient is warned about the signs of infection and is given pain medicine and antibiotics based on surgeon's preference.
- After 6 to 8 weeks the pin can be removed and therapy follows the same guidelines outlined in the nonoperative rehabilitation section (see Nonoperative Rehabilitation for Mallet Finger).

JERSEY FINGER

- Understand the type of surgical repair performed
- Understanding of the anatomic structures and their rate of healing
- Understand positions and activities that stress the healing structure
- Proper selection of manual therapy intervention applied at the appropriate phase of healing
- Postoperative flexor tendon therapy includes early active, passive, and initial immobilization protocols. Selection of the specific protocol depends on the specific tendon repair technique, any associated injuries and the capacity of the patient to be compliant with a detailed home program and to observe strict precautions regarding splint use and avoidance of unguarded hand use.
- Too much motion early on during healing is indicative of a tendon that is gliding without much restriction from scar tissue. Although this may seem good, it is actually problematic: scar formation around the repair site provides the strength to the repair as it heals.

Phase I (days 0 to 5 postoperatively): Immediate Postoperative Period[1]

Goals

- Protect the repaired FDP tendon from rupture.
- Promote early gliding of the repaired tendon and minimize adhesion formation.
- Decrease pain and edema.
- Maintain motion of uninvolved joints.

Protection

- Dorsal block splint positioning the wrist in 30 to 40° of flexion, the MCP joints at 30° flexion, PIP joints at 0, and the rest of the uninvolved digits in extension. This splint extends proximally two thirds the length of the forearm and distally to the tips of the fingers (Fig. 16-13).
- Dorsal finger splint: Evans[1] recommends a separate dorsal splint for the involved DIP joint to position the DIP joint in 40 to 45° of flexion. This splint should extend from the distal portion of the PIP joint to the distal tip of the involved finger.
- Custom fabricated splints are recommended because precise fit of the splint is critical to prevent rupture of the tendon and for patient comfort
- The splint is worn 24 hours a day. If the patient is believed to be compliant with postoperative restrictions, the splint may be removed for hygiene and wound/skin checks at home
  - If the patient's compliance is in question, then hygiene and wound/skin care will be managed by the therapist.

[1]*Prehabilitation, if appropriate, is described in the Nonoperative Rehabilitation section of this chapter.*

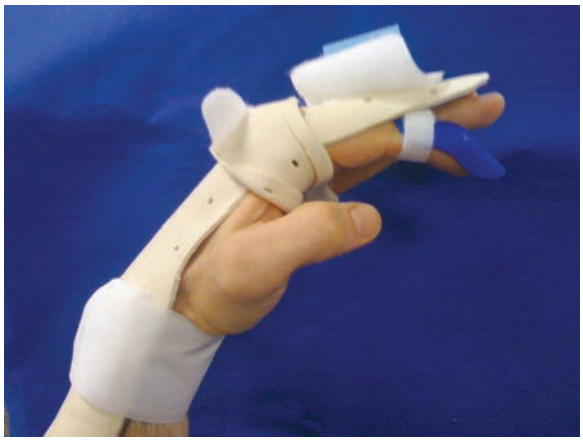

FIGURE 16-13. Dorsal block protective splint/orthosis with separate dorsal DIP joint block with the DIP joint positioned at 40 to 45° of flexion.

Management of Pain and Swelling

- Oral pain medications as recommended by the surgeon
- Heat and ice: If swelling is not significant, heat can be used prior to therapy or performing exercises. Ice can be used after an exercise session.
- Elevation of the affected limb above the heart between exercises
- The use of self-adhesive wraps around fingers to apply gentle compression
- The use of compression garments if edema engulfs hand and forearm
- Patient education
  - Perform exercises gently
  - Some discomfort is anticipated but if pain is increasing, the patient needs to perform the exercises at a lesser intensity.

Techniques for Progressive Increase in Range of Motion

Manual Therapy Techniques

- Precautions
  - All exercises are performed gently within the limits of the dorsal block splints.
  - No passive composite finger extension (simultaneous extension of MCP, PIP, and DIP joints); no blocking exercises for DIP joint active flexion
  - No use of the involved hand for ADL
- Passive motion protocol
  - The DIP, PIP, and MP joints are all flexed passively individually to the full available range of motion, but not permitted to extend beyond the confines of the splints.
  - Modified hook fist: PIP and MP joints are flexed simultaneously within the confines of the splints.
  - Composite fist: MP, PIP, and DIP joints are simultaneously flexed at the same time.
- Active motion protocol
  - Begin with passive motion exercises as above to overcome any resistance to motion and reduce swelling.
  - Active motion exercises are permitted as follows:
    - Active extension of the digits is allowed within the confines of the splints.
    - Assisted active flexion of the fingers in a partial fist position (Fig. 16-14)
    - Place-and-hold technique: The uninvolved hand places the injured fingers into a gentle fist (MP joints at 75 to 80° flexion, the PIP joints at 70 to 75° flexion, and the DIP joints at 40° flexion. The uninvolved hand then lets go and the patient is asked to gently contract the muscles of the involved hand to hold this position for a five count (Fig. 16-15*A*,*B*).

TIMELINE 16-2: **Postoperative Rehabilitation after Zone 1 Flexor Tendon Repair or Mallet Finger**

PHASE I (days 0 to 5)

- Use of two custom-fabricated splints
  - Forearm-based dorsal block orthosis positioning the wrist in 30 to 40° of flexion, the MCP joints at 30° flexion, PIP joints at 0, and the uninvolved digits in extension
  - Finger-based dorsal orthosis to maintain the DIP joint in 40 to 45° of flexion
- Patient education regarding importance of uninterrupted orthosis/splint use
- Cryotherapy, edema management as needed
- Exercises will depend on surgeon's choice of protocol.
  - Passive motion protocol
    - The DIP, PIP, and MP joints are all flexed passively individually.
    - Passive modified hook fist
    - Passive composite fist
  - Active motion protocol
    - In addition to the PROM exercise previously described, the patient is allowed to perform:
      - Active extension to the limit of the dorsal block splint
      - Place-and-hold finger flexion
      - Active assisted range of motion into a partial fist
- Two to three therapy visits per week depending on limits in ROM
- No sports or resistive activities performed with injured hand

PHASE II (day 5 to week 4)

- Continue use of both splints.
- Cryotherapy, edema management as needed
- At 21 to 25 days DIP splint can be discharged and DIP extension is allowed.
- At 4 weeks the dorsal block splint is remolded with the wrist positioned in neutral and the MCP joints are placed in slight flexion, with IP joints gently extended.
- The patient continues with the above exercises.
- If excessive motion is noted the patient is not progressed any further with the exercises.
- Tenodesis exercises are added between 1 and 2 weeks.
- FDS gliding exercises are added between 3 and 4 weeks.
- Once the wound is closed, scar management strategies are started.
- If tendon glide is limited, modalities can be used as needed.
- No sports or resistive activities performed with injured hand

FIGURE 16-14. Active assisted flexion of the fingers within the confines of the dorsal block splint/orthosis performed during early phases of rehabilitation. *(Courtesy of Ross Evans.)*

Clinical Pearl

It is critical that the patient understands that this force is gentle. Excessive force will rupture the repair site. (Patients are often told: "pretend you are holding an egg".) A Haldex pinch meter can be used to measure force by tying a string to the patient's finger and around the Haldex meter. A force of 15 to 20° is recommended.

Active extension of the digits is allowed within the confines of the splints.

Other Therapeutic Exercises

- Athletes are encouraged to refrain from physical activity; excessive activity will promote swelling in a thermoplastic splint and create an unsanitary environment healing.

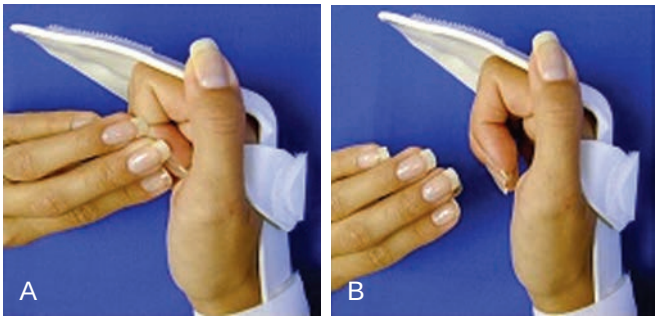

FIGURE 16-15. Place and hold exercise involves (a) the fingers placed in a flexed position and (b) the patient attempts to actively hold the flexed position without passive assistance.

Activation of Primary Muscles Involved in Injury Area or Surgical Structures

- No activation of primary muscles is recommended beyond the scope of what has previously been discussed because this could potentially rupture the repair site.

Phase II (day 5 to week 4 postoperatively)

Goals

- Protect the repaired FDP.
  - Promote protected gliding of the repaired FDP.
  - Prevent restrictive adhesion formation.
  - Maintain ROM of uninvolved joints.

TIMELINE 16-2: **Postoperative Rehabilitation after Zone 1 Flexor Tendon Repair or Mallet Finger** (Continued)

PHASE III (weeks 4 to 8)

- Dorsal block splint is discharged at 7 to 9 weeks.
- Extension splint fabricated as needed to correct MP or PIP contractures
- No sustained passive stretching of the finger is permitted before 8 weeks postoperatively.
- Cryotherapy, scar and edema management continue.
- Static progressive splints may be issued to correct DIP contractures beginning at 8 weeks after surgery.
- The patient can progress to gentle tendon gliding exercises and blocking exercises after the dorsal splint is discharged.
- Blocking exercises can begin if active DIP joint flexion is limited indicating passive tendon adherence.
- Passive ROM exercises discussed in the previous section may continue.
- Ultrasound or iontophoresis with saline may be used if scar adhesions are believed to be present.
- The athlete may return to cardiovascular and lower body exercises but is encouraged to avoid resistive gripping activities.

PHASE IV (weeks 8 to 12)

- All ROM and soft tissue techniques previously described are continued.
- All modalities are continued on an as-needed basis.
- Light putty exercises may be issued.
- The use of electrical stimulation can be initiated to increase tendon glide.
- After discharge from therapy, the patient may return to light weight lifting activities and progress gradually in the absence of pain.
- May return to sports but can use buddy tape as needed

- Limit excessive motion.
- Minimize pain and edema.

Protection

- Continue use of both splints; however, between 21 and 25 days use of the dorsal digital splint can be discontinued, but no passive extension of the DIP joint is allowed. At 4 weeks the dorsal block splint is remolded with the wrist positioned in neutral and the MCP joints are placed in slight flexion, with IP joints gently extended

Management of Pain and Swelling

- Oral pain medications as recommended by the surgeon
- Heat and ice: If swelling is not significant, heat can be used prior to therapy or performing exercises. Ice can be used after an exercise session.
- Elevation of the affected limb above the heart between exercises
- The use of self-adhesive wraps around fingers to apply gentle compression
- The use of compression garments if edema engulfs hand and forearm
- Patient education
  - Perform exercises gently.
  - Some discomfort is anticipated but if pain is increasing the patient needs to perform the exercises more gently and adjust the frequency and duration of the exercises.
  - The patient is instructed to avoid attempts to use the involved hand.

Techniques for Progressive Increase in Range of Motion

Manual Therapy Techniques

- Precautions
  - Are the same as previously discussed, but if the patient begins to show excessive motion (i.e., full or almost-full composite fist) he or she will not be progressed any further until 4 to 5 weeks.
- Passive and active motion protocols
  - Are the same as previously discussed, with the addition of FDS tendon gliding exercises: the uninvolved digits are held in extension to the limit of the splint (Fig. 16-16). The involved finger is allowed to gently flex and extend at the PIP joint.
  - Synergistic wrist motion (tenodesis) can be added with both protocols (Fig. 16-17 *A*,*B*) added between 1 and 2 weeks.
  - These exercises are first performed under therapist supervision. If the patient shows good understanding of exercises and compliance with postoperative protocols the patient may be instructed to add this exercise to the home exercise program.
  - If tendon excursion is limited, the exercise program may be upgraded by increasing frequency, adding physical agents, and carefully modifying the exercises to promote increased FDP tendon function.

FIGURE 16-16. Gliding exercise of the flexor digitorum superficialis: Within the confines of the splint/orthosis, the digits adjacent to the involved digit are held in extension to the limit of the splint and the patient attempts to actively flex the PIP joint of the involved digit.

  - PROM exercises will remain the same as previously discussed.

Soft Tissue Techniques

- Gentle scar massage once wound is closed.
- Scar pad fabricated from Elastomere or Otoform. The patient may also purchase name-brand silicon scar pads found in most pharmacies.
- Edema massage as needed

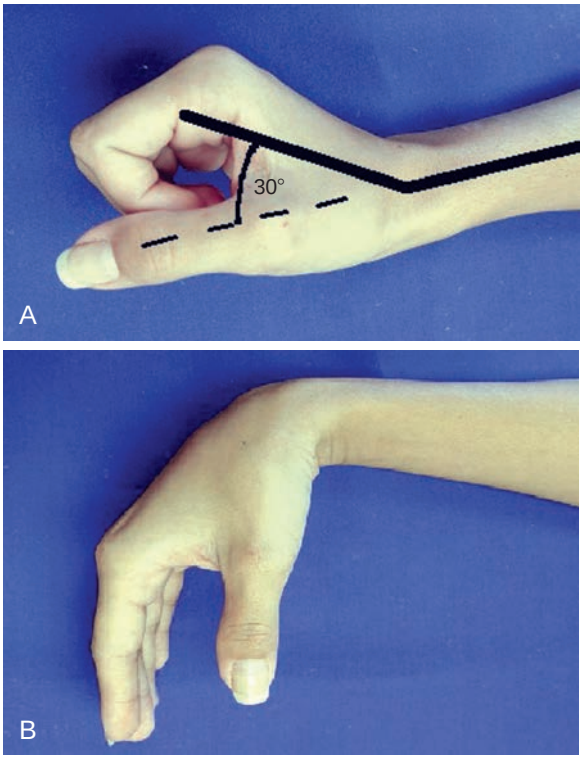

FIGURE 16-17. Tenodesis exercise/synergistic motion involves (a) wrist extension to 30° which results in passive flexion of the digits; this is followed by (b) active flexion of the wrist resulting in passive extension of the digits.

Stretching and Flexibility Techniques for the Musculotendinous Unit

- Not permitted during this phase; stretching of the FDP musculotendinous unit puts it in danger of rupture or gapping at the repair site.

Other Therapeutic Exercises

- Once the wound is closed and the patient shows good compliance, they light aerobic activities (such as seated stationary bike) may be allowed. It is important that these activities do not allow the patient to bear weight or grasp using the injured hand. The patient must understand the importance of cleaning the hand/splint after the activity while maintaining the postoperative restrictions.
- Activities such as running (outside or on a treadmill) are not recommended because if the patient falls on a hard surface, even with the splint, the repair site may rupture.

Activation of Primary Muscles Involved in Injury Area or Surgical Structures

- AROM of the elbow and shoulder is still encouraged but the patient is restricted from resistive activities.

Sensorimotor Exercises

- Not appropriate for this diagnosis. Both mallet finger and jersey finger involve the distal joint of a finger. Because only a small portion of the finger is involved, balance, overall strength, and endurance are not adversely affected.

Phase III (weeks 4 to 8 postoperatively)

Goals

- Protect the repaired FDP.
- Promote gliding of the repaired FDP tendon.
- Maintain ROM of uninvolved joints.
- Limit excessive motion.
- Minimize pain and edema.
- Progress patient to a full composite fist and full DIP extension.

Protection

- Use of the dorsal block splint is discontinued at 7 to 9 weeks.
- Once the dorsal block splint is discontinued, if a flexion contracture is present at the MP or PIP joint an extension splint can be made that positions the involved joint and digit at the end range of comfortable active extension. The splint also can be worn at night and for intervals during the day to achieve greater extension. This splint can be brought in once a week to be gradually adjusted into more extension by the therapist.
- No sustained passive stretching of the finger is permitted before 8 weeks postoperatively.
- Static progressive splints may be issued to correct DIP contractures beginning at 8 weeks after surgery.

Clinical Pearl

> Do not allow the patient to throw away any of the splints. Part or all of any thermoplastic splint can be used to fabricate another splint. This can save a therapist time in a clinical setting and reduce cost for the patient.

Management of Pain and Swelling

- Pain medications as prescribed by the surgeon.
- Heat and ice: If swelling is not significant, heat can be used prior to therapy or performing exercises. Ice can be used after an exercise session.
- Elevation of the affected limb above the heart between exercises
- The use of self-adhesive compressive wraps around fingers to apply gentle compression
  - The use of compression garments if edema engulfs hand and forearm
- Patient education
  - Perform exercises gently.
  - Some discomfort is anticipated but if pain is increasing, the patient needs to perform the exercises more gently and adjust the frequency and duration to lessen discomfort.

Techniques for Progressive Increase in Range of Motion

Manual Therapy Techniques

- AROM: The patient can progress to gentle tendon gliding exercises and blocking exercises after the dorsal splint is discharged. It is recommended that exercises start out gently and progress depending on the patient's reports of pain and the amount of tendon glide.
- Blocking exercises can begin if DIP joint flexion is limited indicating scar adherence of the repaired FDP tendon. Blocking involves stabilization of the PIP joint in neutral as the patient attempts to actively flex the DIP joint (Fig. 16-18).

Clinical Pearl

> If the patient has difficulty performing isolated DIP blocking exercises a blocking splint can be fabricated to hold the PIP in extension.

- PROM: Continue as discussed in prior section.
- Joint mobilization is indicated if joint stiffness is noted prior to treatment.
- If the tendon seems to be adherent, ultrasound or iontophoresis with saline can be administered.

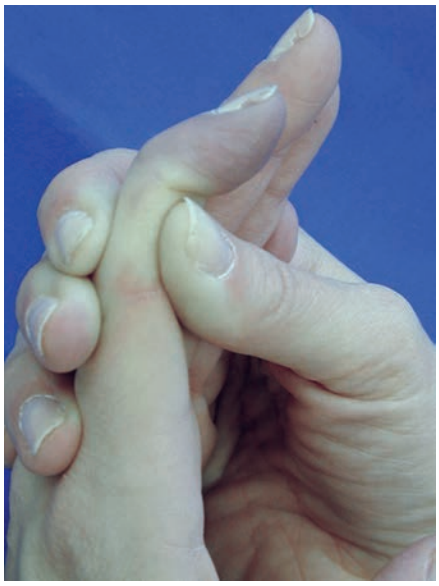

FIGURE 16-18. Blocking exercises are performed in the later phases of rehabilitation following surgery for Jersey finger. The proximal PIP joint is held in neutral extension and the patient attempts to actively flex the involved DIP joint.

Soft Tissue Techniques

- Continue as discussed in the prior section.

Other Therapeutic Exercises

- Cardiovascular: Once the splint is discharged the patient may participate in light aerobic activities. However, the patient is encouraged to refrain from strenuous gripping activities.
- Lower body strengthening may begin in the form of squats, lunges, leg press, etc., as long as the patient is aware he is not to perform strenuous gripping activities. As such upper body strengthening is omitted.
- Core activities that do not require excessive force of the involved hand may be started.

Activation of Primary Muscles Involved in Injury Area or Surgical Structures

- The same as discussed in prior section

Sensorimotor Exercises

- The same as discussed in prior section

Phase IV (weeks 8 to 12 postoperatively)

Goals

- Protect the repaired FDP.
- Promote gliding of the repaired FDP tendon.
- Maintain good ROM of uninvolved joints.
- Minimize pain and edema.
- Progress patient to a full composite fist and full DIP extension.
- Strengthening may begin at 10 weeks.

Management of Pain and Swelling

- Pain medications prescribed by the surgeon depending on the surgeon preference
- Heat and ice: If swelling is not significant, heat can be used prior to therapy or performing exercises. Ice can be used after an exercise session.
- The use of self-adhesive wraps around fingers to apply gentle compression
  - The use of compression garments if edema engulfs hand and forearm
- Patient education
  - Perform exercises gently.
  - Some discomfort is to be anticipated but if pain is increasing, the patient needs to perform the exercises more gently and adjust the frequency and duration of the exercise sessions to lessen discomfort at a lesser intensity.

Techniques for Progressive Increase in Range of Motion

Manual Therapy Techniques

- Passive and active range of motion protocols: the same as discussed in prior section
- If tendon gliding is still limited, the use of neuromuscular electrical stimulation can be used to enhance the contraction of the FDP muscle.
- Strengthening with light putty
- Assist with contractions of the FDP of the involved finger.

Soft Tissue Techniques

- The same as in prior section

Stretching and Flexibility Techniques for the Musculotendinous Unit

- Not indicated or appropriate for this diagnosis

Sport-Specific Exercises

- Once the patients/athletes are discharged/cleared from a therapy program they can then gradually return to their sports without difficulty. In most instances after therapy patients are instructed to return to weight lifting and sport activities at about 50% of the resistance and progress under their own supervision as their tolerance and symptoms permit pending their pain.

Outcome Measures

- Patient-reported outcome scales should be completed on the initial therapy evaluation and followed up at weeks 4, 8, and 12 and at the final day of therapy.
- Disabilities of the Arm, Shoulder, and Hand (DASH), Quick Dash, The Patient Rated Wrist Evaluation

(PRWE), and the Patient Rated Wrist and Hand Evaluation (PRWHE) are recommended.
- All have all been shown to be effective.

Criteria for Return to Sport

General

- Functional AROM
- Minimal to no pain or edema
- Minimum of 80% (side-to-side) symmetry of grip strength

Sport-Specific

- Implementation of return to sport criteria must include a demand/needs analysis of the chosen sport. The rehabilitation specialist should be able to analyze the demands on the hand and finger through a series of tests and exercises to ensure readiness for return to preinjury levels of activity.

After Return to Sport

Continuing Fitness or Rehabilitation Exercises

- Total arm and total body strengthening exercises

Exercises and Other Techniques for Prevention of Recurrent Injury

- There are no exercises to prevent jersey or mallet finger. However, once a patient returns to her or his sport they may wish to buddy tape the rehabilitated finger for protection.

Evidence

Evans RB: A study of the zone 1 flexor tendon injury and implications for the treatment. *J Hand Ther* 24:275–280, 1990.

This article describes early motion protocol for patients who have had surgical repair of Zone 1 Flexor tendon injuries then reviews the clinical results. (Level IV evidence)

Evans RB: Zone 1 flexor tendon rehabilitation with limited extension and active flexion. *J Hand Ther* 18(2):128–140, 2005.

This study looks at the outcomes for 41 patients who had surgical repairs of Zone 1 FDP tendon injuries. Surgery was followed by therapy in which the patient performed an early active flexion protocol with limited extension. These patients were followed for 10 years and showed a mean total active range of motion that was 81% of their normal motion. (Level IV evidence)

Groth NG: Pyramid of progressive force exercise to the injured flexor tendon. *J Hand Ther* 17:31–42, 2004.

This article is a literature review and case study. It describes the application and rational for using exercises in a systematic and progressive way to reduce the risk of rupture and adhesion formation. (Case study)

Handoll HH, Vaghela MV: Interventions for treating mallet finger injuries. *Cochrane Database Syst Rev* (3):CD004574, 2004.

This review looked at randomized or quasi-randomized clinical trials evaluating different interventions, including no intervention for treating mallet finger injuries, and included four trials that involved 283 mallet finger injuries. The authors concluded that there was insufficient evidence to establish the relative effectiveness of different, either custom-made or off-the-shelf, finger splints used for treating mallet finger injury. (Review)

Lunn PG, Lamb DW: "Ruby Finger"—avulsion of profundus of ring finger. *J Hand Surg BR* 9:69–77, 1984.

This is a study of nine patients who sustained an isolated avulsion injury of the FDP tendon, all to the ring finger while playing rugby. The patients all presented later than 4 weeks and were treated surgically with palmaris tendon grafting, followed by 6 to 9 weeks of physiotherapy. The mean follow up was 4.3 years and hand function improved in all cases. The authors subsequently recommended that experienced surgeons should use this technique for the treatment of young and motivated individuals. (Level IV evidence)

Tuttle HG, Olvey SP, Stern PJ: Tendon avulsion injuries of the distal phalanx. *Clin Orthop Relat Res* 445:157–168, 2006.

This is one of the latest review articles about jersey finger. The authors concisely summarized the current FDP tendon avulsion classification system (Types 1 to 5). (Review)

Multiple-Choice Questions

QUESTION 1. When can place and hold exercises be started?

A. When the surgical repair supports the use of active motion as determined by the referring surgeon
B. When the patient shows the capacity to follow and be compliant with instructions and precautions
C. Within the first 3 to 5 days after surgery
D. All of the above

QUESTION 2. Which of the following is an appropriate exercise for jersey finger in the first 3 weeks postop?

A. Forceful flexion to a full composite fist
B. A dorsal block splint to maintain wrist/MPs flexed while DIP/PIPs are held at 0° extension
C. PROM into full fist and full extension
D. Gentle wrist tenodesis under therapist supervision

QUESTION 3. When is it safe to discharge the dorsal finger splint (with continued use of the wrist and hand dorsal splint)?

A. 21 to 28 days
B. 28 to 38 days
C. 5 weeks
D. 6 weeks

QUESTION 4. According to Evans, at what angle should the DIP joint be positioned when the initial dorsal DIPJ splint is fabricated?

A. 0 to 10
B. 10 to 25
C. 20 to 35
D. 40 to 45

QUESTION 5. What is considered when upgrading a patient's therapy program to include light strengthening?

A. Timeframe from surgery
B. The degree of gliding of the repaired FDP
C. The patient's functional requirements
D. All of the above

Answer Key

QUESTION 1. Correct answer: **D** (see Techniques for Progressive Increase in Range of Motion)

QUESTION 2. Correct answer: **D** (see Phase II)

QUESTION 3. Correct answer: **A** (see Phase II)

QUESTION 4. Correct answer: **D** (see Phase I)

QUESTION 5. Correct answer: **D** (see Phase II)

Chapter 17

Thumb Ulnar Collateral Ligament Injuries

INTRODUCTION

Mohamed Khalid, MD, MCh, FRCS

Epidemiology

Age

- 40 years (average)

Sex

- Male : female ratio: 3 : 2

Sports

- Skiing, snowboarding, ball-handling sports, hockey, cycling, wrestling, break dancing
- The incidence is 3% of all skiing injuries. The most common injuries resulting from skiing are knee injuries (medial collateral ligament sprain, anterior cruciate ligament damage, and meniscal injury) 30% to 40%; and shoulder girdle injuries (dislocation of shoulder and acromioclavicular joints, fracture of clavicle, humerus, and wrist) 25% to 30%; followed by ankle sprains 17%; and head injuries 10% to 15%

Position

- Sudden forced radial deviation (abduction)

Pathophysiology

Intrinsic Factors

- Anatomical: The shallow articulating surfaces of the thumb metacarpophalangeal (MCP) joint provide very little inherent stability.
- For its stability the MCP joint relies on muscles (adductor pollicis), static ligaments such as the ulnar collateral ligament, accessory collateral ligament, and volar plate (Figures 17-1 and 17-2). The proper ulnar collateral ligament runs from the head of metacarpal to volar surface of the base of proximal phalanx. It is the primary restraint to an abduction force to the MCP joint and tightens in flexion and relaxes in extension. The accessory ulnar collateral ligament also provides stability to the ulnar aspect of the MCP joint and tightens in extension and relaxes in extension.
- The ulnar collateral ligament is the key stabilizer of the thumb MCP joint.

Extrinsic Factors

- Improper use of ski pole straps (Figure 17-3*A*,*B*)

Traumatic Factors

- The mechanism of the injury is forceful abduction of the thumb associated with striking the ground, striking the ski pole handle, or forced abduction of the thumb, which is caught in the ski pole strap.
- When a skier falls onto the hand the pole handle in the palm can act as a lever across the MCP joint and force it into abduction/radial deviation (Figure 17-4).

Classic Pathological Findings

- Strain, partial tears, or complete rupture of ulnar collateral ligament
- The tear is most often at the distal attachment. Ruptures within the substance of the ligament or avulsion of the ligament from the metacarpal ligament can also occur.

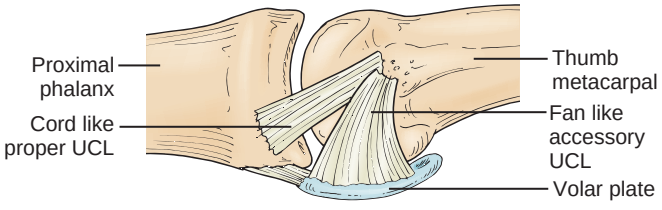

FIGURE 17-1. Stabilizers of the metacarpophalangeal joint of the thumb.

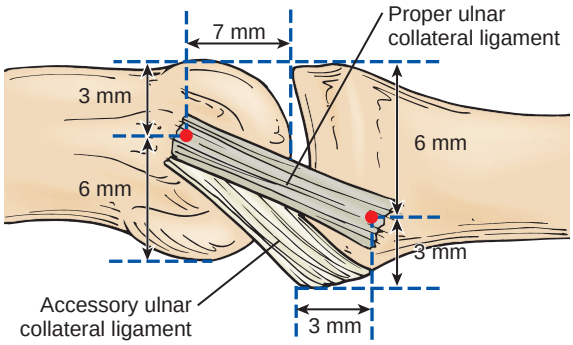

FIGURE 17-2. The proper ulnar collateral ligament runs from the head of metacarpal to volar surface of the base of proximal phalanx. It is the primary restraint to an abduction force to the MCPJ and tightens in flexion and relaxes in extension. The accessory ulnar collateral ligament also provides stability to the ulnar aspect of the MCPJ and tightens in extension and relaxes in extension. *(Redrawn from Hand Clinics 25(3):437–442, 2009.)*

- Associated lesions might include injury to dorsal capsule, a rent in adductor aponeurosis, extensor expansion, volar plate or avulsion fracture.

Clinical Presentation

History

- History of combined hyperextension and forced abduction to the thumb
- Acutely painful MCP joint and swelling

Physical Examination

Abnormal Findings

- Tenderness, ecchymosis, and swelling along the ulnar border of MCP joint
- Laxity in excess of 35° and/or 15° greater than the contralateral thumb on valgus stress testing (Figure 17-5)
- A weak pincer grip

Pertinent Normal Findings

- No tenderness over the radial border of the thumb (vs. radial collateral ligament injury, MCP joint dislocation)
- No increased warmth (vs. septic or crystal arthropathy)

Imaging

- Plain radiographs, including stress views
- Ultrasonography
- Magnetic resonance imaging

Differential Diagnosis

- MCP joint dislocation
- Peri-articular fractures around the MCP joint

Treatment

Nonoperative Management

- Rest, ice, compression, and elevation (RICE)
- Splinting, functional versus rigid
- Casting in a thumb spica

Guidelines for Choosing Among Nonoperative Treatments

- Presence of an end point to valgus stress
- Absence of a Stener lesion. A Stener lesion is avulsion of the distal attachment of the ulnar collateral ligament with interposition of the adductor aponeurosis between

FIGURE 17-3. Proper **(A)** and improper **(B)** use of ski pole straps.

FIGURE 17-4. Mechanism of injury resulting in ulnar collateral ligament damage.

the avulsed ligament and its site of original attachment to the base of the proximal phalanx (Figure 17-6).
- Absence of displaced fractures

Surgical Indications

Absolute Indications

- Complete avulsion with interposition of adductor aponeurosis (Stener lesion)
- Displaced (greater than 2 mm) avulsion fractures (ulnar base of the proximal phalanx, metacarpal head, and shearing fractures of the volar surface of the radial condyle of the metacarpal head) (Figure 17-7)

Relative Indication

- Minimally displaced intraarticular avulsion fracture

Aspects of History, Demographics, or Exam Findings That Affect Choice of Treatment

- Weak pincer grip
- Lack of end point on abduction stressing

Aspects of Clinical Decision Making When Surgery Is Indicated

- Complete versus incomplete rupture/strain (definite end point or not on abduction stressing

FIGURE 17-5. Unstable thumb following an ulnar collateral ligament injury.

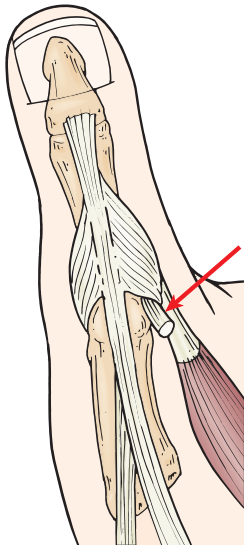

FIGURE 17-6. Stener lesion.

- 30° laxity of the ulnar side of the joint when stressed radially in extension and 40° of flexion (the latter is more reliable)
- 15° more laxity compared with contralateral thumb
- Presence of a Stener lesion
- Presence of a palpable "tumor" (mass) at the level of UCL just proximal to the MCP joint
- Retracted ligament on ultrasonography or MRI
- Greater than 2 mm displacement of fracture
- Joint incongruity
- Rotated fragment

Evidence

Abrahamsson SO, Sollerman C, Lundborg G, et al: Diagnosis of displaced ulnar collateral ligament of the metacarpophalangeal joint of the thumb. Preoperative diagnosis. *J Bone Joint Surg* 68-A:1320–1326, 1986.

FIGURE 17-7. Displaced avulsion fracture.

In this study the authors prospectively studied 24 consecutive patients with posttraumatic instability of the metacarpophalangeal joint of the thumb. Clinical examination including instability tests and palpation of displaced ulnar collateral ligaments was used to separate the patients into two groups, nondisplaced and displaced ruptures. Palpable displaced ruptures were treated surgically, whereas nonpalpable ruptures were interpreted as nondisplaced and were treated with plaster, irrespective of the instability. At follow-up 1 year later both groups showed similar results with respect to stability, strength, and function. They concluded that it was possible to determine the surgical candidates reliably with clinical examination alone. (Level II evidence)

Bowers WH, Hurst LC: Gamekeeper's thumb. Evaluation by arthrography and stress Roentgenography. *J Bone Joint Surg* 59A:519–524, 1977.

This study correlated stress radiographs, arthrography, and findings at surgical exploration and found that valgus angulation of greater than 30° was predictive of a complete UCL rupture, but that arthrography was needed to diagnose Stener lesion accurately. (Level III evidence)

Hergan K, Mittler C, Olser W: Ulnar collateral ligament: Differentiation of displaced and nondisplaced tears with ultrasound and MR imaging. *Radiology* 194(1):65–71, 1995.

The comparative usefulness of ultrasound versus MRI in UCL ruptures was studied in 17 patients and 21 normal volunteers. Ultrasound had a sensitivity of 88% and a specificity of 83% for displaced, and 91% for nondisplaced UCL tears. MRI had a sensitivity and specificity were both 100%. The authors concluded that MRI was superior to ultrasound, but both were useful diagnostic modalities. (Level II evidence)

Heyman P, Gelberman RH, Duncan K, et al: Injuries of the ulnar collateral ligament of the thumb metacarpophalangeal joint. Biomechanical and prospective clinical studies on the usefulness of valgus stress testing. *Clin Orthop Relat Res* 292:165–171, 1993.

This evidence study reported that the presence of valgus angulation of more than 35° with the joint in extension and 30° with the joint in flexion was predictive of a complete tear with a Stener lesion in 15 of 17 cases (sensitivity, 94%; specificity, 57%; accuracy, 83%; positive predictive value, 83%; negative predictive value, 80%). (Level II evidence)

Stener B: Displacement of the ruptured ulnar collateral ligament of the metacarpophalangeal joint of the thumb: A clinical and anatomical study. *J Bone Joint Surg Br* 44:869–879, 1962.

In this classical study, the author prospectively studied 40 clinical cases of complete rupture of UCL supplemented with 42 cadaveric dissections. He demonstrated that in a displaced complete rupture of the UCL the adductor aponeurosis interposed between the ruptured end of the ligament and the phalangeal attachment of the ligament.

Multiple Choice Questions

QUESTION 1. Thumb ulnar collateral ligament injury is common in all the following injuries except

A. skiing.
B. break dancing.
C. netball.
D. table tennis.

QUESTION 2. Ulnar collateral ligament injuries constitute what percentage of all skiing injuries?

A. 5%
B. 3%
C. 40%
D. 8%

QUESTION 3. Stabilizers of thumb MCP joint include all of the following except

A. adductor pollicis.
B. abductor pollicis.
C. ulnar collateral ligament.
D. volar plate.

QUESTION 4. The ulnar collateral ligament commonly avulses off of what attachment?

A. Distal
B. Midsubstance
C. Proximal
D. b+c

QUESTION 5. The most sensitive and specific modality of diagnosing an unstable UCL injury is

A. history.
B. clinical examination.
C. ultrasonography.
D. MRI.

Answer Key

QUESTION 1. Correct answer: **D** (see Epidemiology)

QUESTION 2. Correct answer: **B** (see Epidemiology)

QUESTION 3. Correct answer: **B** (see Anatomy)

QUESTION 4. Correct answer: **A** (see Pathological findings)

QUESTION 5. Correct answer: **D** (see Evidence)

NONOPERATIVE REHABILITATION OF THUMB ULNAR COLLATERAL LIGAMENT INJURIES

Mohamed Khalid, MD, MCh, FRCS, Bradley Kent Earnest, OTR/L, CHT, and Mark Simenson, OTR/L, CHT

GUIDING PRINCIPLES OF NONOPERATIVE REHABILITATION

- Protect
- Monitor pain, edema, and range of motion
- Maximizing strength and activities of daily living (ADLs) independence

Phase I (weeks 0 to 4)

Protection

- Hand-based IP free thumb spica splint with no more than 30° of abduction (Figure 17-8).

Management of Pain and Swelling

- Compression
- Ice
- Elevation

Techniques for Progressive Increase in Range of Motion

Stretching and Flexibility Techniques for the Musculotendinous Unit

- Allow active flexion/extension of thumb MP joint (10 reps, three times per day) but no opposition movements at this time.

Functional Exercises

- Gentle/light hygiene (avoid radial MP joint stress)

FIGURE 17-8. Static hand-based splint.

Milestones for Progression to the Next Phase

- Decreased pain per patient report
- Decreased tenderness to palpation and edema
- Increased stability (within 15 degrees radial deviation (MP joint) of noninjured thumb
- If not progressing continue phase I for 2 more weeks and if criteria is still not met refer back to MD for further evaluation

Phase II (weeks 4 to 6)

Protection

- Continue splinting with heavy use and while sleeping.
- Splint may be removed for light ADL (2 lb or less).

Management of Pain and Swelling

- Continue as for Phase I.
- Retrograde massage may be added if needed for edema.

Techniques for Progressive Increase in Range of Motion

Manual Therapy Technique

- Retrograde massage

Stretching and Flexibility Techniques for the Musculotendinous Unit

- Continue with active MP joint flexion and extension exercises as in Phase I.
- Active opposition added to treatment and home program

Other Therapeutic Exercises

- ADL (2 lb or less) with splint removed

Activation of Primary Muscles Involved

- Same as for Phase I

Functional Exercises

- ADL (2 lb or less) with splint removed

Milestones for Progression to the Next Phase

- Pain at rest 0/10. Pain/tenderness 2/10 or less with palpation over UCL and with gentle use.
- MP joint stable with flexion, extension, and active opposition

Phase III (weeks 6 to 10)

Protection

- Wean from splint for ADL and nighttime use. Continue splinting with heavy use.

Management of Pain and Swelling

- Continue with ice, retrograde massage, and compression.
- Modalities such as ultrasound and neuromuscular electrical stimulation (NMES) may be added.

Techniques for Progressive Increase in Range of Motion

Manual Therapy Techniques

- Joint mobilization and passive range of motion initiated to MP joint

Soft Tissue Techniques

- Scar massage initiated over UCL for internal scarring management

Stretching and Flexibility Techniques for the Musculotendinous Unit

- Initiate place and hold exercises in MP flexion, extension and opposition.

Other Therapeutic Exercises

- If UCL is stable and pain free outside of splint with ADL then extra-soft (yellow) Theraputty exercises are initiated for flexion, extension and opposition.

Activation of Primary Muscles Involved

- Same as for Phase I

Techniques to Increase Muscle Strength, Power, and Endurance

- Yellow Theraputty activities of pinch and grip initiated three times per day for 5-minute sessions.

Functional Exercises

- Resisted three-jaw chuck, palmar, and tip pinch initiated under therapist supervision.

Milestones for Progression to the Next Phase

- No tenderness to palpation over UCL ligament
- Minimal pain with activities outside of splint

Phase IV (weeks 10 to 12)

Protection

- Continue splinting with heavy use.
- Taping may be initiated for protection with sport related activities (Figure 17-9*A-D*).

Management of Pain and Swelling

- Same as for Phase III

Techniques for Progressive Increase in Range of Motion

Manual Therapy Techniques

- Increase aggressiveness of joint mobilization and active/passive range of motion.

Soft Tissue Techniques

- Manual and vibration scar massage.

Stretching and Flexibility Techniques for the Musculotendinous Unit

- Dynamic splinting to increase MP joint flexion and thumb opposition (Figure 17-10) as needed

Other Therapeutic Exercises

- Increase resistance grade of Theraputty
- Power web, upper body exerciser, and graded clothes pins
- NMES

Activation of Primary Muscles Involved

- Same as for Phase I

Techniques to Increase Muscle Strength, Power, and Endurance

- Same as above

Functional Exercises

- Use for all ADL outside of splint.

TIMELINE 17-1: **Nonoperative Rehabilitation of Thumb Ulnar Collateral Ligament Injuries**

PHASE I (weeks 1 to 4)	PHASE II (weeks 4 to 6)
• Hand-based IP free thumb spica splint • Compression/ice/elevation • Active flexion/extension MP joint • Gentle hygiene allowed	• Splinting for protection and nighttime wear • Splint removed for light ADL (2 lb or less) • Add retrograde massage as needed to decrease edema • Add active opposition

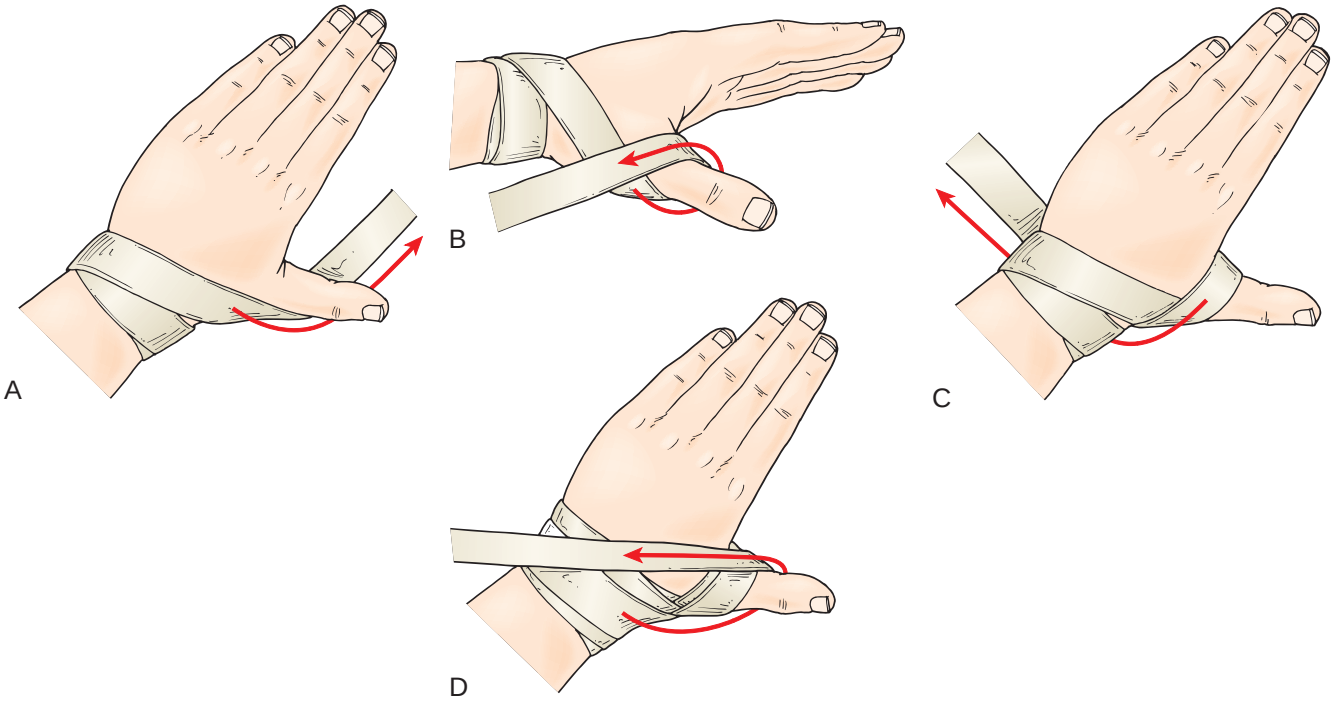

FIGURE 17-9. A–D, Taping for protection during sporting activity.

FIGURE 17-10. Dynamic splinting.

Sport-Specific Exercises

- Trainer input

Milestones for Progression to Advanced Sport-Specific Training and Conditioning

- No reported pain (rest/general use)
- UCL stability
- Functional pinch/grip strength

Criteria for Abandoning Nonoperative Treatment and Proceeding to Surgery or More Intensive Intervention

- Significant pain outside of splint
- Instability of UCL
- Stener lesion

Tips and Guidelines for Transitioning to Performance Enhancement

- Trainer input

Performance Enhancement and Beyond Rehabilitation: Training/ Trainer and

- Trainer input

TIMELINE 17-1: **Nonoperative Rehabilitation of Thumb Ulnar Collateral Ligament Injuries** (Continued)

PHASE III (weeks 6 to 10)	PHASE IV (weeks 10 to 12)
• Wean from splint for ADL and nighttime • Splint worn with heavy use • Modalities as needed • Joint mobs and passive range of motion • Scar massage • Place and hold exercises • Yellow Theraputty exercises • Resisted pinching in clinic	• Splint only with heavy use • Taping with sport-related activities • Apply dynamic or static progressive splinting as needed • Power web/upper body exerciser

Optimization of Athletic Performance

- Trainer input

Evidence

There are no key evidence-based trials.

Multiple Choice Questions

QUESTION 1. What splint would best protect the UCL in the first 4 weeks of injury?

A. Wrist cock-up
B. Hand base thumb spica
C. Neoprene thumb wrap
D. Mallet

QUESTION 2. What degree of thumb abduction is advised in the splint?

A. 0
B. 30
C. 60
D. 90

QUESTION 3. What active thumb motion is introduced in week 5?

A. Flexion
B. Extension
C. Adduction
D. Opposition

QUESTION 4. When are modalities (ultrasound/NMES) added to the treatment plan?

A. Phase I
B. Phase II
C. Phase III
D. Phase IV

QUESTION 5. What type of splint is added in Phase IV?

A. Dynamic
B. Static progressive
C. No splint
D. Silver ring

Answer Key

QUESTION 1. Correct answer: **B** (see Phase I)

QUESTION 2. Correct answer: **B** (see Phase I)

QUESTION 3. Correct answer: **D** (see Phase II)

QUESTION 4. Correct answer: **C** (see Phase III)

QUESTION 5. Correct answer: **A** (see Phase IV)

POSTOPERATIVE REHABILITATION OF THUMB ULNAR COLLATERAL LIGAMENT INJURIES

Mohamed Khalid, MD, MCh, FRCS, Bradley Kent Earnest, OTR/L, CHT, and Mark Simenson, OTR/L, CHT

Indications for Surgical Treatment

- Failure of nonsurgical treatment
- Stener lesion
- Gross instability

Brief Summary of Surgical Treatment

Major Surgical Steps

- General or regional anesthesia
- Patient supine with upper extremity on arm table; tourniquet control
- Lazy S incision with the distal limb volar to the midaxial line to provide sufficient access to the volar plate (Figure 17-11). Identify and protect branches of superficial radial nerve.
- The proximal edge of adductor aponeurosis is identified (Figure 17-12). If a Stener lesion (avulsion of the distal attachment of the ulnar collateral ligament with interposition of the adductor aponeurosis between the avulsed ligament and its site of original attachment to the base of the proximal phalanx) is present, this

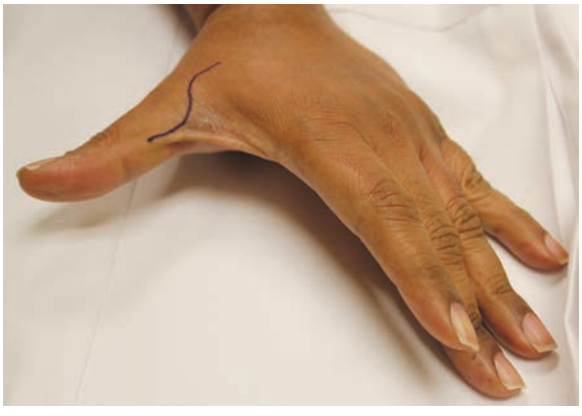

FIGURE 17-11. Dorsoulnar incision for thumb UCL repair.

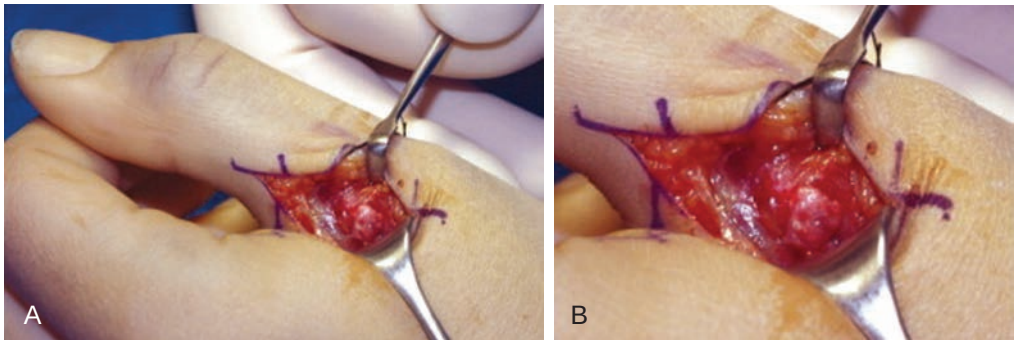

FIGURE 17-12. The adductor aponeurosis is identified. The proximal stump of the torn UCL may be identified at the proximal margin of the adductor aponeurosis if a Stener lesion is present. *(From Glickel SZ, Catalanolli LW: Repair of acute ulnar collateral ligament injury of the thumb. Procedure 7. In Chung KC, editor: Operative techniques. Hand and wrist surgery. Philadelphia, 2008, Elsevier.)*

usually well-defined edge may appear edematous and bulbous and thus less distinct.

- A longitudinal incision is made in the adductor aponeurosis parallel and volar to the ulnar border of the extensor pollicis longus tendon. This exposes the ulnar aspect of the metacarpophalangeal (MCP) joint (Figure 17-13*A*,*B*). The joint is examined to determine the extent of cartilaginous injury and if a cartilaginous shear fragment is identified, the same is removed.
- The ligament is usually avulsed distally. It is re-attached with a small bone anchor or with a suture (pullout after healing in clinic) technique. The repair is tensioned with the MCP joint in 45° of flexion to avoid overtightening. Less commonly, there may be a midsubstance tear, which can be repaired with figure-eight or horizontal mattress sutures using nonabsorbable braided synthetic suture material such as 4/0 fiber wire.
- If a fragment of bone is attached to the avulsed ligament, and it is small (less than 15% of the articular surface), the same is excised. If it is a larger fragment, it should be reduced anatomically and fixed with a K-wire, pullout suture, bone screws, or an interosseous wire.
- The adductor aponeurosis is repaired with as absorbable suture such as 4/0 Vicryl. Skin is re-approximated with a running monofilament subcuticular suture such as Monocryl.
- The thumb is immobilized in a thumb spica cast with the IP joint left free to prevent adhesions of the extensor mechanism, and the distal phalanx of the thumb is allowed to move freely after the case.

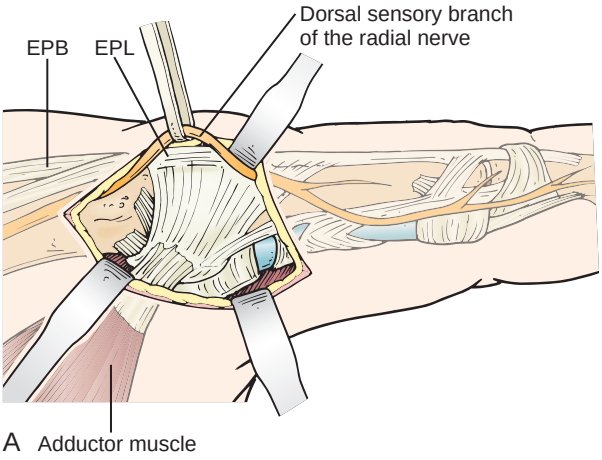

FIGURE 17-13. A, Dorsoulnar approach to the metacarpophalangeal (MCP) joint of the thumb, identifying the structures. **B,** *Dorsoulnar approach to the MCP joint of the thumb. EPB, Extensor pollicis brevis tendon; EPL, extensor pollicis longus tendon. (**A, B,** From Dorsoulnar to MCP Joint. AO Foundation. Available at: https://www2.aofoundation.org/wps/portal/surgery?showPage=approach&contentUrl=srg/76/04-Approaches/12-Dorsoulnar-MCP-JoinThumb.jsp&bone=Hand&segment=Thumb&approach=Dorsoulnar%20to%20MCP%20joint.)*

Other Surgical Techniques and Options

- Arthroscopic assisted percutaneous fixation of avulsed fracture fragment has been described by Ryu and Fagan,[1] Badia,[2] and others. Badia's technique involves using a 1.9-mm arthroscope introduced via a longitudinal portal radial to extensor pollicis longus tendon; the fractured fragmented is de-rotated and reduced and transfixed with a 0.035 K-wire under fluoroscopic guidance. The MP joint is left undisturbed.
- Because the extensor mechanism, adductor aponeurosis, and capsule are undisturbed, the rehabilitation is said to be shorter with a faster fracture healing time.

GUIDING PRINCIPLES OF POSTOPERATIVE REHABILITATION

- Protect surgical repair from lateral force
- Control pain and edema
- Maximize range of motion
- Maximize strength and ADL independence

Phase I (days 0 to 14):[1] Immediate Postoperative Period

Clinical Pearl

It is important that the patient minimize lateral stress on the MCP joint when performing hygiene activities outside of splint.

Goals

- Patient will understand the importance of postoperative splint wear and will be allowed activity to prevent extensor mechanism adhesions.
- Patient will understand ADL limitations such as repetitive and resisted pinch.
- Patient will experience controlled pain and edema.

Protection

- Hand-based IP free thumb spica splint with no more than 30° of abduction.
- Splint removal allowed for hygiene purposes.

Management of Pain and Swelling

- Ice as needed for pain.
- Light compressive wrap such as Coban as needed, ice and elevation for swelling.

Techniques for Progressive Increase in Range of Motion

Stretching and Flexibility Techniques for the Musculotendinous Unit

- Active motion of IP and wrist joints.

Activation of Primary Muscles Involved in Injury Area or Surgical Structures

- Extrinsic/intrinsic thumb musculature

Functional Exercises

- Light ADL use within splint such as eating, grooming, writing, and dressing.

[1]*Prehabilitation, if appropriate, is described in the Nonoperative Rehabilitation section of this chapter.*

Milestones for Progression to the Next Phase

- Minimal pain with light ADL use.

Phase II (postoperative weeks 2 to 6)

Clinical Pearl

It is important that the patient understands the difference between active and passive motions of the MCP joint to protect the UCL from lateral forces while healing.

Goals

- Pain and edema control
- Patient will perform active range of motion to involved joint in therapy and as instructed at home.
- Increasing active range of motion of MCP joint
- Minimize hypertrophy of scar and begin collagen remodeling.
- Minimize scar hypersensitivity.

Protection

- Continue with splint wear except when performing exercises and hygiene.

Management of Pain and Swelling

- Ice as needed for pain.
- Elevation, compression, active motion of involved upper extremity, including MCP, for swelling.

Techniques for Progressive Increase in Range of Motion

Soft Tissue Techniques

- Massage and scar mobilization may be initiated at 4 weeks.

Stretching and Flexibility Techniques for the Musculotendinous Unit

- Active extension and flexion are performed in therapy and added to home program. Patient will perform three

TIMELINE 17-2: **Postoperative Rehabilitation After Ulnar Collateral Ligament Repair**

PHASE I (weeks 1 to 2)	PHASE II (weeks 3 to 6)	PHASE III (weeks 6 to 10)
• Hand-based IP free thumb spica splint • Compression/ice/elevation • Active flexion/extension MP joint • Gentle hygiene allowed	• Splinting for protection and nighttime wear • Splint removed for light ADL (2 lb or less) • Add retrograde massage as needed to decrease edema • Add active opposition	• Wean from splint for ADL and nighttime • Splint worn with heavy use • Modalities as needed • Joint mobs and passive range of motion • Scar massage • Place and hold exercises • Yellow Theraputty exercises • Resisted pinching in clinic

sets of 10 repetitions per day. Opposition is added at week 4.

Activation of Primary Muscles Involved in Injury Area or Surgical Structures

- Same as for Phase I

Functional Exercises

- Same as for Phase I

Milestones for Progression to the Next Phase

- Pain at rest 0/10
- Pain/tenderness 2/10 or less with palpation over UCL and during ADL use.

Phase III (postoperative weeks 6 to 10)

Clinical Pearl

It is important that the patient understand the lateral force component of ADL and will wear the splint for protection during heavy use.

Goals

- Patient will understand and begin gentle use of involved hand with splint removed.
- Patient will understand and begin static progressive splinting of MCP joint.
- Control pain and edema.
- Continue protection of UCL.

Protection

- Patient may begin weaning from splint for ADL.
- Continue splinting with heavy use.

Management of Pain and Swelling

- Continue with ice, retrograde massage, and compression.
- Modalities such as ultrasound and neuromuscular electrical stimulation (NMES) may be added.
- For swelling, the guidelines are the same as for Phase II.

Techniques for Progressive Increase in Range of Motion

Manual Therapy Techniques

- Joint mobilization and passive range of motion may be initiated at MCP joint.

Soft Tissue Techniques

- Same as for Phase II.

Stretching and Flexibility Techniques for the Musculotendinous Unit

- Initiate place and hold exercises in MP flexion, extension, and opposition.

Activation of Primary Muscles Involved in Injury Area or Surgical Structures

- Same as for Phase I.

Techniques to Increase Muscle Strength, Power, and Endurance

- Extra-soft (yellow) Theraputty activities of pinch and grip initiated three times per day for 5-minute sessions.

Functional Exercises

- Resisted three-jaw chuck, palmar, and tip pinch initiated under therapist supervision

Milestones for Progression to the Next Phase

- No tenderness to palpation over UCL ligament and minimal pain with activities outside of splint.

Phase IV (postoperative weeks 10 to 14)

Clinical Pearl

- Patient education should focus on sport specific protection to prevent future UCL injury.
- Patient can reenter athletic activity with monitoring of pain, edema, instability, and stiffness.

TIMELINE 17-2: **Postoperative Rehabilitation After Ulnar Collateral Ligament Repair** (Continued)

PHASE IV (weeks 10 to14)	PHASE V (weeks 14 to 24)	PHASE VI (weeks 24 to 52)
• Splint only with heavy use • Taping with sport-related activities • Apply dynamic or static progressive splinting as needed • Power web/upper body exerciser/ increase resistance of Theraputty	• Short opponens splint as needed for aggressive sport-specific use • Trainer input for strength, power, endurance, and sport-specific exercises	• Return to sport/Trainer input

Goals

- Patient will regain full functional active motion of involved thumb.
- Scar formation will be limited.
- Pinch and grip strength will be functional.
- Patient will progress to sport-specific training and conditioning.

Protection

- Continue splinting with heavy use. Taping may be initiated for protection with sport-related activities.

Management of Pain and Swelling

- Same as for Phase III.

Techniques for Progressive Increase in Range of Motion

Manual Therapy Techniques

- Increase aggressiveness of joint mobilization and active/passive range of motion.

Soft Tissue Techniques

- Same as for Phase III.

Stretching and Flexibility Techniques for the Musculotendinous Unit

- Dynamic splinting to increase MP joint flexion and thumb opposition as needed.

Activation of Primary Muscles Involved in Injury Area or Surgical Structures

- Same as for Phase I.

Techniques to Increase Muscle Strength, Power, and Endurance

- Increase resistance grade of Theraputty.
- Power web, upper body exerciser and graded clothes pins, NMES.

Functional Exercises

- Use for all ADLs outside of splint.

Sport-Specific Exercises

- Use of a power web, flex bar and calibrated hand gripper

Milestones for Progression to the Next Phase

- No reported pain (rest/general use)
- UCL stability
- Functional pinch/grip strength

Phase V (postoperative weeks 14 to 24)

Clinical Pearls

> Focus on the patient's ability to reenter sport-specific training, avoiding reinjury to the UCL. At this phase the patient should be reaching use of the affected thumb at the same level as before the injury.

Goals

- Patient will initiate sustained power pinch.
- Patient may consider wearing the short opponens splint to protect thumb with aggressive sport-specific use.
- Return to unrestricted activity.
- Return to unrestricted sport-specific training under the guidance of a qualified trainer.

Protection

- Short opponens splint as needed for aggressive sport-specific use.

Management of Pain and Swelling

- Same as for Phase III

Techniques for Progressive Increase in Range of Motion

Manual Therapy Techniques

- Same as for Phase IV

Soft Tissue Techniques

- Same as for Phase III

Stretching and Flexibility Techniques for the Musculotendinous Unit

- Same as for Phase IV

Activation of Primary Muscles Involved in Injury Area or Surgical Structures

- Same as for Phase I

Functional Exercises

- Unrestricted

Sport-Specific Exercises

- Variety of hand tools with the BTE/bodyblade.

Milestones for Progression to the Next Phase

- Pain, edema, stability, strength, will be near pre-injury levels to allow the final sport- specific abilities under the supervision of a qualified trainer.

Phase VI (postoperative weeks 24 to 52)

Clinical Pearls

The patient will combine the last five stages, allowing strength, stability, pain-free mobility, and full functional use to return to sport.

Goals

- Full range of motion with UCL stability
- Pain free
- Return to sport

Protection

- Splint/tape only as needed

Management of Pain and Swelling

- Same as for Phase III

Techniques for Progressive Increase in Range of Motion

Manual Therapy Techniques

- Same as for Phase IV

Soft Tissue Techniques

- Same as for Phase III

Stretching and Flexibility Techniques for the Musculotendinous Unit

- Same as for Phase III

Activation of Primary Muscles Involved in Injury Area or Surgical Structures

- Same as for Phase I

Functional Exercises

- Unrestricted

Sport-Specific Exercises

- Same as for Phase V

Milestones for Progression to the Next Phase

- Full sport participation

Criteria for Return to Sport

General

- Pain free
- Within 10% of total active motion of the nonaffected thumb
- Stable with lateral pinch

Sport-Specific

- Trainer input

After Return to Sport

Continuing Fitness or Rehabilitation Exercises

- Fitness/rehabilitation exercises per direction of sport-specific trainer

Exercises and Other Techniques for Prevention of Recurrent Injury

- Continued patient education
- Continued strengthening of extrinsic/intrinsic thumb musculature
- Consider NMES/biofeedback to the above muscle groups
- Splinting/Taping as needed

Evidence

There are no key evidence-based trials.

Multiple Choice Questions

QUESTION 1. What splint would best protect the UCL in the first 4 weeks of injury?

A. Wrist cock-up
B. Hand base thumb spica
C. Neoprene thumb wrap
D. Mallet

QUESTION 2. Splint may be removed for light activities of daily living 2 lb or less in what phase?

A. Phase I
B. Phase II
C. Phase III
D. Phase IV

QUESTION 3. What type of splint is added in Phase IV?

A. Dynamic
B. Static progressive
C. No splint
D. Silver ring

QUESTION 4. When are modalities (ultrasound/NMES) added to the treatment plan?

A. Phase 1
B. Phase 2
C. Phase 3
D. Phase 4

QUESTION 5. The patient will initiate sustained power pinch in what phase?

A. Phase 3
B. Phase 4
C. Phase 5
D. No phase

Answer Key

QUESTION 1. Correct answer: **B** (see Phase I)

QUESTION 2. Correct answer: **B** (see Phase II)

QUESTION 3. Correct answer: **A** (see phase IV)

QUESTION 4. Correct answer: **C** (see Phase III)

QUESTION 5. Correct answer: **C** (see Phase V)

BEYOND BASIC REHABILITATION: RETURN TO SKIING AFTER NONOPERATIVE OR OPERATIVE TREATMENT OF THUMB ULNAR COLLATERAL LIGAMENT INJURIES

Mohamed Khalid, MD, MCh, FRCS

Introduction

Aspects of Skiing That Require Special Attention In Rehabilitation

- Optimal handling of the ski pole with reference to the technique, grip strength, and flexibility
- Ability to control the body's movement during descent in various positions
- Improved agility and quickness to be able to better handle quick lateral movements
- Good joint mobility and appropriate muscle balance, especially in relation to quadriceps and hamstrings
- Optimal core and back strength in order to control the body's movements, especially in highly variable conditions like glades, steeps, mixed crud, and bumps
- Skiing is the most common upper extremity injury experienced by skiers.
- Return to sports is advised when there is minimal or no pain and swelling, strength has been fully regained, and stability of the MCPJ is fully restored. The specific requirements of the sport are also an important consideration. This usually takes 6 to 8 weeks in partial (grade I and II) tears. According to Lane a risk of re-rupture exists if the patient with a complete (grade III) rupture returns to sport within 3 months following surgical repair.[1] He recommends that the patients be counseled regarding this and with this understanding they can be conditionally allowed to return to sports at 4 to 6 weeks in the orthosis, and the orthosis can be discontinued at 12 weeks postoperative.
- Foye et al.[2] recommend 6 to 8 weeks of immobilization followed by return to sport with a protective splint.

Phase I: Advanced Strength and Conditioning Programs

Periodization

- Undulating
- Macrocycles
- Mesocycles
- Microcycles

TIMELINE 17-3: **Return to Skiing After Nonoperative or Operative Treatment of Thumb Ulnar Collateral Ligament Injuries**

PHASE I (weeks 1 to 2)	PHASE II (weeks 3 to 6)
• Hand-based IP free thumb spica splint • Compression/ice/elevation • Active flexion/extension MP joint • Gentle hygiene allowed	• Splinting for protection and nighttime wear • Splint removed for light ADL (2 lb or less) • Add retrograde massage as needed to decrease edema • Add active opposition

Program Design/Performance Training Program

Sport-Specific Concepts of Integrated Training

- Training continuum
- Flexibility/joint mobility for joint stability
- Training with optimum posture
- Sensorimotor and balance training
- Core training
- Cardiorespiratory training
- Multiplanar training activities
- Training for optimum muscle balance
- Training for optimum muscle functional strength
- Training for optimum muscle functional power
- Neuromuscular dynamic stability exercises
- Plyometric training

Olympic Lifts Used in the Training Program

- Not appropriate until full healing and recovery of the thumb has taken place (usually about 12 weeks)

Training Principles Used in the Design of the Program

- Principle of progression
- Principle of overload
- Principle of variation
- Principle of individualization
- Principles of specificity-specific adaptation to imposed demands (SAID)

Application of Acute Training Variables

- Repetitions: as many as possible in 60 seconds
- Sets: 1 to 4
- Rest interval: as short as possible while maintaining proper form
- Intensity: beginning at 60% to 70% of target heart rate (THR) and working toward a 75% to 85% THR (as calculated by the Karvonen formula)
- Repetition tempo: The aim is to develop/maintain basic strength; therefore the appropriate repetition tempo is 2/0/2 (eccentric/isometric/concentric).
- Training frequency: Three per week
- Training duration: 45 to 60 minutes
- Specific exercises used in the training:
  - Exercises that do not involve use of the injured hand
  - Should perform warmup and stretching before performing these exercises
- Lower body circuit:
  - **Ski Jumps:** Aim to stay in a squatted position while jumping first 90° to the left, then back to the center, then 90° to the right, finishing back at the center (Figure 17-14).
  - **Machine Squat:** Avoid locking the legs. Maintain the knee flexion angle at a minimum of 90° (Figure 17-15).
  - **Jump Lunges:** One leg forward in the bottom of a lunge position, with shin vertical. Start by explosively jumping in the air and switch legs so that the opposite leg comes in the forward position (Figure 17-16).
  - **Box Jumps:** The box is set to at least a 15- to 20-inch high. Jump up explosively on to the box and jump back down immediately. Spring right back up for the next jump (Figure 17-17).
  - **Seated Leg Extension:** Performed in a smooth motion avoiding locking of the legs with the back straight. Can be performed double leg or single leg with weights adjusted accordingly (Figure 17-18).
  - **Abductor and Adductor Machine:** Aim to hold the leg abducted for at least 3 seconds before lowering under control and repeating (Figure 17-19).
  - **Pulsing Squat:** Performed in small movements. Stay in a squatted position and pulse three to five times. Add suitable weights for progression (Figure 17-20).
  - **Hamstring Curls:** Making sure that Hamstring stretches are performed before using the machine. Suitable weights selected and performed in a smooth motion. Weights can be increased for progression (Figure 17-21).

FIGURE 17-14. Ski jump.

TIMELINE 17-3: **Return to Skiing After Nonoperative or Operative Treatment of Thumb Ulnar Collateral Ligament Injuries** (Continued)

PHASE III (weeks 6 to 10)	PHASE IV (weeks 10 to 14)	PHASE V (weeks 14 to 24)
• Wean from splint for ADL and nighttime • Splint worn with heavy use • Modalities as needed • Joint mobs and passive range of motion • Scar massage • Place and hold exercises • Yellow Theraputty exercises • Resisted pinching in clinic	• Splint only with heavy use • Taping with sport related activities • Apply dynamic or static progressive splinting as needed • Power web/upper body exerciser/ increase resistance of Theraputty	• Short opponens splint as needed for aggressive sport-specific use • Trainer input for strength, power, endurance, and sport-specific exercises

FIGURE 17-15. Machine squat.

FIGURE 17-16. A–C, Jump lunge.

FIGURE 17-17. Box jump.

FIGURE 17-18. Seated leg extension.

FIGURE 17-19. A,B, Abductor and adductor machine.

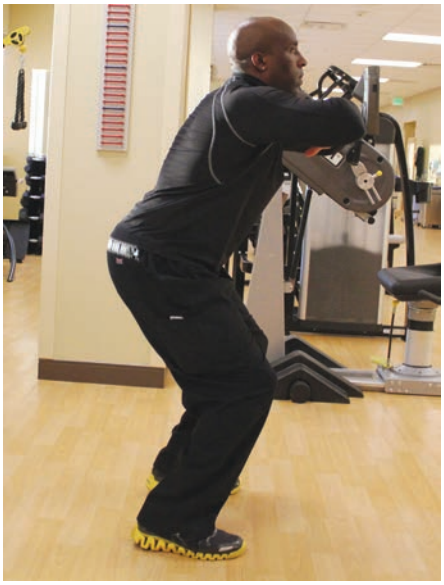

FIGURE 17-20. Pulsing squat.

FIGURE 17-21. Hamstring curl.

FIGURE 17-22. Body weight squat.

- **Body Weight Squats:** Start with arms out straight with the feet slightly wider than the shoulder width, looking straight, and back flat to slightly arched. The squat is initiated from the hips by sitting back and down, keeping the weight on the heels and coming down to a position where the thighs are approximately parallel to the ground. Press back to the starting position following the same movement pattern (Figure 17-22).

- **Abdominal Circuit:**
  - **Normal Sit-Ups:** Keep the chin off the chest (Figure 17-23).
  - **Elbow to Knee Sit-Ups:** Alternate elbows to knees; count reps on one side only (Figure 17-24)
  - **Hand to Foot Sit-Ups:** Alternate hands to feet; count reps on one side only (Figure 17-25)

Application of Chronic Training Variables

- In general, the preparatory phase consists of reviewing the previous season's performance and identifying and addressing the deficiencies.
- The duration of this phase depends upon the phase (early, mid, or late) the injury occurred.

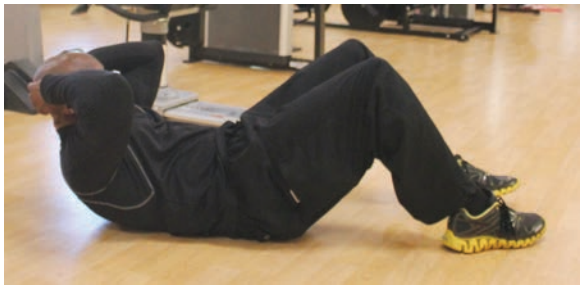

FIGURE 17-23. Normal sit up.

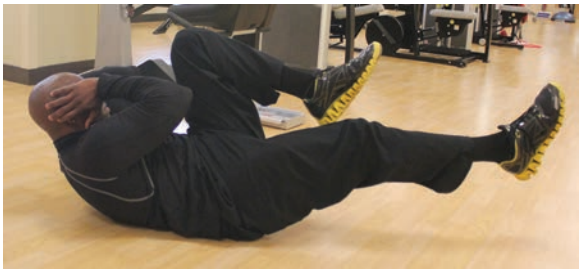

FIGURE 17-24. Elbow to knee sit up.

Phase II: Performance Enhancement Training Techniques

Periodization

- Undulating
- Macrocycles
- Mesocycles
- Microcycles

Program Design/Performance Training Program

Sport-Specific Concepts of Integrated Training

- In this period the emphasis is on high-intensity weight lifting and anaerobic exercises.
- By the start of this phase the injured hand should have recovered sufficiently for it to be used; therefore it would be appropriate to use the hand for performing various exercises.
- The following concepts are used:
  - Training continuum
  - Flexibility/joint mobility for joint stability
  - Training with optimum posture
  - Sensorimotor and balance training
  - Core training
  - Cardiorespiratory training

FIGURE 17-25. Hand to foot sit up.

- Multiplanar training activities
- Training for optimum muscle balance
- Training for optimum muscle functional strength
- Training for optimum muscle functional power
- Neuromuscular dynamic stability exercises
- Training for speed, agility, quickness (SAQ)
- Plyometric training
- Functional training

Olympic Lifts Used in the Training Program

- Snatch
- Clean and jerk
- Power clean

Training Principles Used in the Design of the Program

- Principle of progression
- Principle of overload
- Principle of variation
- Principle of individualization
- Principles of SAID

Application of Acute Training Variables

- Repetitions: 6 to 12
- Sets: five
- Rest interval: as short as possible while maintaining proper form
- Intensity: 70% to 80% of THR (as calculated by the Karvonen formula)
- Repetition tempo: maximal strength and hypertrophy is the goal; therefore the appropriate tempo is 4/2/1 to 2/0/2.
- Training frequency: daily except 1 day off per week
- Training duration: 60 to 90 minutes
- Specific exercises used in the training
- **Lower body circuit** (as described in Phase I)
- **Leg circuit**
  - **Two-Footed Squat Thrusts** (Figure 17-26)
    - With the hands flat facing forward under the shoulders, start with your feet together and extended.
    - Staying on the toes, thrust the knees upwards in the direction of the chest.
    - Once the feet have landed up by the chest, thrust them back smoothly to the starting position before repeating.

FIGURE 17-26. Two-footed squat thrust.

FIGURE 17-27. Walking lunge.

    - Aim for a 12-inch jump
  - **Walking Lunge Forward** (Figure 17-27)
    - Stand upright, feet together, holding two light (5- to 8-lb) dumbbells at your sides (palms facing in).
    - Take a controlled step forward with your right leg.
    - Lower hips toward the floor and bend both knees (almost at 90° angles). The back knee should come close but never touch the ground. Your front knee should be directly over the ankle and the back knee should be pointing down toward the floor.
    - Push off with your right foot and bring it forward to starting position. This completes one repetition.
  - **Alternate Leg Squat Thrusts** (Figure 17-28)
    - Place your hands flat on the floor, with fingers facing forward directly under the shoulder joint.
    - Keeping on the toes during the exercise, take one leg from the rear, up toward the chest in a smooth motion. You will find that this exercise will also work your shoulder muscles.
    - Once the foot of this leg reaches the ground, the other leg should then start to come up toward the chest, and at the same time the leading leg should go back to the starting position.
- **Upper body circuit**
  - **Wide Arm Press-Up** (Figure 17-29)**:** With elbows as spread out to the side as possible
  - **Normal Press-Ups** (Figure 17-30)**:** Keeping a straight line through the back
  - **Close Hand Press-Ups** (Figure 17-31)**:** Aiming to keep the thumbs touching each other
- **Abdominal Circuit** (as described in Phase I)

FIGURE 17-28. Alternate leg squat thrust.

FIGURE 17-29. Wide arm press up.

Application of Chronic Training Variables

- **Cardiovascular:** 20 to 60 minutes per session 3 to 6 times a week
- **Muscular Strength:** 30 to 40 minutes per session 2 to 3 times a week
- **Flexibility:** 20 to 30 minutes per session 2 to 3 times a week

Phase III: Sport-Specific Training

Periodization

- Undulating
- Macrocycles
- Mesocycles
- Microcycles

Program Design/Performance Training Program

Sport-Specific Concepts of Integrated Training

- In general, body-weight-based exercises and free-weighted exercises, such as squatting, lunging, jumping, stepping, pressing, pulling, and deadlifting, which mimic natural movement patterns are preferred over machine-based exercises, which follow a fixed motion path.
- Plyometric training, especially focused on soft landing with the hips and knees flexed, is very useful.
- Because skiing predominantly involves eccentric movements, exercises such as walking lunges, and jump style lunges that have a major eccentric component are particularly useful.

FIGURE 17-30. Normal press up.

FIGURE 17-31. Close hand press up.

- The ability to make a quick side-to-side movement such as lateral hops across a line are useful in training the body for situations such as skiing the bumps or dicing quickly with ease through the trees in the glades.
- Alpine skiing is predominantly an interval endurance activity and hence is well suited for an interval training workout.
- Training continuum
- Flexibility/joint mobility for joint stability
- Training with optimum posture
- Sensorimotor and balance training
- Core training
- Cardiorespiratory training
- Multiplanar training activities
- Training for optimum muscle balance
- Training for optimum muscle functional strength
- Training for optimum muscle functional power
- Neuromuscular dynamic stability exercises
- Training for SAQ
- Sport-specific training

Olympic Lifts Used in the Training Program

- Snatch
- Clean and jerk
- Power clean

Training Principles Used in the Design of the Program

- Principle of progression
- Principle of overload
- Principle of variation
- Principle of individualization
- Principles of SAID

Application of Acute Training Variables

- Repetitions: 20 to 25
- Sets: four
- Rest interval: 10 seconds
- Repetition tempo: 2/0/2
- Intensity: 70% to 80% of THR (as calculated by the Karvonen formula)
- Training frequency: at least twice a week
- Training duration: 60 to 90 minutes
- Specific exercises used in the training:
  - As in Phase II

- True technique-specific training can take place only on a ski slope, but in most places this is hard to achieve because the snow season may not last long enough. If there is access to simulators such as the ski-power simulator,[3] technique-specific training can be done under controlled conditions.

Application of Chronic Training Variables

- As described in Phase II

Sports Performance Testing

General Information

- General history: demographic information, previous experience in skiing, intensity of perceived exertion (Borg's scale, 4 = very light, 20 = very intense)
- Medical history: diabetes, cardiovascular conditions, and neurological conditions
- Sports injury history: hand injuries, knee injuries, hip injuries, and spinal/head injuries
- Surgical history: repair of ligament injuries and fractures
- Chronic conditions/medications: beta blockers, insulin, oral antidiabetics

Objective Tests

- Physiological assessments: muscular strength, anaerobic power, aerobic power, flexibility
- Body composition tests: height, weight and percentage of body fat. Body fat is calculated by measuring skin fold thickness using a Harpenden skin fold calipers, with values taken from multiple sites.
- Anaerobic power is assessed by measuring squat jump power and percent height loss during 45 seconds of repeated counter movement jumps using a Quattro jump force plate.
- Aerobic power: continuous incremental cycling test on an electromagnetically braked cycle ergometer. During these incremental exercises, oxygen uptake is continually measured using a calibrated spirometry system.
- Static/dynamic postural assessments: 20 meter shuttle run, double leg jumps, 60-second or 90-second repeated box jumps

Specific Criteria for Progression to the Next Stage to Determine Readiness for Skiing

- While the athlete is recovering from the thumb injury he or she should continue with exercises designed to maintain muscle strength, anaerobic/aerobic power, and flexibility even while the thumb is in a protective cast/splint.
- Depending on whether the UCL injury was partial (grade 1/2) or complete (grade 3/4) the athlete can start using the previously injured hand for actual skiing practice in 6 to 12 weeks, respectively.
- A clinical assessment evaluating tenderness, stability, and range of motion is performed and forms the basis for progression to performing exercises involving the hand and finally to actual practice on the ski slopes.

Criteria for Release to Unsupervised Complete Participation in Skiing

- Absence of thumb/hand pain
- Range of motion (ROM) of the metacarpophalangeal joint of 80% to 90% of the uninjured thumb and nearly full ROM of the interphalangeal joint
- Pinch and grip strength within 5% to 10% of the contralateral uninjured side

Recommended Ongoing Exercises

- Stretching
- Flexibility training
- Cardiovascular fitness exercises
- Aerobic and anaerobic exercises

Evidence

Breil FA, et al: Block training periodization in alpine skiing: effects of 11 day HIT on VO_{2max} and Performance. *Eur J Appl Physiol* 109:1077–1086, 2010.

In this prospective study the authors investigated the effect of block training periodization on maximal oxygen consumption and parameters of exercise performance in elite junior alpine skiers. They concluded that in for competitive alpine skiers, block periodization of HIT offers a promising way to efficiently improve VO_{2max} and performance. (Level XX evidence)

Malliou P, et al: Proprioceptive training for learning downhill Skiing. *Percept Motor Skills* 99(1):149–154, 2004.

The aim of this prospective study was to assess whether balance training would improve downhill skiing for 30 physical education students who had no previous skiing experience and were randomly assigned to two groups. The control group attended only ski lessons for two weeks, 2 to 4 hours daily. The experimental group attended downhill ski lessons and indoor balance training on a balance board, wearing ski boots, for 20 minutes every second day in the afternoon. All participants before training completed a balance assessment (stability indices). After the completion of the ski classes, all repeated the balance assessment and two downhill ski tests of agility, slalom and snow-ploughing techniques. Analysis of variance with repeated measures showed both groups improved balance similarly, but the experimental group performed significantly better on the downhill-slalom agility test, so the specific indoor balance training was helpful. (Level XX evidence)

Muller E, et al: Specific fitness training and testing in competitive sports. *Med Sci Sports Exer* 32(1):216–220, 2000.

This prospective study deals, in part, with the kinematic assessment and development of a specific training device for Alpine skiers to enable sport-specific training. (Level XX evidence)

Neumayr G, et al: Physical and physiological factors associated with success in Alpine skiing. *Int J Sports Med* 24(8):571–575, 2003.

In this prospective study the authors describe the physical and physiological characteristics of World Cup (WC) skiers. Twenty female and 28 male members of the Austrian WC ski team were examined pre- and post-seasonally from 1997 to

2000. Physical parameters such as age, height, body mass, body mass index, percent body fat and thigh circumference were recorded from each athlete. The physiological variables investigated consisted in the aerobic power and in the muscle strength of the lower limbs. Racing performance was defined by the WC ranking position. The athlete's aerobic performance capacity was assessed by maximal exercise testing on a bicycle ergometer, and the isokinetic muscle strength of the knee extensor and flexor muscles by the use of a computer-interfaced dynamometer. The study suggests that success in professional alpine skiing is not related to single physiological variables. Two main factors, however, are crucial, that is, high levels of aerobic power and muscle strength. (Level XX evidence)

Turnbull JR, Kilding AE, Keogh JWL: Physiology of Alpine skiing. *Scand J Med Sci Sports* 19:146–155, 2009.

Excellent review article comprising more than 30 years of research including 29 on snow investigations of specific physiology relating to the various ski racing disciplines, nine off snow investigations of off snow investigations of the physiological capacities of ski racers of varying ability and four review articles. (Level XX evidence)

Multiple Choice Questions

QUESTION 1. The most common upper extremity injury in skiers is

A. anterior cruciate ligament rupture.
B. fracture of scaphoid.
C. ulnar collateral ligament damage.
D. radial collateral ligament damage.

QUESTION 2. Return to sport after a skier's thumb injury is dependent upon

A. The age of the athlete.
B. The performance level of the athlete.
C. the motivation of the athlete.
D. the grade of the athlete's injury.

QUESTION 3. A commonly used physiological parameter to assess the intensity of conditioning workout is

A. target heart rate.
B. resting blood pressure.
C. resting heart rate.
D. body core temperature.

QUESTION 4. The optimal repetition program (eccentric-isometric-concentric) for a strength conditioning program is

A. 2-1-2.
B. 1-1-2.
C. 4-2-4.
D. 2-0-2.

QUESTION 5. Skiing predominantly involves _____ muscle contraction.

A. eccentric
B. concentric
C. isometric
D. tetanic

Answer Key

QUESTION 1. Correct answer: **C** (see Introduction)

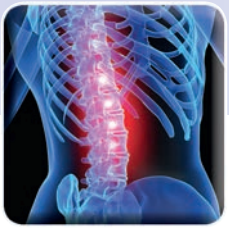
QUESTION 2. Correct answer: **D** (see Introduction)

QUESTION 3. Correct answer: **A** (see Phase I)

QUESTION 4. Correct answer: **D** (see Phase I)

QUESTION 5. Correct answer: **A** (see Phase III)

Chapter 18



Lumbar Spine Strains and Sprains

INTRODUCTION

Christopher J. Durall, PT, DPT, MS, SCS, LAT, CSCS, and Brian K. Allen, DO

Epidemiology

- Lumbar spine injuries in athletes are relatively common and most of these are thought to be strains (partial or complete tears of muscle-tendon units) and/or sprains (partial or complete tears of ligamentous/capsular/discal tissues).[1]
- Among collegiate athletes, men's wrestling, football, and women's gymnastics have the highest rates of low back injury, with an occurrence of 0.36 to 0.49 injuries per 1000 athlete exposures. Approximately 80% of these are thought to be lumbar strains or sprains.[2-4]
- Among high school athletes, 7% to 13% of all sports injuries are lower back injuries, of which muscle strains account for roughly 60%.[5]
- Low back injuries are the most common type of injury in competitive weightlifters, affecting approximately 23% of these individuals. Roughly 82% of these injuries are believed to be strains/tendonitis or sprains.[6]
- Low back pain is the most common musculoskeletal problem reported by both amateur and professional golfers, and most of these injuries are thought to be strains or sprains.[7,8]
- The majority of low back injuries occur during competition, although women's basketball, volleyball, and field hockey have higher rates of low back injury during practice.[2-4]
- Among football players, linemen seem to be more vulnerable to low back injury compared with other positions.

Pathophysiology

Intrinsic Factors

- History of previous back injury or back surgery, obesity, structural deformity (e.g., scoliosis, spondylolysis, hypermobility, leg-length inequality) all appear to elevate risk of future low back sprain/strain.
- Reduced trunk extensor muscle endurance has been found to be a risk factor for nonspecific LBP.[9]
- Lack of adequate trunk muscle endurance, in general, may lead to increased loading of the passive low-back structures (ligaments, capsules, discs), which may increase the risk of future lumbar sprain.[10]
- Contrary to popular belief, a correlation between lumbar mobility/flexibility and low back symptomatology has not been conclusively demonstrated, at least in gymnasts.[11,12]

Extrinsic Factors

- Improper technique/biomechanics leading to excessive tissue loading
- Excessive training/participation resulting in cumulative overload
- Intense training/participation (aggressiveness, "win at all costs" syndrome, etc.).[13]
- Sports-specific demands/biomechanics (e.g., extension loading in gymnasts and football lineman)
- Involvement in impact sports (e.g., football) appears to be a risk factor for lumbar strain/sprain due to loading and repetition demands of these activities.[13]
- Sports that require *repetitive end-range of motion loading (e.g., hyperextension in gymnastics)*, are associated with a greater risk of *lumbar strain/sprain*. Weightlifting, as a sport, or as a performance-enhancing modality for other sports, increases the load on the spine and, thus, the potential for injury.

Traumatic Factors

- Sudden forceful tensile loading (e.g., twisting, bending)

- Muscular overexertion, with either movement or sustained positioning (strains)

Classic Pathological Findings

- Identifiable pathological findings are rare with lumbar strains/sprains.
- Reactive muscle spasm and/or muscular trigger points may be present in some individuals.[14]

Clinical Presentation

History

- The athlete may or may not recall a specific mechanism of injury (e.g., fall).
- Some athletes may report recent increases in training frequency and/or intensity.
- Pain of a lower lumbar sprain or strain generally originates in the lower back and upper buttocks, although it may refer into surrounding areas, including the thighs. The pain is usually movement-related and may be provoked only when the athlete moves in a particular way. Because of this mechanical pain, the athlete may complain of loss of function, such as an inability to turn, twist, or bend normally.
- The athlete may report painful muscle spasms.[15]

Physical Examination

Abnormal Findings

- Trunk active range of motion is typically reduced, presumably due to pain from loading injured tissues (Figure 18-1).
- Gait may be mildly antalgic during the acute phase of injury to avoid loading injured tissues.
- Palpation of the muscles in the lumbar area may reveal local tenderness, trigger points, and/or spasm.

FIGURE 18-1. Trunk active range of motion is typically reduced following a lumbar strain/sprain, presumably because of pain from loading injured tissues.

- Edema, erythema, and elevated skin temperature may be apparent when the injured tissues are superficial.
- With a lumbar sprain, passive posterior-to-anterior "springing" of vertebrae adjacent to affected ligaments/capsule/disc is usually provocative.
- Contraction or palpation of affected muscles is provocative with a lumbar strain, whereas passive posterior-to-anterior "springing" of the lumbar vertebrae is usually not provocative.

Pertinent Normal Findings

- Structural deformities (e.g., sciatic list, "step-off" deformity) should be absent.
- Neurological symptoms (e.g., myotomal weakness, lower extremity reflex aberrations, dermatomal sensory changes) should be absent.
- Pain should not markedly intensify with lumbar extension. (If it does, consider spondylolysis, particularly in young athletes whose sport or position requires repetitive extension, such as gymnasts or football linemen).
- Radicular symptoms (narrow band of pain radiating into legs), particularly those below the knee, should be absent with lumbar sprains/strains.
- The straight-leg raising test may provoke mild low back pain but should not produce leg symptoms below the knee.
- Tests for sacroiliac dysfunction (e.g., posterior thigh thrust, gapping) should be negative.

Imaging

- Imaging is usually not appropriate for lumbar strain/sprain injuries, unless the injury is the result of recent significant trauma.[16]
- Plain radiography may be appropriate to rule out avulsion fractures when pain is localized to tendon-bone interface.
- Imaging should be considered in patients with severe, unremitting pain or neurological findings; pain that developed after an acute traumatic event or pain that persists longer than 6 weeks.
- Imaging should be considered earlier in young athletes because early identification of acute spondylolisthesis can influence outcomes.[17]
- Anteroposterior, lateral, 45° right and left oblique views and collimated lateral views of the lumbar spine should be obtained.
- CT, MR, or scintography may be appropriate for select patients to rule out other potential causes of back pain, such as fracture, infection, tumor, or involvement of spinal nerve roots.

Differential Diagnosis

- Visceral injury/disease (e.g., renal disease, pyelonephritis)
- Vascular disease (e.g., abdominal aortic aneurysm)
- Lumbosacral disc injuries
- Lumbosacral facet syndrome
- Lumbosacral instability
- Lumbosacral radiculopathy
- Lumbosacral spine acute fracture

- Lumbosacral spondylolisthesis
- Lumbosacral spondylolysis
- Piriformis syndrome
- Early discitis before onset of fever
- Rheumatic disease: white blood cell count, erythrocyte sedimentation rate, and human leukocyte antigen assay for HLA-B27 may be used to assess for underlying rheumatic disease.
- Sacroiliac joint injury

Treatment

Nonoperative Management

- Oral, topical, or injectable analgesics
- Oral, topical, or injectable antiinflammatories
- Muscle relaxants
- Pain/symptom modulating modalities (e.g., sensory electrical stimulation, cryotherapy)
- Spinal mobilization (nonthrust) or manipulation (thrust)
- Therapeutic massage/soft tissue mobilization
- Relative rest
- Therapeutic exercise
- Aquatic therapy
- Patient education (e.g., warm-up routines appear to have a positive effect on preventing low back injuries in golfers if they are at least 10 minutes long)[18]

Guidelines for Choosing Among Nonoperative Treatments

- Pain/symptom modulating modalities should be considered during the acute phase of injury. Once the athlete is able to tolerate active treatment, these should be discontinued or used sparingly to minimize iatrogenic effects of exercise or spinal mobilization/manipulation.
- Muscle relaxants: Medication such as Skelaxin and Flexeril has no direct effect on the muscle motor unit. Their mechanism of action is through modifying the central nervous system response to painful stimuli. They do work synergistically with pain medication allowing lower doses of pain medication to have the same pain relieving effect.
- Spinal mobilization (nonthrust) or manipulation (thrust) should be considered in the acute or sub-acute period for athletes with low-to-moderate levels of symptom irritability when the following variables are satisfied: symptom duration less than 16 days, low work-related fear-avoidance belief scores, lumbar hypomobility, hip internal rotation range of motion at least 35° on one or both sides, no symptoms distal to the knee.[19]
- Relative rest: Most athletes who experience a lumbar strain or sprain will require a period of reduced or modified activity, including removal from competition. Symptom-limited alternative activities and exercises should be encouraged to minimize deconditioning.
- Low-level therapeutic exercise should begin as soon as possible after the injury to avoid the deleterious effects of immobilization. The intensity, duration, and complexity of therapeutic exercise should be increased over time in accordance with the athlete's symptomatic and objective improvement.
- Patients who are intolerant of land exercise may tolerate aquatic therapy. Many land exercises can be replicated in a pool, with the benefits of reduced spinal weightbearing (via buoyancy), and increased spinal stabilization (via hydrostatic pressure).
- The majority of lumbar strains/sprains will be self-limiting and resolve within 6 weeks regardless of the type of treatment.[13]
- Most athletes can return to full unrestricted play after sufficient resolution of pain and restoration of range of motion and strength.

Surgical Indications

- There are no absolute indications for surgery with lumbar strain/sprains

Aspects of History, Demographics, or Exam Findings That Affect Choice of Treatment

- See general guidelines in the preceding.

Aspects of Clinical Decision Making When Surgery Is Indicated

- Lumbar strains/sprains are typically benign in nature, transient and self-limiting. Failure to respond to conservative management within 4 to 6 weeks may warrant referral for further specialized testing.

Evidence

Biering-Sorensen F: Physical measurements as risk indicators for low-back trouble over a one-year period. *Spine* 9:106–119, 1984.

In this prospective study of 449 men and 479 women aged 30 to 60, the authors examined the prognostic value of several physical measurements (anthropometric measurements, flexibility measurements of the back and hamstrings, trunk muscle strength, and endurance) for first-time occurrence of low back pain (LBP) and for recurrence or persistence of LBP. The main findings at the 12-month follow-up were that good isometric endurance of the back (extensor) muscles may prevent first-time occurrence of LBP in men and that men with hypermobile backs are more liable to contract LBP. Weak trunk muscles and reduced flexibility of the back and hamstrings were found as residual signs, in particular, among those with recurrent or persistent LBP. (Level IV evidence)

Davis PC, Wippold FJ, 2nd, Brunberg JA, et al: ACR Appropriateness Criteria on low back pain. *J Am Coll Radiol* 6(6):401–407, 2009.

This is an expert-panel consensus document by the American College of Radiology (ACR). Based on a review of the best-available evidence, the authors conclude that uncomplicated acute LBP is a benign, self-limited condition that does not warrant any imaging studies. Radiographs are recommended when any of several red flags are present, including recent significant trauma. Additional guidelines for recognition of patients with more complicated status can be used to identify those who require further evaluation for suspicion of more serious problems and contribute to appropriate imaging utilization. (Level V evidence)

Flynn T, Fritz J, Whitman J, et al: A clinical prediction rule for classifying patients with low back pain who demonstrate short-term improvement with spinal manipulation. *Spine* 27(24):2835–2843, 2002.

This was a prospective, cohort study of 71 patients with nonradicular LBP who were all treated with spinal manipulation. Thirty-two patients had success with the manipulation intervention, determined using change in disability scores. Five pretreatment variables were associated with treatment success: symptom duration less than 16 days, low work-related fear-avoidance belief scores, lumbar hypomobility, hip internal rotation range of motion at least 35° on one or both sides, and no symptoms distal to the knee. The presence of four of five of these variables increased the probability of success with manipulation from 45% to 95% (positive likelihood ratio = 24.38). (Level IV evidence)

Greene HS, Cholewicki J, Galloway MT, et al: A history of low back injury is a risk factor for recurrent back injuries in varsity athletes. *Am J Sports Med* 29(6):795–800, 2001.

In this prospective study, 18.3% (124) of 679 Yale varsity athletes surveyed in 1999 reported that they had sustained a low back injury within the past 5 years, and 6.8% (46) sustained a low back injury in the follow-up season. A history of low back injury was the significant predictor for sustaining low back injury in the following year, and athletes who reported previous low back injury were at three times greater risk. (Level IV evidence)

Lawrence JP, Greene HS, Grauer JN: Back pain in athletes. *J Am Acad Orthop Surg* 14(13):726–735, 2006.

In this review article, the authors provide evidence-based guidance on treating back pain in athletes. The authors suggest that self-limited symptoms must be distinguished from persistent or recurrent symptoms associated with identifiable pathology. Athletes involved in impact sports and those who participate in longer and more intense training appear to have higher incidence rates of back pain. Data suggest that the recreational athlete may be protected from lumbar injury with physical conditioning. Treatment of athletes with back pain usually is nonsurgical, and symptoms generally are self-limited. However, a systematic approach involving a thorough history and physical examination, pertinent imaging, and treatment algorithms designed for specific diagnoses can facilitate symptomatic improvement and return to play. (Level V evidence)

Multiple Choice Questions

QUESTION 1. Which collegiate sports have the highest rates of low back injury?

A. Golf and competitive weightlifting (i.e., powerlifting)
B. Men's wrestling, football, women's gymnastics
C. Men's rugby and women's field hockey
D. Soccer and tennis

QUESTION 2. Which of the following factors have been shown to increase risk of lumbar spine injury?

A. History of previous back injury
B. Inadequate lumbar flexibility
C. Inadequate stretching before activity
D. Lack of motivation

QUESTION 3. Which of the following is NOT a typical/common finding in patients with lumbar strain/sprain?

A. Ankle dorsiflexor weakness
B. Decreased trunk range of motion
C. Mildly antalgic gait
D. Muscle spasms and/or muscular trigger points

QUESTION 4. Which of the following statements is correct?

A. Imaging is not usually appropriate following a lumbar strain or sprain unless the injury occurred recently.
B. Imaging is not usually appropriate following a lumbar strain or sprain unless the injury occurred during football practice or competition.
C. Imaging is not usually appropriate following a lumbar strain or sprain unless the injury occurred during gymnastics practice or competition.
D. Imaging is not usually appropriate following a lumbar strain or sprain unless the injury is the result of recent significant trauma.

QUESTION 5. Which of the following statements is NOT correct?

A. Most athletes who experience a lumbar strain or sprain will require a period of reduced or modified activity, including removal from competition.
B. Most athletes suffering from a lumbar strain or sprain will require spinal surgery.
C. Some athletes who have sustained a lumbar strain or sprain will benefit from pain modulating modalities.
D. Some athletes who have sustained a lumbar strain or sprain may be appropriate for spinal manipulation treatment.

Answer Key

QUESTION 1. Correct answer: **B** (see Epidemiology)

QUESTION 2. Correct answer: **A** (see Pathophysiology)

QUESTION 3. Correct answer: **A** (see Clinical Presentation)

QUESTION 4. Correct answer: **D** (see Clinical Presentation)

QUESTION 5. Correct answer: **B** (see Treatment)

NONOPERATIVE REHABILITATION OF LUMBAR SPINE STRAINS AND SPRAINS

Christopher J. Durall, PT, DPT, MS, SCS, LAT, CSCS, and Brian K. Allen, DO

GUIDING PRINCIPLES OF NONOPERATIVE REHABILITATION

- Consider the unique requirements of the athlete's sport in addition to the identified deficits when prescribing exercises.
- Maintain or improve sport-specific fitness/conditioning via cross-training.
- Athlete must be able to adequately control lumbar spine and pelvis throughout ranges of motion required by the sport.
- Return to full, unrestricted activity should be predicated on symptom response to activity.

In lieu of trying to identify and treat the injured lumbar spine tissues, an effort should be made to determine the specific treatment approach (manipulation, stabilization exercise, or directionally specific exercise) that is likely to be most beneficial for the injured athlete. Outcomes can be improved when individuals with low back pain receive treatments that are matched to their clinical features.[1] Thus, patients with lumbar hypermobility may be appropriate for stabilization exercise, whereas those with lumbar hypomobility may benefit from manipulation.[2,3] Individuals with a directional preference for movement (e.g., flexion or extension) tend to fare better when the treatment is matched to the directional preference.[4] Guidelines are available to help clinicians match clinical findings with different treatment approaches for LBP.[2–4]

Phase I (weeks 1 to 2)

Protection

- Bracing (e.g., lumbar corset) is not recommended for lumbar sprains or strains because of a lack of proven efficacy and concerns over the deleterious effects of prolonged immobilization on connective tissue integrity. Nonetheless, there are anecdotal reports of patients with severe low back pain benefiting from transient use of bracing with activities of daily living. For this reason, any lumbar bracing should be discontinued as soon as possible.

Management of Pain and Swelling

- Sensory electrical stimulation, moist heat, or cryotherapy may be used to reduce pain and swelling.
- Unlike peripheral joints, anecdotal evidence suggests that superficial heating may be beneficial for treating acute spine pain.
- Fatiguing motor-level electrical stimulation or ultrasound combined with motor-level electrical stimulation may be effective for reducing muscle spasm or for deactivating muscle trigger points.

Techniques for Progressive Increase in Range of Motion

Manual Therapy Techniques

- The presence of the following variables may increase the likelihood of success with lumbar manipulation or mobilization: symptom duration less than 16 days, low work-related fear-avoidance belief scores, lumbar hypomobility, hip internal rotation range of motion (ROM) at least 35° on one or both sides, and no symptoms distal to the knee.[3]

Soft Tissue Techniques

- Deep massage or ischemic compression may be used for trigger points or muscle spasms.

Stretching and Flexibility Techniques for the Musculotendinous Unit

- Gentle lumbar spine self-mobilization exercises should be initiated as soon as possible in a pain-free ROM to

FIGURE 18-2. Weight shifting in quadruped. From a quadruped position, slowly shift weight forward, backward, left, right, or along a diagonal to increase trunk range of motion.

limit the adverse effects of immobilization and to stimulate the synthesis and proper alignment of collagen.[5] These exercises can be performed in supine (e.g., knee to chest, posterior pelvic tilting), prone (e.g., prone press-ups), or quadruped (e.g., weight shifting/rocking in different directions) (Figure 18-2).
  - Athletes who feel better in lumbar extension may tolerate extension activities/exercises, whereas those who feel better in lumbar flexion should be encouraged to try various flexion activities/exercises. Outcomes for LBP tend to be better when treatment is matched to the patient's directional preference, and worse when the patient is given a directionally opposite treatment.[4]
- Stretching exercises should be included for the hip flexors, rotators, adductors, quadriceps, gastrocnemius/soleus, and hamstring muscles (Figure 18-3).
  - Hip/leg stretching exercises should be performed with abdominal bracing (see description that follows) while maintaining a neutral (i.e., mid-ROM) lumbar spine to avoid symptom exacerbation.

Other Therapeutic Exercises

- The presence of the following variables may increase the likelihood of success with a stabilization exercise

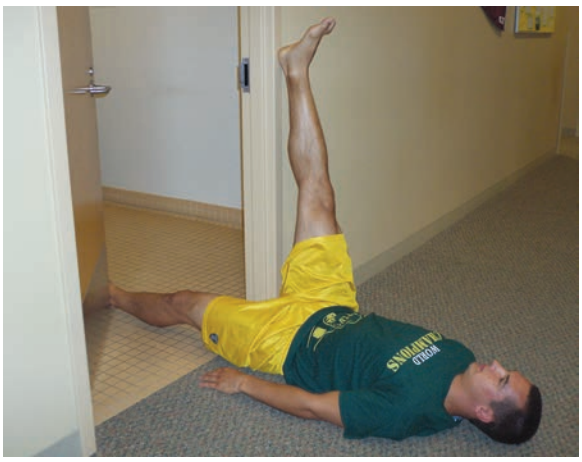

FIGURE 18-3. Hamstring stretch in doorway. Lie on floor with leg to be stretched resting on wall and other leg extended into the open doorway. While maintaining a neutral lumbar spine and an abdominal brace, scoot buttocks toward wall until stretch is felt in hamstrings.

treatment approach: age less than 40, straight-leg raise greater than 91°, positive prone instability test, presence of aberrant motions, lumbar hypermobility with passive testing, and absence of fear-avoidance beliefs.[2]
- Total leg strengthening should be performed, with an emphasis on the gluteus maximus and medius muscles.
  - Gluteal sets/squeezes in prone, supine or hook-lying (i.e., supine with hips and knees flexed and feet on floor)
  - Bridging in hook-lying
- Total arm strengthening should also be performed.
  - Chest press/pushups, rows, shoulder press, latissimus pull-downs, arm curls, elbow extension, wrist extension and flexion
- As with the hip/leg stretching exercises, all leg and arm strengthening exercises should be performed with abdominal bracing while maintaining a neutral (i.e., mid-ROM) lumbar spine to avoid symptom exacerbation.
  - For abdominal bracing, the athlete should tense/tighten his or her entire trunk/core to create a muscular "core-set" (corset), without holding the breath,

TIMELINE 18-1: **Nonoperative Rehabilitation of Lumbar Spine Strains and Sprains**

PHASE I (weeks 1 to 2)	PHASE II (weeks 2 to 4)
• Lumbar bracing prn; discontinue as soon as possible • Modalities prn for pain or swelling • Lumbar manipulation/mobilization if specific factors present • Massage or ischemic compression prn • Pain-free lumbar spine self-mobilization • Lower extremity stretching • Total leg strengthening emphasizing the gluteals • Total arm strengthening as tolerated • Single-leg balancing • Pelvic "clocks" and/or weight-shifting on ball • Single arm or leg unweighting in quadruped • Abdominal bracing in hook-lying ("core-set") • Bent-knee "fallouts" • Marching in hook-lying • Heel slides • Bridging in hook-lying • Walking or sport-specific cardiovascular conditioning on land or in pool	• Modalities prn for pain or swelling • Lumbar manipulation/mobilization if specific factors present • Massage or ischemic compression prn • Progress sport-specific TAS/TLS activities • Progress sport-specific cardiovascular conditioning • Continue lumbar spine stretching/self-mobilization • Exercises from supine bridged position with head and shoulder supported on dome or therapy ball • Exercises while seated on therapy ball • Progress single-leg balance activities • Exercise progression in quadruped • Prone bridging • Supine curlups with greater than or equal to 1 hip in neutral • Emphasize trunk muscle endurance • Lateral walking with cable or elastic band/cord • Oscillations with oscillating blade • Side support on forearm and bent knee • Exercises from supine bridged position with heels on dome • Diagonal chops and lifts in standing

drawing the abdomen in, or pushing the abdomen out.
  - Abdominal bracing has been shown to increase lumbar spine stability to a greater extent than abdominal drawing-in (abdominal hollowing).[6]

NOTE: All of the following exercises should be performed with abdominal bracing while maintaining a neutral lumbar spine

Sensorimotor Exercises

- Single-leg balancing on various surfaces (pillow, dome, foam pad, disc)
- Pelvic "clocks" in hook-lying
- Weight-shifting while seated on therapy ball (anterior-posterior, lateral, circles)

Open and Closed Kinetic Chain Exercises

- Single arm or leg unweighting in quadruped (i.e., from all-fours to three points of contact)

Neuromuscular Dynamic Stability Exercises

- Abdominal bracing in hook-lying ("core-set")
- Bent-knee "fallouts" (Figure 18-4)
- Marching in hook-lying
- Alternating heel slides
- Bridging in hook-lying

Functional Exercises

- Walking on land or in pool

Sport-Specific Exercises

- Sport-specific cardiovascular conditioning should be incorporated to minimize erosion of athletic performance. The athlete should be taught to control lumbopelvic movement during cardiovascular activities.
  - Consider biking for athletes who feel better in slight lumbar flexion versus extension.
  - Consider walking or elliptical trainer for athletes who feel better in lumbar extension versus flexion.
  - Consider sport-specific drills/activities in a pool for athletes who do not tolerate land-based exercise.

FIGURE 18-4. Bent-knee "fallouts." From hook-lying, slowly lower one leg into abduction and external rotation while maintaining a neutral lumbar spine and an abdominal brace.

Milestones for Progression to the Next Phase

- Acute pain, edema and muscle spasms have plateaued or started to subside.
- Activity/exercise tolerance has improved.

Phase II (weeks 2 to 4)

Protection

- Bracing should not be needed by this time.

TIMELINE 18-1: **Nonoperative Rehabilitation of Lumbar Spine Strains and Sprains** (Continued)

PHASE III (weeks 4 to 6)	PHASE IV (weeks 6+)
• Modalities prn for postexercise/activity pain • Lumbar manipulation/mobilization prn • Progress sport-specific TAS/TLS exercises • Progress sport-specific cardiovascular conditioning • Progress lumbar spine stretching/self-mobilization • Diagonal "chops" and "lifts" while seated on therapy ball • Exercise progression from prone bridged position • Single-leg supine bridging • One-arm rows with dumbbell while ½ kneeling on bench • Exercise progression in quadruped • Side support (side bridge) on forearm and feet • Prone bridge with forearms on therapy ball • Exercises from supine bridged position with head and shoulder supported on dome or therapy ball • Sport-specific jumping, hopping, bounding • Depth drop pushups • Single-leg deadlift • Sport-specific, multi-planar activities/exercises	• Modalities prn for postexercise/activity pain • Sport-specific TAS/TLS exercises • Sport-specific cardiovascular conditioning • Progress lumbar spine stretching/self-mobilization • Single-leg deadlift progression • Diagonal "chops" and "lifts" or trunk rotation on one foot • Rotating body bridge • Hanging straight leg raise to 90° hip flexion • Bilateral hip extension over center of plinth • Exercises from supine bridge with heels on therapy ball • Exercises from pushup position with feet on therapy ball • Sport-specific jumping, hopping, bounding • Clapping pushups • Advance intensity, duration, speed and complexity of functional and sport-specific exercises/activities

Management of Pain and Swelling

- Both motor-level electrical stimulation[7] and exercise[8] have been found to be effective for reducing edema during the subacute phase of healing. Exercise is more functional, however, and should be used in lieu of electrical stimulation if tolerated. Sensory-level electrical stimulation and/or cryotherapy may be used to reduce postexercise/activity soreness.

Techniques for Progressive Increase in Range of Motion

Manual Therapy Techniques

- Athletes who responded favorably to spinal mobilization or manipulation during Phase I may benefit from further manual therapy. These interventions may potentiate the effects of therapeutic exercise.

Soft Tissue Techniques

- Deep massage or ischemic compression may be used for trigger points or muscle spasms.

Stretching and Flexibility Techniques for the Musculotendinous Unit

- Stretching/self-mobilization exercises for the lumbar spine should be continued within the pain-free ROM.
  - From kneeling, controlled side-to-side and/or forward-backward rolling with forearms on a therapy ball or wheeled stool (Figure 18-5).
  - From hook-lying, both knees are moved side-to-side under control.
- Continue with stretching exercises for the hip flexors, rotators, adductors, hamstrings, quadriceps and gastrocnemius/soleus muscles, with abdominal bracing while maintaining a neutral lumbar spine.

Other Therapeutic Exercises

- See Phase I
- Modify and progress arm and leg strengthening exercises, making them as sport-specific as possible.

FIGURE 18-5. Controlled rolling from kneeling. From kneeling with forearms on a therapy ball or wheeled stool, roll ball side-to-side or forward-backward under control. Maintain an abdominal brace and do not allow excessive lumbar spine flexion, extension, or rotation.

FIGURE 18-6. Starting position for exercises from supine bridged position with head and shoulders supported on dome.

- Single or double leg squats and forward or backward lunges (for developing total leg strength and isometric spinal stabilization simultaneously).
- Pushups and pullups (for developing total arm strength and isometric spinal stabilization simultaneously).
- Progress sport-specific cardiovascular conditioning (e.g., from walking to jogging).

NOTE: All of the following should be performed with abdominal bracing while maintaining a neutral lumbar spine

Sensorimotor Exercises

- Exercises from supine bridged position with head and shoulders supported on dome or therapy ball (Figure 18-6):
  - Alternate heel lifts
  - Hip abduction with elastic band/cord above knees
  - Controlled up/down bridging
- Exercises while seated on therapy ball
  - Side-to-side shifting
  - Pelvic rocking/tilts
  - "Hula-hoops" (circumduction)
  - Unilateral or bilateral shoulder flexion
  - Marching
  - Marching with contralateral shoulder flexion (Figure 18-7)
  - Single arm rowing with cable or elastic band/cord
- Progress single-leg balance activities by using more challenging surfaces, or adding dynamic elements (e.g., playing catch, walking obstacle courses)

Open and Closed Kinetic Chain Exercises

- Exercises in quadruped
  - Single arm flexion
  - Single hip extension
  - Single arm flexion with contralateral hip extension (bird-dog or pointer)
  - Rhythmic stabilization
- Prone bridging on forearms and toes (planks) (Figure 18-8)
- Curl-ups in supine with one or both hips in neutral. Levels of spinal compression and spinal shear and psoas activity were lower during curl-ups with hips in neutral versus flexion.[9]

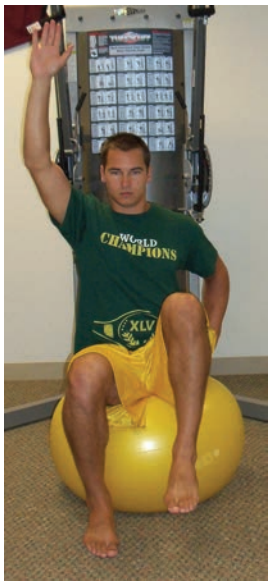

FIGURE 18-7. Marching with contralateral shoulder flexion while seated on a therapy ball. While seated on a therapy ball, flex one hip to lift foot from floor while flexing the opposite shoulder overhead. Maintain an abdominal brace and do not allow excessive lumbar spine flexion, extension, or rotation.

Techniques to Increase Muscle Strength, Power, and Endurance

- Endurance should be emphasized during this phase more than strength.
  - Poor lumbar muscle endurance is a significant risk factor in development of future LBP.[10–12]
  - Trunk muscle endurance training has been shown to be effective in reducing pain and disability in patients with nonspecific low back pain.[13–15]
  - It is particularly important to regain normal bulk and endurance of erector spinae muscles and multifidus.[16]

Neuromuscular Dynamic Stability Exercises

- See sensorimotor exercises in the preceding.
- Lateral walking with cable or elastic band/cord (Figure 18-9)
- Two-handed medial-lateral oscillations of vertically oriented oscillating blade (e.g., Bodyblade) or superior-inferior oscillations of horizontally oriented oscillating blade while standing

FIGURE 18-8. Prone bridging. From a prone position with elbows spaced shoulder-width, arms perpendicular to mat, and hands touching so that the forearms form a V, the pelvis is raised by contracting the trunk flexor muscles.

FIGURE 18-9. Lateral walking with cable or elastic band/cord. Start in an athletic stance with slight hip and knee flexion. Hold handle of cable or elastic band/cord in front of torso at level of lower rib cage. After performing abdominal brace, walk sideways while keeping handle in starting position. Do not rotate torso.

- Side support (side bridge) on forearm and bent knee (Figure 18-10)
- Exercises from supine bridged position with heels on dome (Figure 18-11)
  - Bridging
  - Marching

Functional Exercises

- See sensorimotor exercises in the preceding and sport-specific exercises in the following.

Sport-Specific Exercises

- Diagonal "chops" and/or "lifts" in standing with cable or elastic band/cord, mimicking sport movements as much as possible

FIGURE 18-10. Side support (side bridge) on forearm and bent knee. Start in a side-lying position with both knees bent. Raise the pelvis by contracting the trunk lateral flexor muscles while supporting the upper body on one forearm. A straight line should be maintained from their upper body to the feet (i.e., no trunk or hip flexion or extension). The hand of the non–weight-bearing arm can assist in stabilizing the weight-bearing shoulder.

FIGURE 18-11. Starting position for exercises from supine bridged position with heels on dome.

Milestones for Progression to the Next Phase

- Minimal pain with activity
- Good tolerance for exercises listed in the preceding
- Minimal, transient postexercise/activity pain
- Minimal muscle spasm
- Minimal edema

Phase III (weeks 4 to 6)

Management of Pain and Swelling

- Sensory electrical stimulation and/or cryotherapy may be used to reduce postexercise/activity soreness.

Techniques for Progressive Increase in Range of Motion

Manual Therapy Techniques

- See Phase II recommendations

Soft Tissue Techniques

- See Phase II recommendations

Stretching and Flexibility Techniques for the Musculotendinous Unit

- See Phase II recommendations

Other Therapeutic Exercises

- See Phase II recommendations

NOTE: All of the following should be performed with abdominal bracing while maintaining the lumbar spine in a symptom-free ROM.

Sensorimotor Exercises

- Exercises while seated on therapy ball
  - Diagonal "chops" and/or "lifts" with cable or elastic band/cord

Open and Closed Kinetic Chain Exercises

- Exercise progression from prone bridged position (see Figure 18-8)
  - Single-leg unweighting (i.e., four-point to three-point)
  - Single-arm unweighting
  - Single-leg circles or diagonals

FIGURE 18-12. One-arm rows with dumbbell while half kneeling on bench (lawn mowers). Maintain an abdominal brace and do not allow excessive lumbar spine flexion, extension, or rotation while lifting and lowering weight.

Techniques to Increase Muscle Strength, Power, and Endurance

- See exercises in the preceding and the following.

Neuromuscular Dynamic Stability Exercises

- Single-leg supine bridging
- One-arm rows with dumbbell while half kneeling on bench (lawn mowers) (Figure 18-12)
- Exercise progression in quadruped
  - Arm and/or opposite leg circles (i.e., circumduction) from bird-dog position (i.e., single arm flexion with contralateral hip extension)
  - Arm and/or opposite leg diagonals from bird-dog position
  - Single knee to opposite elbow
- Side support (side bridge) on forearm and feet (Figure 18-13)

FIGURE 18-13. Side support (side bridge): From a side-lying position, the pelvis is raised by contracting the trunk lateral flexor muscles while supporting the upper body on one forearm. A straight line should be maintained from the upper body to the feet (i.e., no trunk or hip flexion or extension). The hand of the non–weight-bearing arm can assist in stabilizing the weight-bearing shoulder.

FIGURE 18-14. Prone bridge with forearms on therapy ball. From a prone position with forearms resting on a therapy ball, elbows spaced shoulder-width, and hands touching so that the forearms form a V, the pelvis is raised by contracting the trunk flexor muscles.

- Prone bridge with forearms on therapy ball (Figure 18-14)
- Exercises from supine bridged position with head and shoulder supported on therapy ball
  - Marching
  - Single-leg bridging
  - Diagonal "chops" and/or "lifts" with cable or elastic band/cord (Figure 18-15)

Plyometrics

- Sport-specific jumping, hopping, bounding activities/exercises for the lower extremities
- Depth drop pushups for the upper extremities using different size boxes

Functional Exercises

- Single-leg deadlift (Figure 18-16)

Sport-Specific Exercises

- Sport-specific, multiplanar activities/exercises should be incorporated and progressed according to the athlete's ability to maintain lumbopelvic control during the activity.
- Resistance with all sport-specific exercises should be adjusted based on the athlete's ability to perform the exercise with good form/technique while maintaining abdominal bracing.
- The intensity, speed and duration of activities should increase over time until they approximate those of the appropriate sport.
- Examples
  - Football lineman may need to initially use unweighted blocking sleds.
  - Weightlifters should initially focus on technical aspects of a particular lift using a relatively light weight.
  - Golfers should gradually increase swing speed according to symptom response.
  - Gymnasts should practice routines at slower than usual speed.
- Consult with athlete and coaches for other sport-specific exercises/activities.

FIGURE 18-15. Diagonal "chops" or "lifts" from supine bridged position with head and shoulders supported on therapy ball. Maintain an abdominal brace and do not allow excessive lumbar spine flexion, extension, or rotation while "chopping" or "lifting."

FIGURE 18-16. Single-leg deadlift: Start in single-leg stance position with arms at sides, then move trunk forward and contralateral leg into extension by flexing stance leg's hip. Stance knee should remain slightly flexed throughout exercise. Continue leaning trunk forward (via flexing at hip) as far as possible while maintaining spinal alignment and control.

Milestones for Progression to the Next Phase

- No pain with activity
- Intermittent short-duration pain with movement
- Minimal, transient postexercise pain
- No observable swelling
- Active and passive joint ROM within normal limits
- Trunk muscle deficits less than 25% with manual muscle testing, isokinetic testing, and/or functional testing

Phase IV (weeks 6+)

Management of Pain and Swelling

- See Phase II recommendations

Techniques for Progressive Increase in Range of Motion

- Joint or soft tissue mobilization and/or stretching/flexibility exercises should continue if deficits persist.

Other Therapeutic Exercises

- See Phase III recommendations

NOTE: All of the following should be performed with abdominal bracing while maintaining the lumbar spine in a symptom-free ROM

Sensorimotor Exercises

- Single-leg deadlift progression
  - With both shoulders abducted 90°
  - With one shoulder flexed 90° reaching to floor (alternate flexed shoulder with each repetition)
  - On labile surface (e.g., foam pad)

Open and Closed Kinetic Chain Exercises

- See exercises in the preceding and the following.

Techniques to Increase Muscle Strength, Power, and Endurance

- See exercises in the preceding and the following.

Neuromuscular Dynamic Stability Exercises

- Diagonal "chops and/or "lifts" or trunk rotation with cable or elastic band/cord balancing on one foot
- Rotating body bridge: Move from side plank/bridge position on one arm (see Figure 18-13) to prone bridge (see Figure 18-8) then to side bridge on opposite arm while maintaining neutral lumbar spine and abdominal brace throughout. Hold each bridged position for 10 seconds. The foot of the upper leg should be placed on the floor for the side bridge to enable rolling into a prone bridge without changing foot alignment.
- Hanging straight leg raise to 90° hip flexion
- Bilateral hip extension over center of plinth (Figure 18-17)

FIGURE 18-17. Bilateral hip extension over center of plinth. While holding onto plinth, lift legs from floor to horizontal under control. Motion should occur about the hips, not the spine to avoid lumbar sprain/strain exacerbation.

FIGURE 18-18. Starting position for exercises from pushup position with lower legs and/or feet on therapy ball.

- Exercises from supine bridged position with heels on therapy ball
  - Bridging
  - Marching
  - Roll ball side-to-side
- Exercises from pushup position with lower legs and/or feet on therapy ball (Figure 18-18)
  - Roll ball side-to-side
  - Alternate hip extension
  - Pushups
  - Bilateral hip and knee flexion (prone tucks) (Figure 18-19)

Plyometrics

- Sport-specific jumping, hopping, bounding
- Clapping pushups

Functional Exercises

- See Phase III recommendations.
- The complexity and speed of activities should increase over time until they approximate those of the appropriate sport.

Sport-Specific Exercises

- See Phase III recommendations.
- The intensity and duration of activities should increase over time until they approximate those of the appropriate sport.

FIGURE 18-19. Prone tucks. Start in pushup position with legs or feet on therapy ball. Roll ball forward then back to starting position while controlling for excessive lumbar spine motion.

Milestones for Progression to Advanced Sport-Specific Training and Conditioning

- Full, pain-free ROM
- Normal trunk muscle strength (as determined by manual testing or dynamometry)
- Good technique with all Phase IV exercises

Criteria for Abandoning Nonoperative Treatment and Proceeding to Surgery or More Intensive Intervention

- Lumbar strains/sprains are typically benign in nature, transient and self-limiting. Failure to respond to conservative management within 4 to 6 weeks may warrant referral for further specialized testing.
- There are no absolute indications for surgery with lumbar strain/sprains.

Tips and Guidelines for Transitioning to Performance Enhancement

- During the last phase of rehabilitation the athlete should be advanced to his or her maximum functional potential.
- A whole-body warm-up should precede activity/exercise.
- Exercises should be performed at roughly the same time of day as practices or events.
- All three energy systems should be trained, with the most sport-specific system(s) emphasized.
- Activities/exercises that closely approximate the specific movements and skill requirements of the sport should be included.
- The level of resistance used during functional strengthening drills should approximate or slightly exceed the intensity of the sport.
- Agility, plyometric, speed, and strengthening activities/exercises should be included at a progressively higher level of performance, intensity, and complexity.
- If appropriate, elements of changing speed, direction, and center of gravity should be introduced.
- It may be appropriate to have the athlete exercise with control into nonneutral ranges of motion once they have demonstrated excellent lumbar spine control in neutral. The need to exercise into nonneutral ranges should be predicated on the sport's movement requirements and balanced against any untoward symptom aggravation.

Specific Criteria for Return to Sports Participation: Tests and Measurements

- Adequate pain-free trunk ROM for given sport
- Normal trunk muscle strength (as determined by manual testing or dynamometry)
- No obvious deficits in lower or upper extremity strength or flexibility

Evidence

Brennan GP, Fritz JM, Hunter SJ, et al: Identifying subgroups of patients with acute/subacute "nonspecific" low back pain: Results of a randomized clinical trial. *Spine* 31(6):623–631, 2006.

In this prospective, randomized study the authors studied the impact of classifying 123 patients with LBP of less than 90 days' duration into one of three subgroups based on the type of treatment believed most likely to benefit the patient (manipulation, stabilization exercise, or specific exercise). Patients who received matched treatments experienced greater reductions in disability after 4 weeks and after 1 year than those who received unmatched treatments. This suggests that nonspecific LBP should not be viewed as a homogenous condition and that outcomes with nonspecific LBP can be improved when subgrouping is used to guide treatment decision making.

Hicks GE, Fritz JM, Delitto A, et al: Preliminary development of a clinical prediction rule for determining which patients with low back pain will respond to a stabilization exercise program. *Arch Phys Med Rehabil* 86(9):1753–1762, 2005.

This prospective, randomized study of 54 patients with nonradicular LBP examined the variables associated with treatment success following an 8-week standardized stabilization exercise program. Based on treatment response, the most important variables associated with success were age less than 40, straight-leg raise greater than 91°, positive prone instability test, presence of aberrant motions, lumbar hypermobility with passive testing, and absence of fear-avoidance beliefs. (Level IV evidence)

Hides JA, Richardson CA, Jull GA: Multifidus muscle recovery is not automatic after resolution of acute, first-episode low back pain. *Spine* 21:2763–2769, 1996.

In this clinical trial, 39 patients with acute, first-episode LBP were randomly allocated to either a control group or specific exercise group with 1-year and 3-year telephone questionnaire follow-ups. The specific exercise group performed exercises intended to specifically challenge the lumbar multifidus (LM) and transversus abdominis muscles. At the 10-week follow-up examination LM cross-section area was greater in the specific exercise group. The control group had decreased LM size at 10 weeks despite resuming normal levels of activity. This suggests that LM atrophy may persist after cessation of LBP without exercise intervention. (Level I evidence)

Kavcic N, Grenier SP, McGill S: Determining the stabilizing role of individual torso muscles during rehabilitation exercises. *Spine* 29:1254–1265, 2004.

In this study, 10 healthy males performed a series of eight different exercises while electromyography, three-dimensional lumbar motion, and external forces were measured. Based on subsequent calculations of spine stability, the authors determined that larger, more "global" muscles are better able to alter spine stability than "local," intersegmental muscles. They also concluded that focusing on a single muscle, or only a few muscles, appears to be misdirected if the goal is to ensure a stable spine. (Level IV evidence)

Koumantakis GA, Watson PJ, Oldham JA: Trunk muscle stabilization training plus general exercise versus general exercise only: Randomized controlled trial of patients with recurrent low back pain. *Phys Ther* 85:209–225, 2005.

This prospective, randomized study of 55 patients with nonspecific subacute or chronic LBP compared outcomes following 8 weeks of general trunk muscle exercise or 5 weeks of lumbar multifidus and transversus abdominis muscle training plus 3 weeks of general muscle trunk muscle exercise. Disability decreased to a greater extent at 8 weeks in the general trunk muscle exercise only group, although no difference was measured between groups at the 3-month follow-up, suggesting that stabilization exercises focused initially on isolated training of the lumbar multifidus and transversus abdominis do not provide additional benefit. (Level I evidence)

Vera-Garcia FJ, Elvira JL, Brown SH, et al: Effects of abdominal stabilization maneuvers on the control of spine motion and stability against sudden trunk perturbations. *J Electromyogr Kinesiol* 17:556–567, 2007.

In this prospective, single-limb trial, the authors studied the effectiveness of abdominal bracing and abdominal hollowing to control spine motion and stability against rapid perturbations in 11 healthy males in a semiseated position. Based on electromyography and lumbar spine kinematics, the authors reported that the abdominal hollowing maneuver was ineffective for stabilizing the lumbar spine after sudden perturbation. In contrast, the abdominal bracing maneuver fostered torso co-contraction, actively stabilized the trunk and decreased lumbar spine displacement after sudden perturbation. (Level IV evidence)

Multiple Choice Questions

QUESTION 1. Following a lumbar sprain or strain, gentle lumbar spine stretching/self-mobilization exercises should be initiated as soon as possible in a minimally painful ROM to

A. limit the adverse effects of immobilization.
B. stimulate collagen synthesis.
C. promote proper collagen alignment.
D. All of the above

QUESTION 2. Which of the following statements concerning abdominal bracing is true?

A. Abdominal bracing has been shown to increase lumbar spine stability to a greater extent than abdominal hollowing.
B. Abdominal bracing should be performed immediately after all leg and arm exercises.
C. Abdominal bracing should be performed by drawing-in or hollowing the abdomen.
D. None of the above is true.

QUESTION 3. Which of the following statements concerning abdominal bracing is true?

A. Poor lumbar muscle endurance appears to be a significant risk factor in development of future LBP.
B. Endurance should be emphasized less during the early phases of lumbar sprain/sprain rehabilitation than strength.
C. Trunk muscle endurance training has been shown to be effective in reducing pain and disability in patients with nonspecific low back pain.
D. It is particularly important to regain endurance of the erector spinae and multifidus muscles.

QUESTION 4. Which of the following is a valid reason for abandoning nonoperative treatment of a lumbar sprain or strain and proceeding to surgery?

A. Subnormal trunk muscle endurance
B. Failure of the lumbar multifidus muscle to recover its normal cross-sectional area
C. Lack of full/normal lumbar spine ROM
D. None of the above

Answer Key

QUESTION 1. Correct answer: **D** (see Phase I)

QUESTION 2. Correct answer: **A** (see Phase I)

QUESTION 3. Correct answer: **B** (see Phase II)

QUESTION 4. Correct answer: **D** (see Phase IV)

Chapter 19

Herniated Lumbar Disc

INTRODUCTION

S. Josh Bell, MD, Stephanie Niño, PT, DPT, FAAOMPT, OCS, and Cheryl Kathleen Obregon, PT, DPT, FAAOMPT

Epidemiology

Age

- All ages can be affected.
- Predominance of patients between ages 30 to 50.
- Trials, such as SPORT trial, have mean enrollment of ages between 40 and 43.

Gender

- Predominance of males
- Males twice as likely to have than females

Sport

- Any sport can cause a disc herniation
- Increased risk with improper technique
- Contact sports
- Repetitive twisting of the back

Position

- Can occur in any position
- Bending and twisting with load cause higher load to disc
- Lifting mechanics, especially with load in front of body away from center axis

Pathophysiology

Intrinsic Factors

- Previous disc herniation
- Male gender
  - 2:1 dominance
  - Ages 30 to 50
- Congenital spinal abnormalities

Extrinsic Factors

- Poor mechanics
- Improper technique
  - Lifting
  - Sport-specific
- Smoking
- Sedentary lifestyle

Traumatic Factors

- High levels of force (traumatic collision sports, such as football)
- Repetitive motions
- Loading of the back (twisting with load)
- Improper technique

Classic Pathological Findings

- Numbness in a dermatomal distribution
  - Dermatomal patterns in the lumbar spine
    - L2—Anterior thigh, medial thigh and groin
    - L3—Anterior thigh and medial knee/calf
    - L4—Anterior knee and medial calf/foot
    - L5—Anterior leg and dorsum foot
    - S1—Posterior leg and lateral/sole foot
- Unilateral weakness
- Leg pain is greater than back pain

Clinical Presentation

History

- Leg pain is greater than back pain
  - Greater back pain indicates the possibility of a lumbar sprain/strain
- Weakness or numbness
  - Specific to muscle groups/nerve distributions
- Low back tightness/spasm

FIGURE 19-1. Dermatomal pattern of a patient with right L5 radiculopathy (hash marks represent dermatomal pattern of decreased sensation).

FIGURE 19-2. Knee reflex testing.

Physical Examination

Abnormal Findings

- Straight leg raise
  - When lifting the straight leg from a supine position pain radiates according to the nerve distribution of the involved nerve
- Numbness in a dermatomal distribution (Figure 19-1)
  - L3—Medial knee
  - L4—Medial leg and medial foot/ankle
  - L5—Anterior leg and anterior foot/ankle
  - S1—Lateral foot/sole of foot
- Loss of relevant reflex (Figure 19-2)
  - L3—Knee reflex
  - L4—Knee reflex
  - S1—Achilles reflex

Pertinent Normal Findings

- Normal bowel and bladder function
- Predominance of leg pain and less back pain
  - To differentiate pathology from nerve root compression and lower back pain
- No evidence of hip pathology
  - Normal motion
  - No pain in groin with resisted hip flexion
  - No pain with log roll maneuver of the leg

Imaging

- Radiographs of lumbar spine
  - AP/LAT
  - Possible flexion/extension (to rule out instability)
- MRI of lumbar spine (Figure 19-3*A*,*B*)
  - Evaluate for compression of nerve roots
  - Should correlate to dermatomal pattern on physical examination
- Potential radiograph of hip to rule out hip pathology

Differential Diagnosis

- Infection
  - Fever may be present
- Tumor
  - Weight loss unexplained
  - Pain at night/rest
- Fracture
  - Significant trauma should be evaluated with radiographs of the spine
- Musculoskeletal back pain (without disc herniation)
  - Lumbar sprain/strain
  - No radiation to legs
- Hip pathology
  - Evaluate with range of motion
  - Evaluate with provocative testing
    - Resisted straight leg raise
    - Muscular strength
    - Log roll
  - Potentially evaluate with radiographs
- Cauda equina syndrome
  - Compression of multiple nerve roots from a large or central disc herniation
  - Present with abnormal bowel or bladder function (retention or loss of control)
- Saddle anesthesia (loss of sensation in the groin area)
- Loss of sensation to bilateral lower extremities

Treatment

Nonoperative Management

- Medication (antiinflammatory: NSAIDS vs. oral steroids or pain medication)
- Stretching and early active rehabilitation
- Workplace and activity restrictions
- Physical therapy
- Epidural steroid injection (ESI)

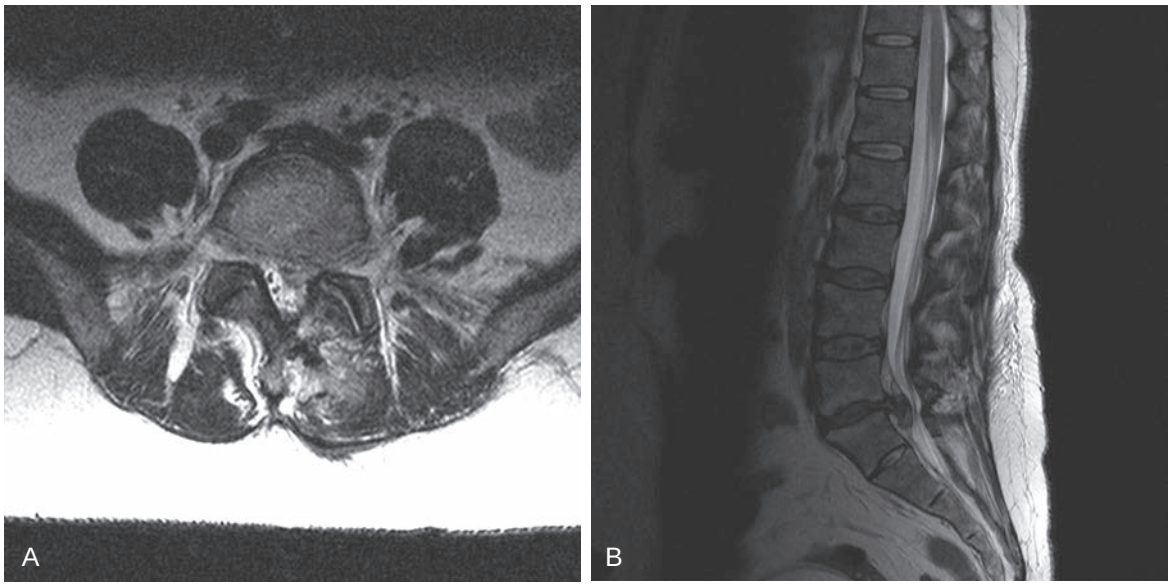

FIGURE 19-3. A, Axial MR image of S1 lumbar disc herniation. **B**, Sagittal MR image of S1 lumbar disc herniation.

Guidelines for Choosing Among Nonoperative Treatments

- No evidence of cauda equina syndrome
- Symptoms managed with medication and activity restrictions
- No progressive weakness or neurological loss

Surgical Indications

- Absolute:
  - Progressive motor and sensory loss
  - Cauda equina syndrome
- Relative:
  - Progressive or persistent symptoms after 6 weeks of nonsurgical care
  - Significant loss of motor strength (e.g., quadriceps)

Aspects of History, Demographics, or Exam Findings that Affect Choice of Treatment

- Progressive neurologic findings affect the decision to proceed to surgery
- Significant weakness in quadriceps or other major motor group
- If patient has persistent or worsening pain that is not relieved with nonoperative treatment

Aspects of Clinical Decision Making When Surgery is Indicated

- Progressive loss of motor function
- Failure of appropriate trial of 6 weeks to 3 months of nonoperative treatment
- Progressive pain not responsive to treatment.

Evidence

Buttermann GR: Treatment of lumbar disc herniation: Epidural steroid injection compared with discectomy. A prospective, randomized study. *J Bone Joint Surg Am* 86:670–679, 2004.

This prospective randomized study of patients with lumbar disc herniation who received discectomy vs. epidural steroid injection. There were 50 patients in each group and a significant amount of crossover between the groups. Patients in the discectomy group had better outcomes. (Level I evidence).

Osterman H, Seitsalo S, Karpinnen J, et al: Effectiveness of microdiscectomy for lumbar disc herniation: A randomized controlled trial with 2 years of follow-up. *Spine* 31:2409–2414, 2006.

This prospective randomized study of patients with lumbar disc herniation who received discectomy vs. isometric physical therapy. There were 28 patients in each group with no statistical difference between groups. (Level I evidence).

Peul WC, van Houwelingen HC, van den Hout WB, et al: Surgery versus prolonged conservative treatment for sciatica. *N Engl J Med* 356:2245–2256, 2007.

A randomized prospective study of patients with surgical and nonsurgical treatment for lumbar disc herniation. This study showed improved outcomes in the surgical group early with no statistical difference at 1 year. (Level I evidence).

Ostelo RW, de Vet HC, Waddell G, et al: Rehabilitation following first-time lumbar disc surgery: A Systematic review within the framework of the Cochrane collaboration. *Spine* 28:209–218, 2003.

This systematic review of randomized controlled trials evaluated the protocol for postoperative rehabilitation after first-time lumbar surgery. No evidence for restriction of activities immediately after surgery was found and strong evidence for intensive exercise. (Level I evidence).

Ostelo RW, Costa LO, Maher CG, et al: Rehabilitation after lumbar disc surgery: An update Cochrane review. *Spine* 34:1839–1848, 2009.

This systematic review of randomized controlled trials evaluated postoperative protocol after lumbar surgery. Exercise

programs after surgery seem to lead to faster decrease in pain postoperatively. (Level I evidence).

Weber H: Lumbar disc herniation: A controlled, prospective study with ten years of observation. *Spine* 8:131–140, 1983.

This prospective study of patients with surgical and nonsurgical treatment for lumbar disc herniation showed improved outcomes in the surgical group at 1 year and no statistical difference at 4- and 10-year follow up. (Level II evidence).

Weinstein JN, Tosteson TD, Lurie JD, et al: Surgical vs. nonoperative treatment for lumbar disk herniation: The Spine Patient Outcomes Research Trial (SPORT), A randomized trial. *JAMA* 296:2441–2450, 2006.

This prospective, randomized study of operative and nonoperative treatment for lumbar disk herniation found better outcomes in surgical patients but the primary differences in the study were not statistically significant. There were large crossovers in the study confounding some conclusions. (Level I evidence).

Multiple-Choice Questions

QUESTION 1. A patient has a disc herniation causing decreased sensation to the area of the right medial malleolus and a decreased knee reflex on the right side. The most likely nerve root effected by this herniation is:

A. Right L2
B. Left S1
C. Right L4
D. Left L4

QUESTION 2. Based on demographics, the most likely patient to get a symptomatic lumbar disc herniation is:

A. 20-year-old female
B. 40-year-old male
C. 65-year-old female
D. 10-year-old male

QUESTION 3. Signs of cauda equina syndrome may include all of the following except:

A. Shortness of breath
B. Loss of normal bowel or bladder function/control
C. Saddle anesthesia
D. Weakness

QUESTION 4. Risk factors for lumbar disc herniation include the following except:

A. Smoking
B. Previous lumbar disc herniation
C. Male
D. Physically fit

QUESTION 5. Appropriate nonoperative treatment for lumbar disc herniation includes the following except:

A. Physical therapy
B. Medication management
C. Work/activity restrictions
D. Trigger point injections

Answer Key

QUESTION 1. Correct answer: **C** (see Pathophysiology)

QUESTION 2. Correct answer: **B** (see Pathophysiology)

QUESTION 3. Correct answer: **A** (see Treatment)

QUESTION 4. Correct answer: **D** (see Pathophysiology)

QUESTION 5. Correct answer: **D** (see Treatment)

NONOPERATIVE REHABILITATION OF HERNIATED LUMBAR DISC

S. Josh Bell, MD, Stephanie Niño, PT, OCS, FAAOMPT, and Cheryl Kathleen Obregon, PT, DPT, FAAOMPT

GUIDING PRINCIPLES OF NONOPERATIVE REHABILITATION

- Pain control
- Pain free mobilization of the spine
- Lower extremity and core strengthening
- Patient specific progression of activities, modalities

Phase I (Weeks 0 to 2, Postinjury)

Goals

- Pain control, decrease of inflammation
- Mobilization, unloading as necessary
- Education

Protection

- Protect with walker as needed
- Use of lumbar support, such as lumbosacral orthosis (LSO), as necessary

Management of Pain and Swelling

- Pharmacologic treatment
  - NSAIDs
  - Oral steroid
  - Pain medication
- Ice or cryotherapy
- Avoidance of painful spinal motions (rest)
- Taping and therapeutic modalities (electrical stimulation)
- Education on log rolling, proper bed mobility, sit to stand transition, hip-hinging exercise for sit to stand and squatting

Techniques for Progressive Increase in Range of Motion

Manual Therapy Techniques

- Manipulation of thoracolumbar (T/L) junction for lower extremity pain modulation
- Side-lying manual distraction
- Grade I, II mobilization (pain control)
- Neural mobilizations
- Correction of standing lateral shift, if present (Figure 19-4)
- Exercises
  - Pelvic neutral and transverse abdominal bracing, progression with LE movement with brace (start with 5 min then progress to 15 min total time with LE movements)
  - If patient has an extension bias, begin with prone lying (start 5 min base time on patient's symptoms decreasing)
  - Body weight support unloaded walking on treadmill (Figure 19-5)
  - Supine mechanical traction or inversion table for symptom relief (start with 25% of body weight for 20 to 30 min intermittent holds)
  - Lumbar spine pain-free ROM
  - Unloaded squats (using functional gym) (i.e. Total Gym)

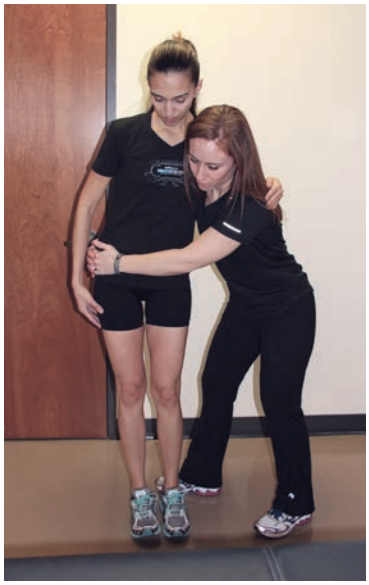

FIGURE 19-4. Correction of lateral shift; pain-free manual correction (by therapist) of pelvis to correct left lateral shift in this patient.

FIGURE 19-5. Body weight support walking on treadmill.

Soft Tissue Techniques

- Paraspinals myofascial release (MFR)
- Soft tissue mobilization (STM) to paraspinals (Figure 19-6)
- Nerve gliding (patient directed) (Figure 19-7)

FIGURE 19-6. Soft tissue paraspinal mobilization (STPM).

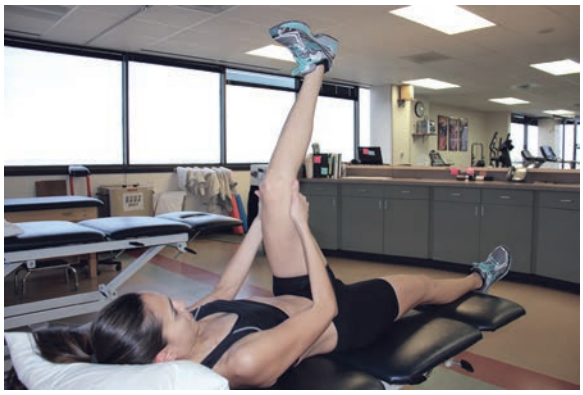

FIGURE 19-7. Patient-directed sciatic nerve gliding.

Stretching and Flexibility Techniques for the Musculotendinous Unit

- Stretching to limit of pain allowable
- Gentle hamstring and/or hip flexor stretching with protected spine position, being cautious of radicular symptoms

Other Therapeutic Exercises

- Encourage functional walking to tolerance
- Lower extremity strengthening to pain tolerance
- Education on wearing and removing LSO brace (as needed)
- Avoid sitting greater than 20 minutes

Activation of Primary Muscles Involved

- Lower extremity strength exercises are encouraged, as tolerated by pain level
- Proper activation of transverse abdominal, external obliques, multifidus, and gluteals

Milestones for Progression to the Next Phase

- Oswestry disability index (ODI), between 20% and 40%
- Able to sit and stand with spinal neutral mechanics
- Pain-free transitional movements (i.e., sit to stand, supine to sit)
- No lateral shift or acute lumbar kyphosis can be present (correct spinal position)

Phase II (weeks 2 to 6, Postinjury, variable progression dependent on herniation and patient factors)

Protection

- Retrain protective movement patterns (i.e., using lumbar roll with sitting, avoiding truck flexion with squatting and sit to stand)
- Wean from LSO brace (if used)

Management of Pain and Swelling

- Use of modalities (heat, electrical stimulation, taping)
- Decrease use of walking aids

TIMELINE 19-1: **Rehabilitation of Herniated Lumbar Disc**

PHASE I (weeks 0 to 2)	PHASE II (weeks 2 to -6)
• Rest • PT modalities • Functional unloading • Stretching/ROM to tolerance • Manipulation of T/L junction • Myofascial release (MFR) paraspinals • Soft tissue mobilization (STM) neural tissue	• Retrain protective movement patterns • PT modalities • Functional unloading • Mechanical traction • Paraspinal MFR Soft tissue mobilization (STM) functional movement patterns • Supine hamstring, hip flexor, piriformis stretches • Progression to quadruped exercise • Hip strengthening exercises • Body mechanics training and education • Pelvic neutral stability ball with progressing to LE movement • Supine and prone lumbar stabilization exercises • Walking program, swimming • Body weight squats and lunges • ADLs retraining

FIGURE 19-8. Side-lying manual mobilization of lumbar facet joints (gapping).

- Pharmacological treatment
  - NSAIDs
  - Decrease use of narcotics

Techniques for Progressive Increase in Range of Motion

Manual Therapy Techniques

- Mobilization and manipulation of thoracic spine, lumbar spine (opening, closing, and gapping techniques) (Figure 19-8)
- Mobilization of SI joint (supine, side lying, prone techniques), hips to correct hypomobility, and for pain modulation
- Muscle energy techniques (METs) for muscular recruitment or inhibition
- Side-lying lumbar distraction

Soft Tissue Techniques

- Paraspinals myofascial release (MFR), soft tissue mobilization (STM) surrounding neural tissue
- STM with movement to restore functional movement patterns

Stretching and Flexibility Techniques for the Musculotendinous Unit

- Supine hamstring, hip flexor
- Figure four piriformis stretches
- Repeat Phase I with progressing to sitting, standing, and quadruped exercise
- Hip/back dissociation exercise (using biofeedback for proper spine alignment while moving at the hips) (Figure 19-9)

Other Therapeutic Exercises

- Hip strengthening exercises
- Continue functional unloading on body weight support treadmill
- Body mechanics training and education

Activation of Primary Muscles Involved

- Lower extremity strength exercises are encouraged, as tolerated by pain level
- Proper activation of transverse abdominus, external obliques, multifidus, and gluteals

TIMELINE 19-1: **Rehabilitation of Herniated Lumbar Disc** (Continued)

PHASE III (weeks 6 to 12)	Phase IV (weeks 10 to 18)	Phase V (weeks 18 to 52)
• Proper protective spine mechanics • PT modalities as needed • Mobilization and manipulation of thoracic spine, lumbar spine, SI joints • Side-lying lumbar distraction • Paraspinal MFR • STM surrounding neural tissue • Supine hamstring, hip flexor, piriformis stretches • Use of resistance with LE strengthening exercise • Increase resistance of long lever challenge on dynamic spine control • Abdominal exercise (plank) • SLS static and dynamic activities • Use of unstable surfaces • Use of resistance bands with UE and LE	• PT modalities as needed • Mobilization and manipulation of thoracic spine, lumbar spine, SI joints • Side-lying lumbar distraction • Paraspinal MFR • STM surrounding neural tissue • Supine hamstring, hip flexor, piriformis stretches • Use of resistance with LE strengthening exercise • Increase resistance of long lever challenge on dynamic spine control • Abdominal exercise (plank) • SLS static and dynamic activities • Use of unstable surfaces • Use of resistance bands with UE and LE • Unloading jumping on reformer progressing to squat jumps, broad jumps	• PT modalities as needed • Mobilization and manipulation of thoracic spine, lumbar spine, SI joints • Side-lying lumbar distraction • Paraspinal MFR • STM surrounding neural tissue • Supine hamstring, hip flexor, piriformis stretches • Use of resistance with LE strengthening exercise • Increase resistance of long lever challenge on dynamic spine control • Abdominal exercise (plank) • SLS static and dynamic activities • Use of unstable surfaces • Use of resistance bands with UE and LE • Unloading jumping on reformer progressing to squat jumps, broad jumps • Progressive resistive exercises (PRE) Lumbar and core • Hip/LE PRE • Upper extremity PRE • Sports-specific drills with protective pivoting • Carioca drills • Slide board • Plyometrics • Agility ladder

FIGURE 19-9. Hip/back dissociation using a stick to give biofeedback for proper spine alignment to allow hip to hinge in normal pattern and allow for proper spine mechanics.

Sensorimotor Exercises

- Balance on unstable surfaces (rocker board, foam with neutral spine)
- Single leg balance (SLB) with resistive bands or pulleys four-way directions (Figure 19-10*A,B*)

Open and Closed Kinetic Chain Exercises

- Pelvic neutral using blood pressure cuff for biofeedback, advancing with lower extremity movements
- Quadruped neutral (Figure 19-11)
- Pelvic neutral on the door with mini squats progressing to upper extremity movements with resistive bands

Techniques to Increase Muscle Strength, Power, and Endurance

- Mini squat in pelvic neutral
- Total or Vigor Gym in pelvic neutral
- Standing lat pulldown with pelvic neutral

Neuromuscular Dynamic Stability Exercises

- Refer to OKC and CKC exercise

Functional Exercises

- Hip hinging series: sit, stand, squat, and stagger squat (keeping spine in position and movement comes from hinging at the hips as opposed to motion through spine)
- Proper log rolling for bed mobility
- Gait training
- Education on getting on/off floor

Milestones for Progression to the Next Phase

- Minimal daily symptoms
- Reduce ODI score <20%
- Able to perform ADLs

Phase III (weeks 6 to 12, Postinjury)

The majority of patients treated in a nonoperative treatment protocol will be advanced to return to sport after this phase. If they require additional treatment/cannot progress, they may require further evaluation and consideration for other treatment modalities (i.e., epidural steroid injection, surgery).

Protection

- Proper protective spine mechanics for high functional activities, return to work, and sport

FIGURE 19-10. **A, B,** Single leg balance with resistive bands.

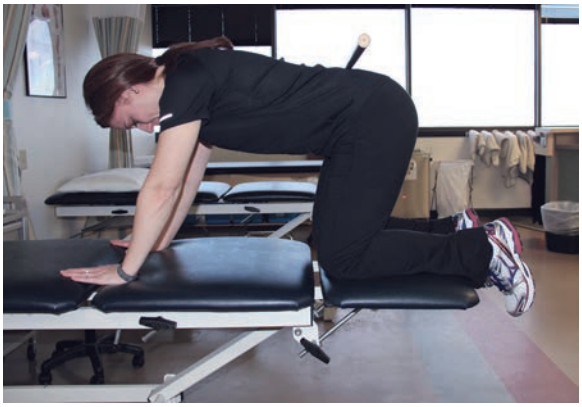

FIGURE 19-11. Quadruped neutral position.

FIGURE 19-12. Pelvic neutral (feedback by therapist) standing upper extremity cable exercises.

Management of Pain and Swelling

- NSAIDs as needed
- Ice or cryotherapy prn
- E-stim/TENS, as necessary

Techniques for Progressive Increase in Range of Motion

Manual Therapy Techniques

- Mobilization and manipulation of thoracic spine, lumbar spine, SI joint, hips to correct hypomobility and for pain modulation
- Side-lying lumbar distraction
- Muscle energy techniques (METs) for muscular recruitment or inhibition

Soft Tissue Techniques

- Neural tissue mobilization
- Paraspinal MFR
- STM functional movement patterns

Stretching and Flexibility Techniques for the Musculotendinous Unit

- Supine hamstring, hip flexor and piriformis stretches

Other Therapeutic Exercises

- Standing upper extremity exercises with cable with pelvic neutral (Figure 19-12)
- Total Gym
- Treadmill

Activation of Primary Muscles Involved

- Use of resistance bands of upper and lower extremities
- Use of unstable surfaces
- Advance of abdominal exercise (plank, etc.) (Figure 19-13)
- Focus on transverse abdominals, external obliques, latissmus dorsi, gluteus maximus, gluteus medius, hamstrings, multifidus, psoas, quadratus lumborum

Sensorimotor Exercises

- Sitting stability ball
- Advance to standing on unstable disc
- Single leg stance (SLS) static and dynamic activities

Open and Closed Kinetic Chain Exercises

- Prone pelvic neutral with blood pressure cuff with lower and upper extremity progression
- Dynamic movements using a stick for biofeedback on neutral spine
- Use of bands and cables in varies directions/resistance in functional hip hinge position

Techniques to Increase Muscle Strength, Power, and Endurance

- Advance abdominal exercise
  - Plank
  - Lateral plank
  - Resisted proprioceptive neuromuscular facilitation (PNF)

FIGURE 19-13. Plank.

- Emphasis on the following muscle groups: gluteals, abdominals, deep back extensors

Neuromuscular Dynamic Stability Exercises

- BOSU ball
- Single leg stance dynamic and static activities
- Improving body sense awareness in cutting, pivoting, and agility work

Plyometrics

- Unloading jumping on reformer to progressing to squat jumps, broad jumps, SL hops

Functional Exercises

- Education and technique for proper spine mechanics
- Increased resistance of long lever challenge on dynamic spine control
- Hip hinging with upper extremity weighted challenge
- Use of resistive bands in functional positions (i.e., lunge)
- Overhead squatting

Sport-Specific Exercises

- Squat jumps, single leg hips
- Agility ladder
- Resisted golf swings

Milestones for Progression to Advanced Sport-Specific Training and Conditioning

- Able to demonstrate neutral spine in all functional positions (using observation and monitoring patients symptoms)
- Pain free and progressive improvement with standing balance activities (measure by patient pain report and time on single leg stance)
- LE strength returned to within 10% of preinjury level (or 10% of expected strength at normal) (measured with manual muscle testing of all myotomes)
- Able to demonstrate proper form in sports-specific skills

Criteria for Abandoning Nonoperative Treatment and Proceeding to Surgery or More Intensive intervention

- Continued pain on activities
- Inability to advance to sport specific drills
- Continued setbacks with rehabilitation caused by pain, weakness or failure to progress
- Progressive neurological decline
- Persistent or worsening pain

Tips and Guidelines for Transitioning to Performance Enhancement

- Proper body mechanics observed and trained
- Proper nutrition and hydration during training
- Advance per progression to prevent a setback or recurrence of symptoms

Performance Enhancement And Beyond Rehabilitation: Training/Trainer and Optimization of Athletic Performance

- Progression of core strength including abdominals and paraspinals are key to injury prevention in the future (i.e., plants, side plants, bridging, lat pulldown, hip hinging with cable resistance)
- Proper technique (sports-specific) can be the keys to progress and continued improved performance

Specific Criteria for Return to Sports Participation: Tests and Measurements

- Pain-free activities
- Core strength and LE strength within 10% of preinjury or "normal" level (measured by manual muscle testing)
- Single leg balance equal side to side (measured by time)
- Any functional tests?

Evidence

Danielson JM, Johnsen R, Kibsgaard SK, et al: Early aggressive exercise for postoperative rehabilitation after discectomy. *Spine* 25:1015–1020, 2000.

This is a randomized controlled trial comparing a training group and a mild exercise group postoperatively. Vigorous medical exercise started 4 weeks after surgery reduced disability and pain after surgery. (Level I evidence).

McGregor AH, Dore CJ, Morris TP, et al: Function after spinal treatment, exercise, and rehabilitation (FASTER). *Spine* 36:1711–1720, 2011.

This multicenter, factorial, randomized controlled trial on the postoperative management of spinal surgery patients. Found no difference at 12 months ODI for usual care versus rehabilitation versus rehabilitation with educational booklet and booklet only. (Level I evidence).

Ostelo RW, Costa LO, Maher CG, et al: Rehabilitation after lumbar disc surgery: An update Cochrane review. *Spine* 34:1839–1848, 2009.

This systematic review of randomized, controlled trials evaluated postoperative protocol after lumbar surgery. Exercise programs after surgery seem to lead to faster decrease in pain postoperatively. (Level I evidence).

Ostelo RW, de Vet HC, Waddell G, et al: Rehabilitation following first-time lumbar disc surgery: A systematic review within the framework of the Cochrane collaboration. *Spine* 28:209–218, 2003.

This systematic review of randomized controlled trials evaluated the protocol for postoperative rehabilitation after first-time lumbar surgery. No evidence for restriction of activities immediately after surgery was found and strong evidence for intensive exercise. (Level I evidence).

Weber H: Lumbar disc herniation: A controlled, prospective study with ten years of observation. *Spine* 8:131–140, 1983.

This prospective study of patients with surgical and nonsurgical treatment for lumbar disc herniation showed improved

outcomes in the surgical group at 1 year and no statistical difference at 4- and 10-year follow up. (Level II evidence).

Weinstein JN, Tosteson TD, Lurie JD, et al: Surgical versus nonoperative treatment for lumbar disk herniation: The spine patient outcomes research trial (SPORT), A randomized trial. *JAMA* 296:2441–2450, 2006.

This prospective, randomized study of operative and nonoperative treatment for lumbar disk herniation found better outcomes in surgical patients, but the primary differences in the study were not statistically significant. There were large crossovers in the study confounding some conclusions. (Level I evidence).

Multiple-Choice Questions

QUESTION 1. Plyometric training should start in what phase of rehabilitation after lumbar disc injury?

A. Phase I (1 to 2 weeks)
B. Phase II (3 to 6 weeks)
C. Phase III (6 to 18 weeks)
D. Any time

QUESTION 2. A key to future injury prevention after lumbar herniation:

A. Lower extremity strength
B. Upper extremity strength
C. Proper technique in sport
D. Level of disc herniation

QUESTION 3. A sign that indicates the possible need for more medical intervention for lumbar disc herniation includes:

A. Increasing pain
B. Inability to progress in rehabilitation protocol
C. Progressive neurological signs and symptoms
D. All of the above

QUESTION 4. Goals for successful nonoperative treatment of lumbar disc herniation include all of the following except:

A. Running endurance
B. Core and lower extremity strength
C. Mobilization of the spine
D. Pain control

QUESTION 5. Manipulation of the thoracolumbar spine is an example of:

A. An exercise in rehabilitation
B. A manual therapy technique
C. A soft tissue technique
D. A strengthening technique

Answer Key

QUESTION 1. Correct answer: **D** (See Phase III)

QUESTION 2. Correct answer: **C** (See Phase III)

QUESTION 3. Correct answer: **D** (See Phase III)

QUESTION 4. Correct answer: **A** (See Phase I)

QUESTION 5. Correct answer: **B** (See Phase I)

POSTOPERATIVE REHABILITATION AFTER LUMBAR DISC HERNIATION SURGERY

S. Josh Bell, MD, Stephanie Niño, PT, OCS, FAAOMPT, and Cheryl Kathleen Obregon, PT, DPT, FAAOMPT

Indications for Surgical Treatment

- Progressive neurological symptoms
- Correlation of symptoms with MRI imaging
- Symptoms that persist after reasonable nonoperative management

Brief Summary of Surgical Treatment

Major Surgical Steps

- General anesthesia prone position, abdomen free fluoroscopy positioned (Figure 19-14)
- Techniques vary from open to microdiscectomy with positioning of tubes for access and instrument passing (Figure 19-15)
- Place needle localization under lateral fluoroscopy to confirm level (Figure 19-16)
- Dissect subperiosteal down spinous process to the lamina on the affected side (Figure 19-17)
- Protect the facet joint capsule
- Place lamina spreader between spinous processes
- Expose ligamentum flavum and incise
- Use minimal resection of lamina (based on level of disc) (Figure 19-18)
- Gently protect dura
- Remove disc fragments (Figure 19-19)

FIGURE 19-14. Patient in prone position with fluoroscopy positioned for lumbar discectomy. *(From Angevine PD, Gigante PR, McCormick PC: Patient positioning for spinal surgery. In: Winn HR:* Youmans Neurological Surgery, *ed 4. Philadelphia: Saunders (Elsevier), 2011, pp. 447–452.)*

- Ensure no remnant fragments are present and that nerve root is free (Figure 19-20)
- No postoperative anticoagulation
- Early mobilization

Factors that May Affect Rehabilitation

Anesthetic

- Local long-acting anesthetics may improve early pain control

Surgical

- Multilevel disc herniation require longer early phases to allow for additional surgical trauma

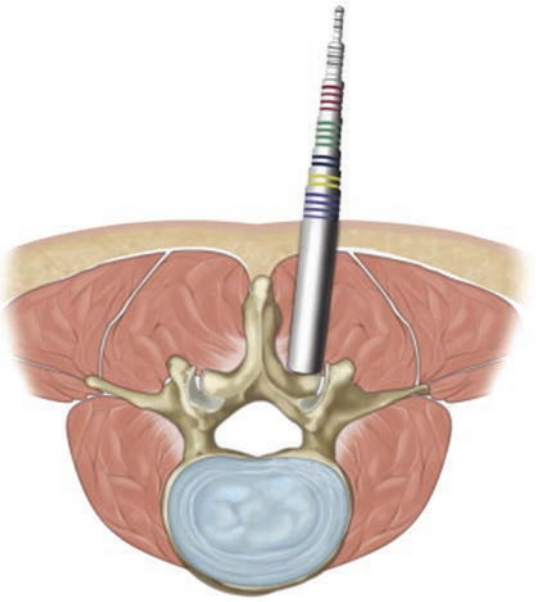

FIGURE 19-15. Use of microdiscectomy dilating tubes to minimize incision. *(From Lee P, Wong AP, Ganju A: Surgical Anatomy and Techniques to the Spine. In* Surgical anatomy and operative techniques of lumbar stenosis. *Philadelphia: Saunders (Elsevier), 2013,* Ch 43.*)*

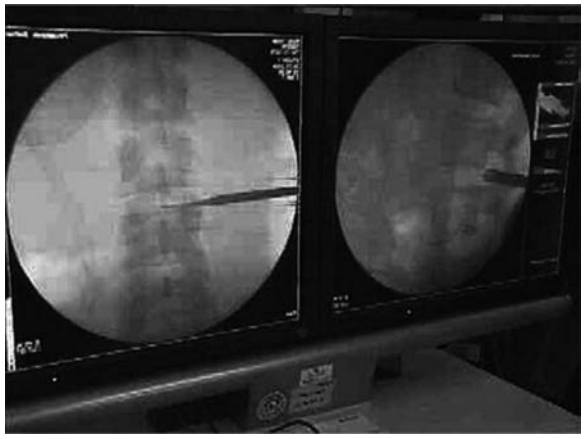

FIGURE 19-16. Intraoperatively fluoroscopically confirmed level for surgical discectomy. *(From Leu HF: Posterior foraminal lumbar decompression. In: Kim DH, Kim Y-C, Kim K-H editors:* Minimally Invasive Percutaneous Spinal Techniques. *Philadelphia: Saunders (Elsevier), 2011, pp 360–366.)*

Before Surgery: Overview of Goals, Milestones, and Guidelines[1]

GUIDING PRINCIPLES OF POSTOPERATIVE REHABILITATION

- Understand the level of disc herniation treated (nerves and levels affected)
- Understand the importance of core muscle groups to support the rehabilitation
- Understand the importance of pain control for advance of therapy
- Proper selection of manual therapy intervention applied at the appropriate phase of healing
- Recognize the importance of reintegration of proper techniques to prevent future injury

Phase I: Immediate Postoperative Period (days 0 to 14)

Clinical Pearls

- Pain control to get the patient to have confidence in the postoperative period is of paramount importance.
- Early mobility with proper pain management to build and restore patient's confidence towards pain-free mobility and progression.

Goals

- Pain control
- Early mobility

[1]*Prehabilitation, if appropriate, is described in the Nonoperative Rehabilitation section of this chapter. For a timeline for postoperative rehabilitation, refer to the Nonoperative Rehabilitation part.*

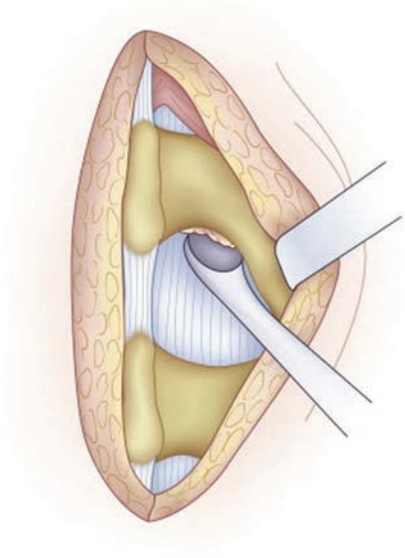

FIGURE 19-17. Dissection down spinous process to expose lamina. *(From Bono CM, Schoenfeld A, Garfin SR: Lumbar disc herniations. In: Herkowitz HN, Garfin SR, Eismont FJ, et al, editors:* Rothman-Simeone The Spine, *ed 6. Philadelphia: Saunders (Elsevier), 2011, pp 887–914.)*

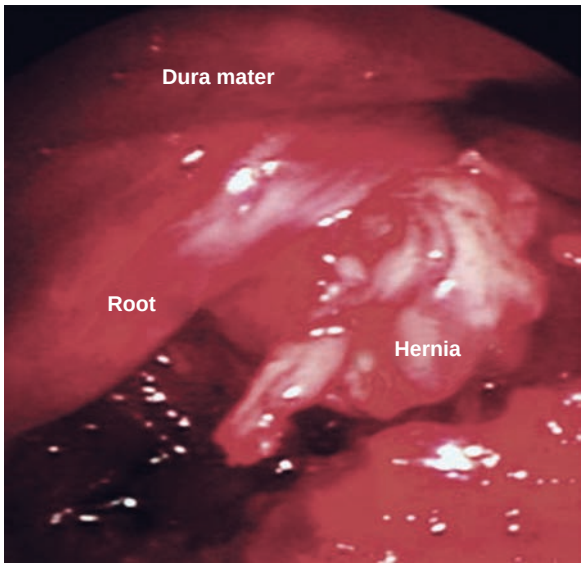

FIGURE 19-19. Herniated material removed with protection of nerve root. *(From Blamoutier A: Surgical discectomy for lumbar disc herniation: Surgical techniques.* Orthop Traumatol Surg Res *99:S187–96, 2013)*

- Support of weight bearing (walking aids, back brace as needed)
- Edema control (medication, ice, and protection from injury)

Protection

- Use of walker for unloading as necessary postoperatively
- Possible use of supportive lumbar brace (LSO)

Management of Pain and Swelling

- In immediate postoperative period, patient will have local anesthetic long-acting for localized pain relief
- Oral pain management with medication
- TENS unit to control pain
- Ice therapy to reduce inflammation and pain
- Patient education regarding avoidance of painful motions
- PT modalities

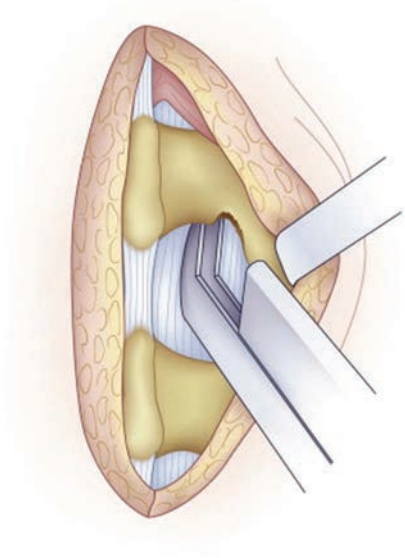

FIGURE 19-18. Minimal resection of lamina to expose herniated disc beneath. *(From Bono CM, Schoenfeld A, Garfin SR: Lumbar disc herniations.. In: Herkowitz HN, Garfin SR, Eismont FJ, et al, editors: Rothman-Simeone The Spine, ed 6. Philadelphia: Saunders (Elsevier), 2011, pp 887–914.)*

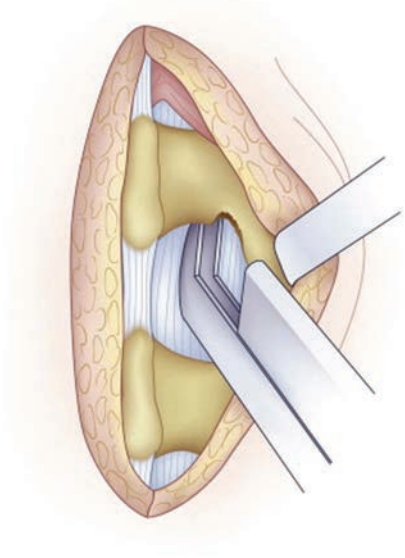

FIGURE 19-20. Ensure area free of disc material and nerve root is not impinged. *(From Bono CM, Schoenfeld A, Garfin SR: Lumbar disc herniations. In: Herkowitz HN, Garfin SR, Eismont FJ, et al, editors: Rothman-Simeone The Spine, ed 6. Philadelphia: Saunders (Elsevier), 2011, pp 887–914.)*

Techniques for Progressive Increase in Range of Motion

Manual Therapy Techniques

- Limited in first several weeks secondary to incision (gentle soft tissue techniques for early treatment)

Stretching and Flexibility Techniques for the Musculotendinous Unit

- Lumbar spine pain-free ROM
- Functional unloading (unloading the spine/soft tissue to eliminate pain in functional activities, i.e., walking/transitional movements, can use functional unloader—weight supported walking)
- Education of log rolling, proper bed mobility, sit-to-stand transitions

Other Therapeutic Exercises

- Walking low intensity level for cardiovascular fitness
- Body-weight support treadmill for walking with additional offloading (Figure 19-21) (Parameters are 65% of body weight ambulating 0.1 to 0.5 mph up to 40 to 50 minutes)

Activation of Primary Muscles Involved in Injury Area or Surgical Structures

- Unloaded squatting using Total Gym

Open and Closed Kinetic Chain Exercises

- Walking program
- Body weight support walking on treadmill if available

Functional Exercises

- ADLs training
- Sit-to-stand transitions
- Log rolling
- Don/doff LSO brace if used

FIGURE 19-21. Body weight support treadmill walking.

Milestones for Progression to the Next Phase

- Healing of the surgical incision
- Pain control to allow sitting and standing
- ODI (Oswestry disability index 20% to 40%)

Phase II: (weeks 2 to 6, Postoperative)

Clinical Pearls

- Closely monitor the athlete's progression as it will vary
- Pay attention to movement patterns and guarding in the patient's movements
- Slow progress early with attention to any adjustments as necessary for any adverse neurological symptoms

Goals

- Protect surgical wound
- Increase core strength
- Improve mobility
- Improve flexibility

Protection

- Discontinue ambulatory aids as tolerated
- Retrain protective movement patterns

Management of Pain and Swelling

- PT modalities (heat, electrical stimulation, taping—Kinesio tape for pain reduction/muscle spasm relief)
- Oral pain medication
- Ice or cryotherapy as necessary to decrease inflammation and swelling

Techniques for Progressive Increase in Range of Motion

- Stretching/flexibility techniques for the musculotendinous unit
- Supine hamstring, hip flexor, piriformis stretches, gluteal stretch (Figures 19-22, 19-23)

Manual Therapy Techniques

- Mobilization and manipulation of thoracic spine, lumbar spine (opening, closing and gapping techniques) (Figure 19-24)
- SI joint (supine, side-lying, and prone techniques), hips to correct hypomobility, and for pain modulation
- Muscle energy techniques (METs) for muscular recruitment or inhibition
- Side-lying lumbar distraction

Soft Tissue Techniques

- Paraspinals myofascial release (MFR)
- Soft tissue manipulation (STM) surrounding neural tissue

FIGURE 19-22. Piriformis figure-of-4 stretch.

FIGURE 19-23. Single knee to chest.

- STM functional movement patterns
- Incisional scar massage

Other Therapeutic Exercises

- Body weight support walking on treadmill (unload 65% of total body weight at 0.1 to 0.5 mph on treadmill for up to 40 to 50 minutes)
- Repeat Phase I with progressing to sitting, standing, and quadruped exercise

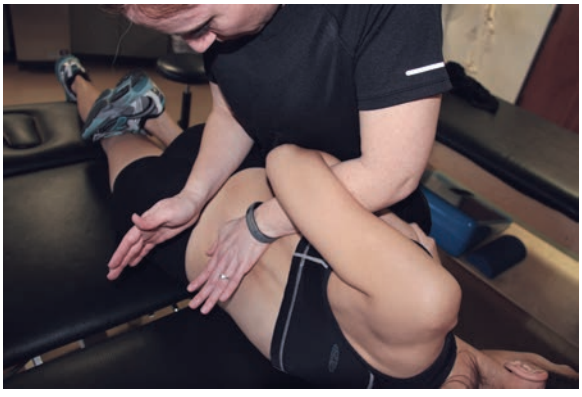

FIGURE 19-24. Side-lying manual lumbar mobilization (gapping).

FIGURE 19-25. Pelvic neutral position with progressive lower extremity mobility challenge (bent knee fallout).

Activation of Primary Muscles Involved in Injury Area or Surgical Structures

- Lower extremity strength exercises are encouraged as tolerated by pain level, proper activation of transverse abdominal, external obliques, multifidus, and gluteals (Figures 19-25 to 19-26). (Begin with 5 minutes at 10 seconds hold for pelvic neutral or abdominal bracing. Then progress to lower extremity movement with neutral spine for 3 to 5 minutes each leg. Total stabilization time is 10 to 15 minutes. All movement should not be painful and repetitious until proper mechanics/muscle activation is done with ease.)
- Hip/back dissociation exercise (biofeedback on spine to allow hips and back to function independently (Figure 19-27) (2 to 3 minutes total: hip hinge exercise)
- Hip strengthening/neuromuscular recruitment exercises (10 seconds hold × 10 reps; progress to 2 to 3 sets)
- Supine hamstring (Figure 19-28), hip flexor, piriformis stretches (1 minutes hold, 3 to 5 reps)

Sensorimotor Exercises

- Pelvic neutral on stability ball with progressing to LE movement (reps to fatigue: when a patient can no longer maintain neutral spine)

FIGURE 19-26. Pelvic neutral position with progressive lower extremity mobility challenge(marching).

FIGURE 19-27. Hip/back dissociation with biofeedback (with stick) on spine to allow for proper alignment and motion through the hip (hinging at the hip) while keeping a pelvic neutral position of the spine.

FIGURE 19-29. Single leg balance with lower extremity resistance bands.

- Sitting on stability ball, static and dynamic movements on unstable surface (reps to fatigue)
- Balance on unstable surfaces (rocker board, foam with neutral spine)
  - Single leg balance (SLB) with resistive bands or pulleys four-way directions (Figure 19-29) (begin with 10 reps in each direction if patient is able to maintain form, progress to up to 20 reps)

Open and Closed Kinetic Chain Exercises

- Lunges (2 to 3 sets, 10 to 15 reps)
- Body weight squats (unloading as necessary) (5 minutes)
- Pelvic neutral using blood pressure cuff for biofeedback, advancing with lower extremity movements (begin with 5 minutes and progress to 15 minutes total time)
  - Quadruped neutral (Figure 19-30)
  - Pelvic neutral on the door with mini squats progressing to upper extremity movements with resistive bands (3 sets to fatigue)

Techniques to Increase Muscle Strength, Power, and Endurance

- Mini squat with pelvic neutral (3 sets to fatigue)
- Total Gym or Vigor Gym in pelvic neutral (5 to 10 minutes)
- Standing lat pulldown with pelvic neutral (10 to 15 reps, 2 to 3 sets)

Neuromuscular Dynamic Stability Exercises

- Refer to OCK and CKC exercise

Functional Exercises

- Proper sitting mechanics, sit-to-stand transitions, squatting, lifting, getting on/off floor, ADLs retraining
- Hip hinging series: sit, stand, squat, and stagger squat
  - Proper log rolling for bed mobility
  - Gait training
  - Education on getting on/off floor

FIGURE 19-28. Supine hamstring stretch.

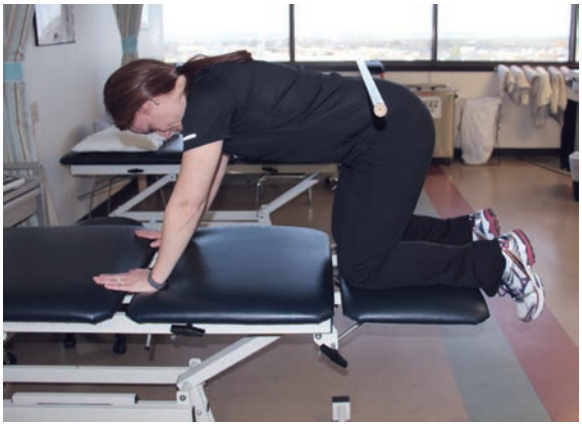

FIGURE 19-30. Quadruped neutral position.

Milestones for Progression to the Next Phase

- Minimal daily symptoms
- Reduce ODI score <20%
- Perform ADLs

Phase III: (weeks 6 to 10, Postoperative)

Clinical Pearls

- Progress of activities with a focus on core strengthening
- Advanced based on ability to perform activities with proper mechanics and technique
- Continue with lifting precautions and protection from injury as any setback or return or neurological symptoms should be avoided.

Goals

- Pain-free transitions
- Demonstrate proper body mechanics with exercises
- Walk 1 mile without pain (trying to approximate up to 20 minutes of loaded activity)

Protection

- Proper protective spine mechanics for high functional activities, return to work, and sport

Management of Pain and Swelling

- NSAIDs as needed

Techniques for Progressive Increase in Range of Motion

Manual Therapy Techniques

- Mobilization and manipulation of thoracic spine, lumbar spine, SI joint, hips to correct hypomobility and for pain modulation
- Side-lying lumbar distraction
- Muscle energy techniques (METs) for muscular recruitment or inhibition

Soft Tissue Techniques

- Neural tissue mobilization
- Paraspinal MFR
- STM functional movement patterns

Stretching and Flexibility Techniques for the Musculotendinous Unit

- Supine hamstring, hip flexor, and piriformis stretches

FIGURE 19-31. Standing cable exercises of upper extremities with pelvic neutral position.

Other Therapeutic Exercises

- Standing cable exercises of the upper extremities with pelvic neutral (Figure 19-31)
- Total Gym
- Body weight support treadmill with progression to regular treadmill

Activation of Primary Muscles Involved in Injury Area or Surgical Structures

- Use of resistance bands of upper and lower extremities
- Use of unstable surfaces
- Advance of abdominal exercise (plank, etc.)
- Focus on transverse abdominals, external obliques, latissmus dorsi, gluteus maximus, gluteus medius, hamstrings, multifidus, psoas, quadratus lumborum

Sensorimotor Exercises

- Sitting on stability ball
- Advance to standing on unstable disc
- Single leg stance (SLS) static and dynamic activities

Open and Closed Kinetic Chain Exercises

- Prone pelvic neutral with blood pressure cuff with lower and upper extremity progression
- Dynamic movements using a stick for biofeedback on neutral spine
- Use of bands and cables in varies directions/resistance in functional hip hinge position

Techniques to Increase Muscle Strength, Power, and Endurance

- Advance abdominal exercise
  - Plank
  - Lateral plank
  - Resisted proprioceptive neuromuscular facilitation (PNF)
- Emphasis on the following muscle groups: gluteals, abdominals, deep back extensors

Neuromuscular Dynamic Stability Exercises

- BOSU ball
  - Single leg stance dynamic and static activities
  - Improving body sense awareness in cutting, pivoting, and agility work

Functional Exercises

- Education and technique for proper spine mechanics
  - Increased resistance of long lever challenge on dynamic spine control
  - Hip hinging with upper extremity weighted challenge
  - Use of resistive bands in functional positions, i.e. lunge
  - Overhead squatting (use of bar overhead during squat maneuver; no weight)

Milestones for Progression to the Next Phase

- Complete resolution of pain
- Able to demonstrate neutral spine in all functional positions (both subjective feedback and also qualitative from the therapist observing the motions and positions)

Phase IV: (weeks 10 to 14, Postoperative)

Clinical Pearls

- Use core strengthening exercises as a foundation for total fitness.
- Use exercises focusing on sport specific routine is important at this stage of rehabilitation.
- Ensure proper technique throughout the exercises is important to reinforce spine mechanics and build the foundation for future return to sports.

Goals

- Fluid motion in normal spine activities
- Elimination of abnormal spinal mechanics
- Walking program progression (greater than 1 mile)
- Light lifting program
- ADLs without pain

Protection

- Reinforce proper spine mechanics throughout all activities

Techniques for Progressive Increase in Range of Motion

Manual Therapy Techniques

- Muscle energy techniques (METs) for muscular recruitment or inhibition (any setbacks with small resurgence of symptoms may require treatment)

Stretching and Flexibility Techniques for the Musculotendinous Unit

- Supine hamstring, hip flexor, and piriformis stretches

Other Therapeutic Exercises

- Total Gym workout
- Swimming
- Treadmill
- Elliptical

Activation of Primary Muscles Involved in Injury Area or Surgical Structures

- Use of resistance bands of upper and lower extremities
- Use of unstable surfaces
- Advance of abdominal exercise (plank, etc.)
- Focus on transverse abdominals, external obliques, latissmus dorsi, gluteus maximus, gluteus medius, hamstrings, multifidus, psoas, quadratus lumborum

Sensorimotor Exercises

- Single leg stance (SLS) dynamic activities
- Unstable disc

Open and Closed Kinetic Chain Exercises

- Use of bands and cables in varies directions/resistance in functional hip hinge position (therapist to assist to ensure hip is the hinge for motion allowing for stable spine in exercises) (Figure 19-32)

Techniques to Increase Muscle Strength, Power, and Endurance

- Advance abdominal exercise
  - Plank
  - Lateral plank
  - Resisted proprioceptive neuromuscular facilitation (PNF)

FIGURE 19-32. Therapist providing feedback to keep proper hip position during standing upper extremity cable exercises.

- Emphasis on the following muscle groups: gluteals, abdominals, deep back extensors
- Treadmill and swimming for cardiovascular fitness

Neuromuscular Dynamic Stability Exercises

- BOSU ball
  - Single leg stance dynamic and static activities
  - Improving body sense awareness in cutting, pivoting, and agility work

Plyometrics

- Squat jumps, broad jumps, single leg hops

Functional Exercises

- Education and technique for proper spine mechanics
  - Increased resistance (using upper extremity cables) of long lever challenge on dynamic spine control
  - Hip hinging with upper extremity weighted challenge
- Use of resistive bands in functional positions, i.e., lunge
- Overhead squatting

Sport-Specific Exercises

- Squat jumps, single leg hips
  - Agility ladder
  - Resisted golf swings
- Carioca

Milestones for Progression to the Next Phase

- Proper spinal mechanics (both subjective feedback and qualitative assessment from the therapist observing all positions)
- Complete resolution of pain
- Able to demonstrate neutral spine in all functional positions, using both subjective feedback from the patient and qualitative assessment from the therapist observing the positions

Phase V: (weeks 14 to 24, Postoperative)

Clinical Pearls

- Progress at this point can focus towards sport-specific type of exercises.
- It is important that as progress improves with cardiovascular fitness and strength to ensure proper spine mechanics to prevent further injury.
- Therapist to evaluate overall body mechanics to correct deficiency in kinetic chain.

Goals

- Improve cardiovascular fitness
- Incorporate sport-specific protocols
- Encourage proper spine mechanics throughout kinetic chain (from foot to head)

Protection

- Continue to monitor for proper form during activities

Management of Pain and Swelling

- NSAIDs as needed

Techniques for Progressive Increase in Range of Motion

Manual Therapy Techniques

- Muscle energy techniques (METs) for muscular recruitment or inhibition (as necessary)

Stretching and Flexibility Techniques for the Musculotendinous Unit

- Supine hamstring, hip flexor and piriformis stretches
- Stretching of gastroc-soleus complex

Other Therapeutic Exercises

- Standing cable upper extremity exercises with pelvic neutral
- Total Gym
- Swimming
- Treadmill or elliptical

Activation of Primary Muscles Involved in Injury Area or Surgical Structures

- Use of resistance bands of upper and lower extremities
- Use of unstable surfaces
- Advance of abdominal exercise (plank, etc.)
- Focus on transverse abdominals, external obliques, latissmus dorsi, gluteus maximus, gluteus medius, hamstrings, multifidus, psoas, quadratus lumborum

Sensorimotor Exercises

- Standing on unstable disc
- Single leg stance (SLS) static and dynamic activities
- BOSU ball

Open and Closed Kinetic Chain Exercises

- Use of bands and cables in variable directions/resistance in functional hip hinge position

Techniques to Increase Muscle Strength, Power, and Endurance

- Plank
- Lateral plank
- Resisted proprioceptive neuromuscular facilitation (PNF)
- Progress from previous phases to include hip flexors, quads, gastroc soleous, hip abductors and external obliques

Neuromuscular Dynamic Stability Exercises

- Single leg stance dynamic and static activities
- Improving body sense awareness in cutting, pivoting, and agility work
- Rocker-board activities
- Single leg stance (SLS) with lower body resistance bands

Plyometrics

- Squat jumps, broad jumps, single leg hops

Functional Exercises

- Education and technique for proper spine mechanics
- Increased resistance of long lever challenge on dynamic spine control
- Hip hinging with upper extremity weighted challenge
- Use of resistive bands in functional positions, i.e., lunge
- Overhead squatting

Sport-Specific Exercises

- Squat jumps, single leg hips
- Agility ladder
- Resisted golf swings

Milestones for Progression to the Next Phase

- Pain-free activities
- Core strength and LE strength within 10% of preinjury or "normal" level
- Single leg balance equal side to side

Phase VI: (weeks 24 to 52, Postoperative)

Clinical Pearls

> Transition to sport should emphasize proper technique and spinal mechanics with restoration of sport activity. Proper spinal mechanics should be emphasized over performance until the ability to maintain those mechanics with endurance are achieved.

Goals

- Progress to normal activities and sport
- Regain normal sport velocity
- Establish endurance for sport and core body strength (depends on specific sport technique to be able to determine return to play)

Techniques for Progressive Increase in Range of Motion

- Manual therapy techniques not applicable, except as necessary as per previous phases
- Stretching of parapinals, piriformis, hip flexors

Other Therapeutic Exercises

- Progression to cardiovascular endurance
- Progression of UE and LE resistance exercises with focus on proper form and endurance

Activation of Primary Muscles Involved in Injury Area or Surgical Structures

- Focus on transverse abdominals, external obliques, latissimus dorsi, gluteus maximus, hip abductors, hamstrings and lower extremity strengthening

Sensorimotor Exercises

- Stability ball
- Rocker board
- Single leg stance dynamic activities

Open and Closed Kinetic Chain Exercises

- Use of bands and cables in varies directions/resistance in functional hip hinge position

Techniques to Increase Muscle Strength, Power, and Endurance

- Cardiovascular fitness to include treadmill, swimming
- Plank exercises
- Resisted PNF

Neuromuscular Dynamic Stability Exercises

- Agility work with cutting and pivoting/weight transfer
- Single leg stance dynamic and static activities

Plyometrics

- Lunges multidirectional
- Squat jumps
- Single leg jumps

Functional Exercises

- Increased resistance of long lever challenge on dynamic spine control
- Hip hinging with upper extremity weighted challenge
- Observation and correction of spine mechanics during exercise

Sport-Specific Exercises

- Agility ladder
- Carioca
- Pivot drills
- Resisted swinging (golf)

Milestones for Progression to the Next Phase

- Proper technique to and through fatigue
- Return to 10% of estimated or previous strength (manual muscle testing from therapist or isokinetic testing)
- LE strength within 10% of each other (manual muscle testing from physical therapist or isokinetic testing)

Criteria for Return to Sport

General

- Within 10% of normal or previous (preinjury) core strength (How measured?)
- Proper mechanics to and through fatigue
- Pain-free mobility with activity and throughout agility drills
- Demonstration of sport skills with proper mechanics and pain free

Sport-Specific

- Golf
  - Pain-free proper mechanics of swing

  - With attention to hip turn, spine position, and shoulder turn
- Football/contact sports
  - Ensure pain-free noncontact full speed prior to return
  - Gradual return to full contact (protected contact (player initiated) prior to open full contact)
  - Monitor closely during practice to ensure that athlete is progressing with proper mechanics/technique

After Return to Sport

Continuing Fitness or Rehabilitation Exercises

- Proper spine mechanics throughout activity (observed)
- Core strengthening exercises: plank, lateral plank
- Lower extremity strength and conditioning

Exercises and Other Techniques for Prevention of Recurrent Injury

- Lower extremity flexibility important for injury prevention
- Proper technique in sport
- Core (lumbar and abdominal) strength and endurance

Evidence

Danielson JM, Johnsen R, Kibsgaard SK, et al: Early aggressive exercise for postoperative rehabilitation after discectomy. *Spine* 25:1015–1020, 2000.

This is a randomized controlled trial comparing a training group and a mild exercise group postoperatively. Vigorous medical exercise started 4 weeks after surgery reduced disability and pain after surgery. (Level I evidence).

McGregor AH, Dore CJ, Morris TP, et al: Function after spinal treatment, exercise, and rehabilitation (FASTER). *Spine* 36: 1711–1720, 2011.

This multicenter, factorial, randomized controlled trial on the postoperative management of spinal surgery patients. Found no difference at 12 months ODI for usual care versus rehabilitation versus rehabilitation with educational booklet and booklet only. (Level I evidence).

Ostelo RW, Costa LO, Maher CG, et al: Rehabilitation after lumbar disc surgery: An update Cochrane review. *Spine* 34:1839–1848, 2009.

This systematic review of randomized controlled trials evaluated postoperative protocol after lumbar surgery. Exercise programs after surgery seem to lead to faster decrease in pain postoperatively. (Level I evidence).

Ostelo RW, de Vet HC, Waddell G, et al: Rehabilitation following first-time lumbar disc surgery; A systematic review within the framework of the Cochrane collaboration. *Spine* 28:209–218, 2003.

This systematic review of randomized controlled trials evaluated the protocol for postoperative rehabilitation after first time lumbar surgery. No evidence for restriction of activities immediately after surgery was found and strong evidence for intensive exercise. (Level I evidence).

Weber H: Lumbar disc herniation: A controlled, prospective study with ten years of observation. *Spine* 8:131–140, 1983.

This prospective study of patients with surgical and nonsurgical treatment for lumbar disc herniation showed improved outcomes in the surgical group at 1 year and no statistical difference at 4- and 10-year follow up. (Level 2 evidence).

Weinstein JN, Tosteson TD, Lurie JD, et al: Surgical versus nonoperative treatment for lumbar disk herniation: The spine patient outcomes research trial (SPORT)—A randomized trial. *JAMA* 296:2441–2450, 2006.

This prospective, randomized study of operative and nonoperative treatment for lumbar disk herniation found better outcomes in surgical patients, but the primary differences in the study were not statistically significant. There were large crossovers in the study confounding some conclusions. (Level I evidence).

Multiple-Choice Questions

QUESTION 1. An important aspect of the surgical technique includes all of the following except:

A. Broad exposure of disc removing lamina for visualization
B. Protection of the dura
C. Fluoroscopic confirmation of level
D. Removal of disc fragments

QUESTION 2. Pain control in Phase I for the patient who had surgical treatment for lumbar disc herniation should include:

A. Narcotic medication
B. Sleep
C. Repeated injection
D. Meditation

QUESTION 3. Squat jumps should first be incorporated into the postop protocol after surgical treatment for lumbar disc herniation in phase:

A. Phase I
B. Phase II
C. Phase III
D. Phase IV

QUESTION 4. Which milestone is important to advance to phase IV?

A. Discontinuation of narcotic pain medication
B. Complete resolution of pain
C. Return to within 10% of preinjury strength
D. The ability to do a plank exercise

QUESTION 5. Which of the following are essential for prevention of injury?

A. Proper spinal mechanics during exercise and sport
B. Return of core strengthening
C. Appropriate lower extremity strength and flexibility
D. All of the above

Answer Key

QUESTION 1. Correct answer: **A** (see Surgical Technique)

QUESTION 2. Correct answer: **A** (see Phase I)

QUESTION 3. Correct answer: **C** (see Phase III)

QUESTION 4. Correct answer: **B** (see Phase III)

QUESTION 5. Correct answer: **D** (see Phase VI)

BEYOND BASIC REHABILITATION: RETURN TO GOLF AFTER LUMBAR DISC HERNIATION

S. Josh Bell, MD, Stephanie Niño, PT, OCS, FAAOMPT, and Cheryl Obregon, PT, DPT, FAAOMPT

Introduction

ASPECTS OF GOLF THAT REQUIRE SPECIAL ATTENTION IN REHABILITATION

- Ensure adequate mobility throughout the kinetic chain (shoulders, hips, thoracic spine, etc.) to reduce load on lumbar spine.
- Hip strength including rotation and abductors.
- Proper spine mechanics throughout the swing.
- Lumbar disc herniation and lumbar strains are very common in golf.
- Surgery is relatively uncommon for golfers when compared to the number of injuries for this condition.
- Lumbar pain after strain, disc herniation, or other injury is very common in the athletic and occasional athletic population.
- Because golf requires trunk rotation to generate the golf swing, these injuries are very problematic for this sport. Appropriate treatment requires evaluation and treatment of the entire kinetic chain.

Advanced Rehabilitation Program

Week 0 to 12

- Follow protocols for postoperative rehabilitation of lumbar disc herniation (see timeline in the Nonoperative Rehabilitation part of this chapter).

Week 12 to 18

- Stretching/flexibility program (all static holds for 1 minute, 3 reps):
  - Half-kneeling hip flexor stretch
  - Child pose (heel to buttocks) to stretch paraspinals
  - Supine hamstring stretches (Figure 19-33)
  - Supine piriformis figure-of-4 stretch (Figure 19-34)
  - Seated torso rotation
  - Seated torso rotation with club (Figure 19-35)
- Strengthening program to include: (10 to 15 reps, 2 to 3 sets)
  - External obliques and transverse abdominals:
    - PNF Standing diagonal, upper extremity with resistive bands or cables (Figure 19-36)
  - Seated resisted torso rotation with golf club
  - Resistive shoulder flies and reverse flies (Figure 19-37)
  - Standard and side planks (begin with 30 seconds, progress to 1 minute)
  - Bird dog (quadruped position with opposite arm and leg off the ground)

FIGURE 19-33. Supine hamstring stretch.

FIGURE 19-34. Piriformis figure-of-4 stretch.

FIGURE 19-35. Seated torso rotation with club.

FIGURE 19-37. Resistive reverse flies, standing.

- Hip abductors:
  - Standing hip abduction with resistive bands
  - Lateral squat stepping with resistive tubing
- Periscapular: (low weight, 3 to 5 minutes)
  - Postural exercise with cervical neutral and scapular retraction (Figure 19-38)
  - Unilateral resisted scapular retraction
- Balance exercise to include:
  - Squats on foam (10 reps, 2 sets)
  - Single-leg stance with and without foam (goal of 1 minute)

Week 18 to 24

- Stretching program to include (all static holds for 1 minute, 3 reps):
  - Half-kneeling hip flexor stretch
  - Child pose (heel to buttocks) to stretch paraspinals
  - Supine hamstring stretches
  - Supine piriformis figure-of-4 stretch
  - Seated torso rotation
  - Seated torso rotation with club
- Strengthening program to include: (10 to 15 reps, 2 to 3 sets)
  - External obliques and transverse abdominals:
    - Seated resisted torso rotation with golf club (Figure 19-39)
    - Resistive shoulder flies and reverse flies on foam
    - Side planks with resisted able pulling
    - Bird dog on foam rolls
  - Hip abductors/rotators:
    - Standing hip rotation on stool with resistance (Figure 19-40)
    - Sideboard in hip hinge position with stick

FIGURE 19-36. Standing diagonal pulley upper extremity resistance with proper spine mechanics.

FIGURE 19-38. Postural exercise with neutral cervical alignment and scapular retraction.

FIGURE 19-39. Seated resisted torso rotation with club.

- Periscapular:
  - Resisted backswings
  - Resisted downswings
  - Resisted through-swings
- Balance exercise to include:
  - Standing on rocker board with golf swing (until patient fatigues)
  - Single-leg stance with resistance bands (Figure 19-41) (start with 10 reps each direction)

Sports Performance Testing

General History

- Previous injury history
- Length of time symptoms have been present

Subjective Questionnaires

- Oswestry disability index (ODI)
- Visual analog scale (VAS)

FIGURE 19-40. Standing hip rotation on stool with resistance.

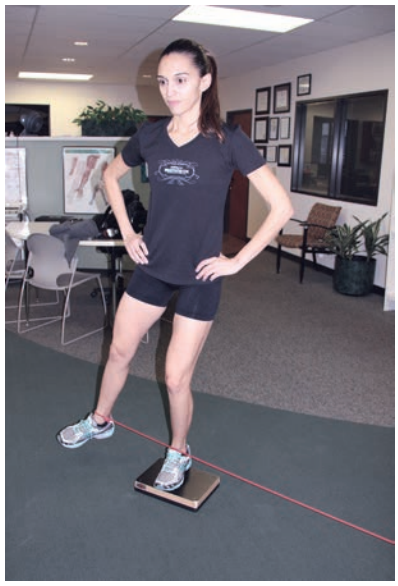

FIGURE 19-41. Single-leg stance exercise with resistance bands.

Medical History

- Other chronic medical conditions
- Previous medical treatment

Sports Injury History

- How has this injury affected performance?
- How long have you trained/performed with this injury?

Surgical History

- Any previous surgery involving the present problem
- Other orthopedic or neurological treatment
- Previous injection history and response to injection

Chronic Conditions/Medication

- Current medications?
- Currently on narcotic medications?
- Do current activities require any medication for function?

Specific Tests

- ODI is used throughout the rehabilitation to assess progress to therapy and ability to advance to the next phase of rehabilitation
- Strength testing (side to side comparison) using manual muscle testing or isokinetic testing
- Single leg activities are used to advance the athlete, such as the Y excursion test
  - Static/dynamic postural assessments
  - Observation of technique during rehabilitation activities to ensure proper form
  - Use of pain-free swings: has athlete progressed back to full swings without pain?

Specific Criteria for Progression to the Next Stage to Determine Readiness for Golf

- Progression and mastery of core and lower extremity strengthening
- Reduction in measured ODI
- Improved performance on stability exercises (e.g., rocker board)

Specific Criteria for Release to Unsupervised Complete Participation in Golf

- Pain-free full swing with proper spine mechanics

Recommended Ongoing Exercises

- Core strengthening including abdominal, lumbar extension, and lower body strengthening should be continued indefinitely.
- Stability and balance exercises, rocker board, and balance ball should be continued.
- Lower extremity and spinal flexibility should be continued indefinitely.

Evidence

Danielson JM, Johnsen R, Kibsgaard SK, et al: Early aggressive exercise for postoperative rehabilitation after discectomy. *Spine* 25:1015–1020, 2000.

This is a randomized controlled trial comparing a training group and a mild exercise group postoperatively. Vigorous medical exercise started 4 weeks after surgery reduced disability and pain after surgery. (Level I evidence).

McGregor AH, Dore CJ, Morris TP, et al: Function after spinal treatment, exercise, and rehabilitation (FASTER). *Spine* 36: 1711–1720, 2011.

This multicenter, factorial, randomized controlled trial on the postoperative management of spinal surgery patients. Found no difference at 12 months ODI for usual care versus rehabilitation versus rehabilitation with educational booklet and booklet only. (Level I evidence).

Ostelo RW, Costa LO, Maher CG, et al: Rehabilitation after lumbar disc surgery: An update Cochrane review. *Spine* 34: 1839–1848, 2009.

Ostelo RW, de Vet HC, Waddell G, et al: Rehabilitation following first-time lumbar disc surgery; a systematic review within the framework of the Cochrane collaboration. *Spine* 28:209–218, 2003.

This systematic review of randomized controlled trials evaluated the protocol for postoperative rehabilitation after first time lumbar surgery. No evidence for restriction of activities immediately after surgery was found and strong evidence for intensive exercise. (Level I evidence).

Weber H: Lumbar disc herniation: A controlled, prospective study with ten years of observation. *Spine* 8:131–140, 1983.

This prospective study of patients with surgical and nonsurgical treatment for lumbar disc herniation showed improved outcomes in the surgical group at 1 year and no statistical difference at 4- and 10-year follow-up. (Level II evidence).

Weinstein JN, Tosteson TD, Lurie JD, et al: Surgical versus nonoperative treatment for lumbar disk herniation: The spine patient outcomes research trial (SPORT), A randomized trial. *JAMA* 296:2441–2450, 2006.

This prospective, randomized study of operative and nonoperative treatment for lumbar disk herniation found better outcomes in surgical patients but the primary differences in the study were not statistically significant. There were large crossovers in the study confounding some conclusions. (Level I evidence).

Multiple-Choice Questions

QUESTION 1. Specific considerations for return to sport for golf activities after lumbar disc herniations include all of these, except:

A. Ensure adequate mobility throughout the kinetic chain (shoulders, hips, thoracic spine, etc.) to reduce load on lumbar spine
B. Hip strength including rotation and abductors
C. Proper spine mechanics throughout the swing
D. Adequate wrist/grip strength for the swing

QUESTION 2. Sport-specific exercises after lumbar disc herniation begin at what interval after surgery?

A. 8 weeks
B. 4 weeks
C. 12 weeks
D. 16 weeks

QUESTION 3. Criteria to return the golfer to full sports activities without supervision include:

A. Pain-free full golf swing with proper spine mechanics
B. Single-leg jump equivalent on both sides
C. Discontinuation of pain medication
D. Upper body strength returned to preinjury level

QUESTION 4. Sport-specific exercises/rehabilitation protocols can start as early as __ weeks after surgery/injury.

A. 2 weeks
B. 18 weeks
C. 4 weeks
D. 12 weeks

QUESTION 5. The proper interval for static stretches in the progress back to sport is:

A. 3 minute stretch for 2 repetitions
B. 30 second stretch for 5 repetitions
C. 1 minute stretch for 3 repetitions
D. 30 second stretch for 3 repetitions

Answer Key

QUESTION 1. Correct answer: **D** (see Introduction)

QUESTION 2. Correct answer: **C** (see Advanced Rehabilitation)

QUESTION 3. Correct answer: **A** (see Specific Tests)

QUESTION 4. Correct answer: **D** (see Introduction)

QUESTION 5. Correct answer: **C** (see Introduction)

Chapter 20

Spondylolysis

INTRODUCTION

Gregg Ziemke, PT, MS, MHA, OCS, Stewart M. Kerr, MD, Leslie C. Hair, PT, DSc, OCS, FAAOMPT, and Charles E. Rainey, PT, DSc, DPT, OCS, SCS, CSCS, FAAOMPT

Epidemiology

Age

- One study reported that children comprise as many as 47% of those who report to a clinic with back pain.
- More common in adolescent athletes, with rates listed from 8% to 15%.
- Age range is from ages 6 to 16, with an increasing incidence that levels off at age 16. Most report it most common during the "school-age years." A child's spine is fully developed at ages 8 to 10 years.
- There is a 2.6% to 4% incidence of spondylolysis in a pediatric population; 5.3% in a population of children with osteogenisis imperfecta (OI).
- Most often in children between 5 and 10 years old.
- Computed tomography is currently considered the most accurate imaging modality for identifying spondylolysis, and it often reveals the presence of nondisplaced spondylolysis.
- Of 855 patients undergoing abdominal computed tomography in Korea, 9% had spondylolysis, males affected more than females.
- The prevalence of a defect in the pars interarticularis is approximately 5% in the general population in the United States.

Gender

- More common in males; some reports indicating a male to female ratio as high as 3:1. In the general population is found to be 3% to 6%.

Sport

- Gymnastics, dance, soccer, football, wrestling, crew, weightlifting, and baseball (batting and weight of bat)

Position

- Football linemen, volleyball servers

Pathophysiology

Intrinsic Factors

- Spondylolysis is an osseous (bone) defect of the pars interarticularis.
- The cause of spondylolysis is not clearly defined. Most specialists believe it is caused by a genetic weakness of the pars interarticularis or results from chronic low-grade trauma, or, less often, acute trauma (Figure 20-1).
- Some list that the developmental process that goes on in the pars predisposes it to stress fracture. Repetitive loading causes fatigue fractures, or a traumatic event may cause a traumatic fracture.
- Increased lumbar lordosis may be a predisposing factor to spondylolysis. One study determined college football players with increased lumbar lordosis were not at increased risk for shortening their career.
- This lesion is most often seen in the adolescent lumbar spine. Adolescents involved in sports have a higher prevalence of spondylolysis than those who are not involved in sports.
- The sports with the highest prevalence of spondylolysis are gymnastics and dance. A common mechanism of injury in these sports is lumbar hyperextension (see Figure 20-23*A* to *D* later in this chapter).
- This condition is often asymptomatic.
- The neural arch is found to increase in strength as we get older. Full ossification is not complete until age 25.
- There may be less cortical bone in the neural arch in general in the adolescent age group, especially in those who have had a fracture.

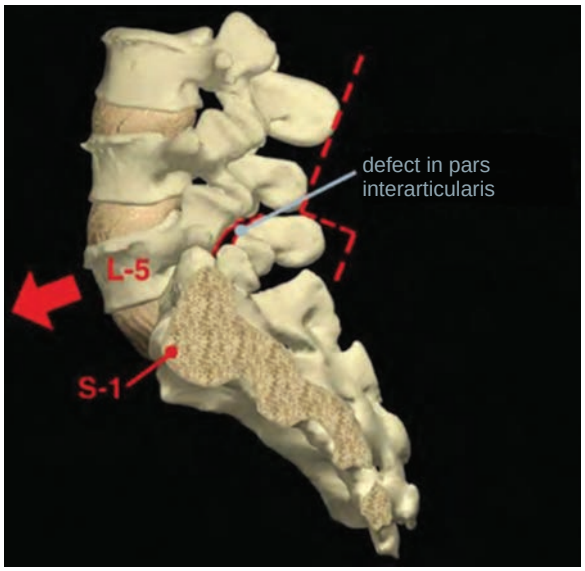

FIGURE 20-1. Spondylolysis. *(From Nau E, Hanney WJ, Kolber MJ: Spinal conditioning for athletes with lumbar spondylolysis and spondylolisthesis. Strength Conditioning J 30:43-52, 2008.)*

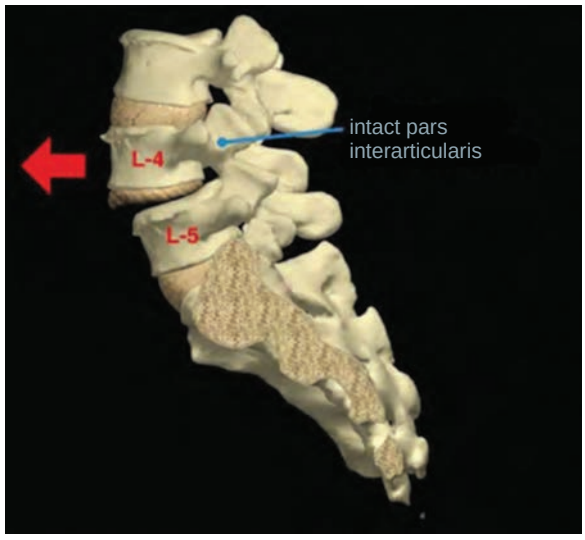

FIGURE 20-2. Spondylolisthesis. *(From Nau E, Hanney WJ, Kolber MJ: Spinal conditioning for athletes with lumbar spondylolysis and spondylolisthesis. Strength Conditioning J 30:43-52, 2008.)*

- Consider the biomechanics of lower lumbar spine; the position of facets is more horizontal, causing forces on the neural arch.
- Most common in forced lumbar extension activity accompanied by lumbar rotation, along with continued flexion to extension.
- May be a relationship between hamstring tightness and amount of lumbar lordosis; spinal active range of motion (AROM).
- Relationship between pars defect and spina bifida occulta.
- May be higher in children with osteogenisis imperfecta.
- May be related to endocrine abnormality.
- Multifidi muscle attaches to the mammillary process and helps to stabilize the vertebral joints. It spans from the sacrum to the cervical spine, endowing stability to each segmental level. The mammillary process is not fully developed until age 25.
- Spondylolisthesis is a forward slippage of one vertebra on another (Figure 20-2), often a result of degenerative changes and/or a vertebral defect.
- Not everyone who has spondylolysis will develop spondylolisthesis; if it does develop, it usually occurs in the 5th lumbar vertebra (85% to 95%) but can involve the 4th vertebra (5% to 15%).
- Initial treatment is always nonsurgical unless traumatic and compromise of the spinal cord is a concern.

Extrinsic Factors

- Cleated sports: traumatic or chronic force
- Baseball: size of bat
- Gymnastics: landing surface
- Football: field conditions
- Wrestling: surface

Traumatic Factors

- Some disagreement, but most seem to agree that spondylolysis is a fatigue/overuse fracture resulting from repetitive motion.
- Most common in forced lumbar extension activity accompanied with lumbar rotation, e.g., gymnastics, dancing and cheerleading.
- Also in football linemen from two- and three-point stance; weightlifting during squatting and supine leg press.
- Volleyball serving
- Wrestling holds

Classic Pathological Findings

- Fracture at pars
- No spondylolisthesis

Clinical Presentation

History

- Pain increases with increased activity; little pain at rest
- Difficult or painful lumbar extension
- May or may not have radiating pain

Physical Examination

Abnormal Findings

- Positive stork test (Figure 20-3)
- Increased lumbar lordosis
- Positive stork test (Figure 20-3)
- Positive stork test (Figure 20-3)
- Tender to palpation at level of pars fracture
- Positive neurological findings generally not found

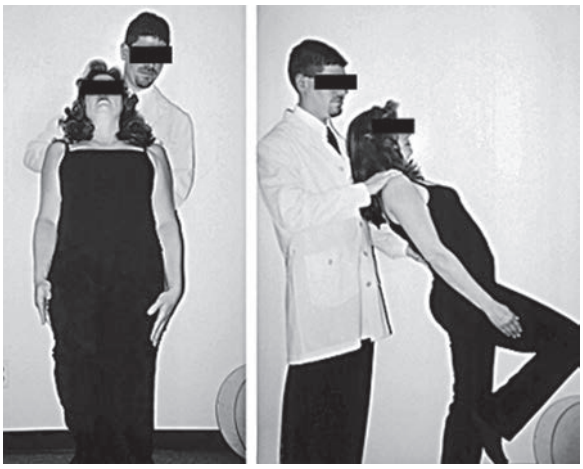

FIGURE 20-3. To assess localized spondylolysis pain, a single-leg hyperextension stork test is performed. The patient stands on one leg and hyperextends and rotates the spine. Reproduction of the patient's pain complaint indicates a diagnosis of spondylolysis until proved otherwise.

Pertinent Normal Findings

- Labs
- Normal neurological exam

Imaging

- Scotty dog on plain radiograph (Figure 20-4*A*). Fracture is demonstrated by a black collar on the Scotty dog (Figure 20-4*B*)
- Computerized Tomography (CT) in a normal spine, intact pars interarticularis (Figure 20-4*C*). CT shows a pars defect (Figure 20-4*D*).
- Bone scan stress reaction at pars interarticularis (Figure 20-4*E*, *F*)

Differential Diagnosis

- Generalized muscular low back pain; duration may help (3 weeks)
- Imaging is key, may need to use algorithm of: plain radiographs/CT/single photon emission tomography (SPECT)/magnetic resonance imaging (MRI).
- Significant neurologic findings

Treatment

Nonoperative Management

- Education
- Core stability
- Aqua/pool therapy
- Bracing (varied opinions here)
- Soft tissue mobilization/manipulation
- Strengthen specific muscle groups (abdominal core, lower extremities); lengthen others (hip flexors)

Guidelines for Choosing Between Nonoperative Treatments

- Primary complaint (pain, AROM)
- Lesion (spondylolysis with no spondylolisthesis)
- Unilateral versus bilateral pars defect
- Radiculopathy versus none
- Availability of pool/soft tissue management
- Type of sport

Surgical Indications

- Abnormal neurologic signs
- Severe and/or progressive neurologic deficits
- Failure of conservative care

Aspects of History, Demographics, or Exam Findings that Affect Choice of Treatment

- Neurologic signs
- Failed treatment over course of one year
- Patients' desires, schedule, and time frame

Aspects of Clinical Decision Making When Surgery is Indicated

- Failed course of conservative care (6 to 12 months)
- Severe and/or progressive neurologic deficits
- Patient's desires

Evidence

Bhatia NN, Chow G, Timon SJ, et al: Diagnostic modalities for the evaluation of pediatric back pain: A prospective study. *J Pediatr Orthop* 28:230, 2008.

This prospective study evaluated and discusses the commonly taught idea that pediatric back pain frequently has an underlying diagnosis. This leads clinicians to order numerous tests. This study examined the rate of diagnosis for pediatric back pain and the value of various diagnostic studies for this problem. (Level II evidence).

Chou R, Qaseem A, Snow V, et al: Diagnosis and treatment of low back pain: A joint clinical practice guideline from the American College of Physicians and the American Pain Society. *Ann Inter Med* 147:478–491, 2007.

This review article discusses and lists seven recommendations to assist with the diagnosis and treatment of patients with low back pain. (Level II evidence).

Hatz D, Espositi PW, Schroeder B, et al: The incidence of spondylolysis and spondylolisthesis in children with osteogenesis imperfecta. *J Pediatric Orthop* 31:655–660, 2011.

Hu SS, Tribus CB, Diab M, et al: Spondylolisthesis and spondylolysis. *J Bone Joint Surg Am* 90:656–671, 2008.

This retrospective review of radiographs found that the incidence of spondylolysis and spondylolisthesis in a group of children with osteogenesis imperfecta was much higher than in the normal pediatric population. (Level IV evidence).

Kim HJ, Green DW: Adolescent back pain. *Curr Opin Pediatr* 20:37, 2008.

This review article discusses previous studies that have suggested a correlation between adolescent back pain and adult-onset back pain. It stresses the importance of a systematic

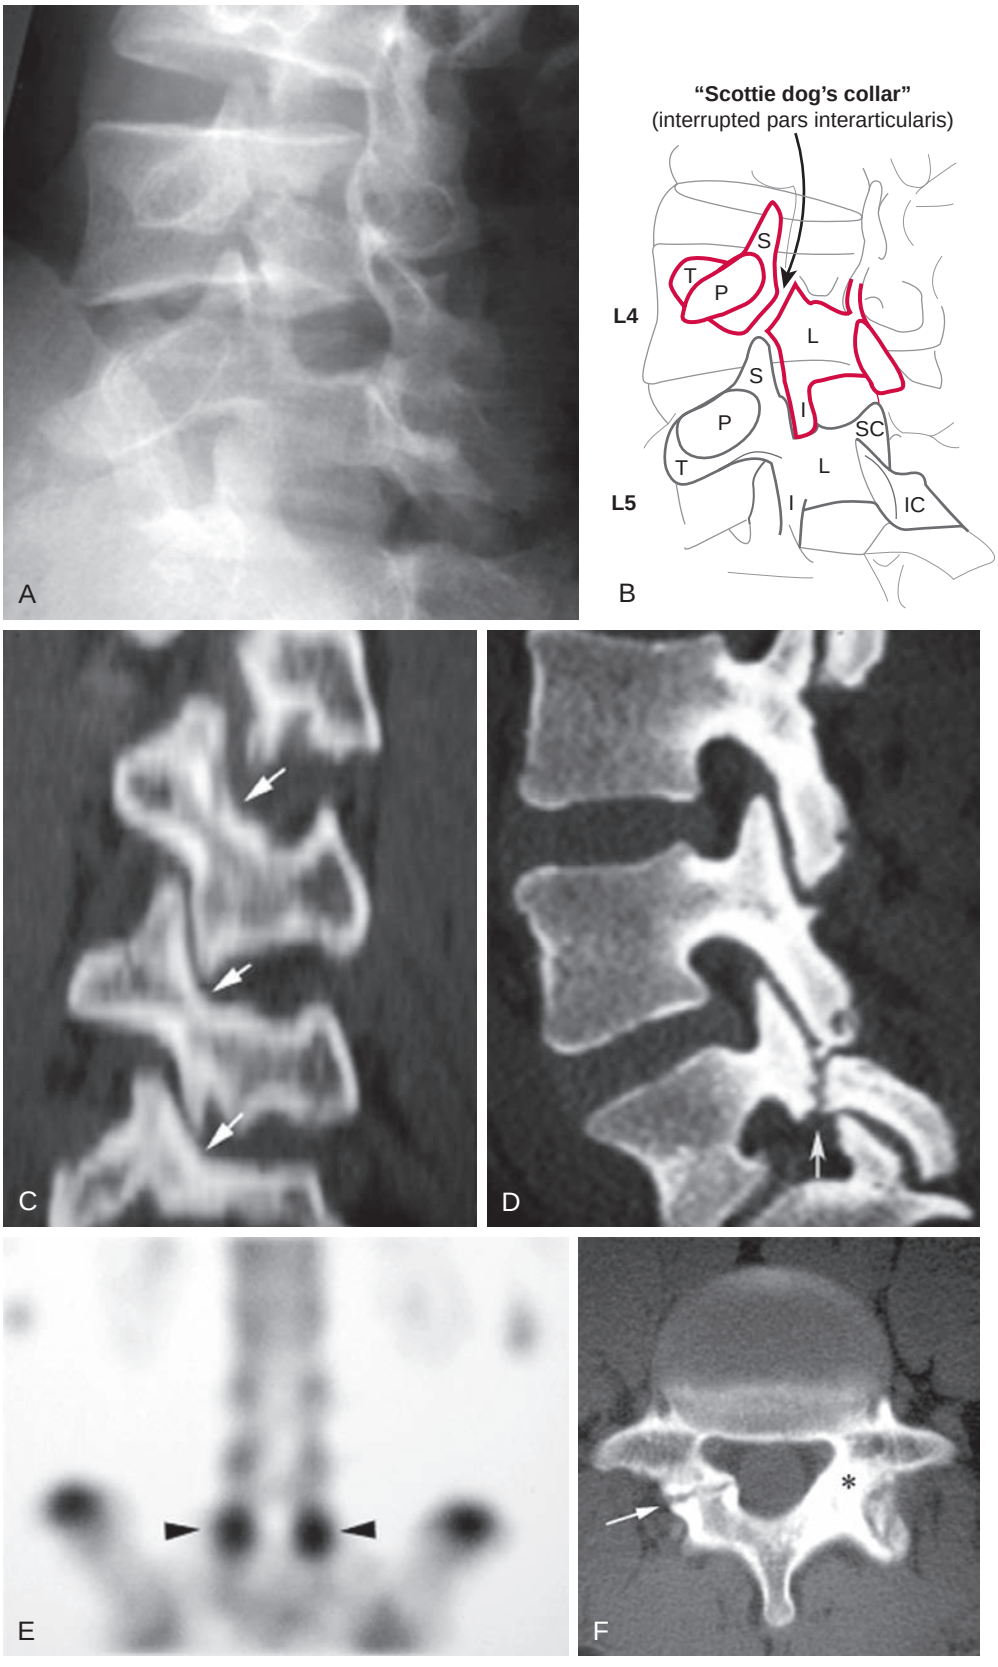

FIGURE 20-4. Spondylolysis. **A** and **B,** Normal and interrupted pars interarticularis. Oblique radiograph (**A**) and corresponding line drawing (**B**) show an intact pars interarticularis at L5 and a pars defect with a collar around the Scottie dog's neck at L4 (arrow in part B). *P*, pedicle (the Scottie dog's eye); *T*, transverse process (nose); *S*, superior articulating facet (ear); *I*, inferior articulating facet (front leg); *L*, lamina (body); *IC*, contralateral inferior articulating facet (rear leg); *SC*, contralateral superior articulating facet (tail). **C,** Oblique sagittal computed tomography (CT) reconstruction in a normal patient. Note the intact pars interarticularis (*arrows*). **D,** Sagittal CT reformat shows a pars defect in L5 (*arrow*). **E,** Radionuclide bone scan of bilateral L5 pars defects. Coronal single-photon emission CT (SPECT) image obtained through the posterior elements shows increased tracer bilaterally at L5 (arrowheads). A CT scan (not shown) was needed to confirm bilateral defects because a unilateral defect with adaptive hypertrophy on the contralateral side could have similar bone scan findings. **F,** Axial CT image of unilateral spondylolysis. Note the spondylolysis on the right (*arrow*). Also note the sclerosis of the contralateral pars interarticularis (*asterisk*). This nonspecific finding may indicate that left-sided adaptive changes caused increased stress because of the right-sided pars defect or an impending left pars stress fracture. *(From Manaster B. Musculoskeletal Imaging: The Requisites. 3rd ed. Philadelphia: Elsevier; 2002.)*

approach to arrive at a clear diagnosis and appropriate treatment for adolescents with low back pain. (Level V evidence).

Ko SB, Lee SW: Prevalence of spondylolysis and its relationship with low back pain in selected population. *Clin Orthop Surg* 3:34–38, 2011.

This retrospective chart review discusses the prevalence of LBP and its association with a patient having a lumbar spondylolysis in a selected population. (Level IIc clinical evidence).

Sairyo K, Sakai T, Yasui N: Conservative treatment of lumbar spondylolysis in childhood and adolescence: The radiological signs which predict healing. *J Bone Joint Surg Br* 91:206, 2009.

This retrospective clinical chart review article suggests a CT /MRI protocol that is a predictor of bony healing of a pars defect in children after conservative treatment. (Level IIIb evidence).

Standaert C, Herring S: Spondylolysis: A critical review. *Br J Sports Med* 34:415–422, 2000.

This review article is from 12 years ago and discusses the natural history, pathophysiology, diagnosis, and treatment of spondylolysis based on the available medical literature at that time. It appears not much has changed. (Level III evidence).

Sys J, Michielsen J, Bracke P, et al: Nonoperative treatment of active spondylolysis in elite athletes with normal X-ray findings: Literature review and results of conservative treatment. *Eur Spine J* 6:498–504, 2001.

This literature review suggests that osseous healing is likely to occur in unilateral spondylolysis although diminishes in bilateral and pseudo-bilateral spondylolysis. Nonunion does not seem to compromise the overall outcome or sports resumption in the short term. (Level III evidence).

Multiple-Choice Questions

QUESTION 1. Spondylolysis is most common in males, with a male/female ratio of:

A. 2:1
B. 3:1
C. 5:1
D. 10:1

QUESTION 2. Spondylolysis occurs most frequently at which spinal level?

A. L2
B. L3
C. L4
D. L5

QUESTION 3. What lumbar motion is predominately painful with a spondylolysis?

A. Flexion
B. Extension
C. Rotation
D. Sidebending

QUESTION 4. A spondylolysis is a fracture demonstrated on a radiograph by what on the Scotty dog?

A. Ears
B. Front legs
C. Rear legs
D. Collar

QUESTION 5. What imaging modality is considered the most accurate for identifying spondylolysis?

A. Radiograph (X-ray)
B. Magnetic resonance imaging (MRI)
C. Computed tomography (CT)
D. Bone scan

Answer Key

QUESTION 1. Correct answer: **B** (see Epidemiology)

QUESTION 2. Correct answer: **D** (see Pathophysiology)

QUESTION 3. Correct answer: **B** (see Clinical Presentation)

QUESTION 4. Correct answer: **D** (see Clinical Presentation)

QUESTION 5. Correct answer: **C** (see Epidemiology)

NONOPERATIVE REHABILITATION OF SPONDYLOLYSIS

Gregg Ziemke, PT, MS, MHA, OCS, Leslie C. Hair, PT, DSc, OCS, FAAOMPT,
Charles E. Rainey, PT, DSc, DPT, OCS, SCS, CSCS, FAAOMPT, and Stewart M. Kerr, MD

GUIDING PRINCIPLES OF NONOPERATIVE REHABILITATION

- Decrease pain with chosen activity; most important is rest until pain is subsiding
- Increase level of function (without pain) in chosen activity
- Return to sport

Phase I (0 to 3 months)

Goals

- Protect the healing segment.
- Minimize the effect of spinal immobilization.
- No signs or symptoms of instability.
- Rest; avoid sports.

Protection

- For nonoperative care, use of spinal bracing as well as the type of bracing is controversial. Our recommendation is soft bracing (corset) or hard bracing (thoracolumbar sacral orthosis) for at least 3 months.
- After 3 months, pain should be the guide.

Management of Pain and Swelling

- Electrotherapy (TENS) may be used if there is pain, spasm, and muscle guarding
- Oral NSAIDs and analgesic pain medication as needed.
- Cryotherapy as needed

Techniques for Progressive Increase in Range of Motion

- Begins immediately after evaluation by a physician.
- This phase should include evaluation, discussion, and planning. Active physical therapy care will begin once pain is subsiding.

Manual Therapy Techniques

- With the patient in a brace, begin gentle mobilization of extremities and hips to maintain AROM of those structures if needed.
- No manual therapy for lumbar and thoracic spine.

Stretching and Flexibility Techniques for the Musculotendinous Unit

- Letting pain be the guide, limit flexibility training to accessory structures of the upper and lower extremities, specifically the shoulders and hips.
- The intent of treatment at this phase is maintenance of accessory structures.

Other Therapeutic Exercises

- Generalized aerobic conditioning may begin if pain-free.
- Continue bracing at all times or as instructed by physician.
- If patient is allowed to remove brace, it is advisable to recommend wearing the brace for exercise for a 3-month period.
- Nonexercise brace wear will coincide with pain level with activity and radiographic evidence of healing.
- Low-level core stability exercises, such as double/single leg bridges, active straight leg raises, and quadruped diagonals (i.e. bird dogs).
- Education; back school

TIMELINE 20-1: **Nonoperative Rehabilitation of Spondylolysis**

PHASE I (0 to 3 months)

- Immobilization for a minimum of 3 months, with up to 12 months being the gold standard
- For the first 3 months, primarily rest and very little formal treatment
- Protect healing segment:
  - Bracing for 3 months
  - After 3 months, pain is guide
- Minimize effect of spinal immobilization using PT modalities: ice, electrotherapy, NSAIDs
- Manual therapy for extremities
- Check for signs or symptoms of instability
- Rest; avoid sports

PHASE II (3 to 6 months)

- Continue as in Phase I
- Discontinue brace
- Minimize effect of spinal immobilization
- Increase spinal AROM
- Manual therapy for spine

Activation of Primary Muscles Involved

- Avoid all high level muscle activation of spinal musculature for at least 3 months.

Sensorimotor Exercises

- These activities are advisable only in the brace and only if they do not cause pain.

Open and Closed Kinetic Chain Exercises

- Avoid open chain activities.
- Closed chain activities to include walking on level surface (no treadmill walking), low-level stationary bike.

Techniques to Increase Muscle Strength, Power, and Endurance

- Maintain upper extremity (UE) and lower extremity (LE) muscle strength, power, and endurance.

Sport-Specific Exercises

- Maintain low-level aerobic fitness.

Milestones for Progression to the Next Phase

- No pain at rest
- Very little to no pain with increased activity
- Outcome measures
  - Patient reported outcome tools should be implemented at the end of each phase. These tools will assist with the decision to advance to the next phase.
  - These outcome measures can also be used more often (monthly) if desired. Tools that have been used in the literature for spinal rehabilitation include the Fear Avoidance Behavior Questionnaire (FABQ) and (modified) Oswestry Disability Questionnaire.

Phase II (3 to 6 months)

Goals

- Protect healing segment.
- Minimize effect of spinal immobilization.
- Discontinue brace.
- Increase spinal AROM.
- Begin with minimal repetitions to assess tolerance for exercise and progress dosage of sets and repetitions as tolerated.

Protection

- Brace wear can be discontinued after 3 months; earlier if cleared by physician. Continue brace with exercise.

Management of Pain and Swelling

- Electrotherapy (TENS) may be used if there is pain, spasm and muscle guarding.
- Oral NSAIDs and analgesic pain medications as needed.
- Cryotherapy as needed.

Techniques for Progressive Increase in Range of Motion

Manual Therapy Techniques

- Precautions: Initially limit AROM only to spinal flexion and extension without rotation. No manual therapy should be applied to healing segment.
- Slowly increase spinal AROM with AP mobilization techniques grades I to II in flexion and extension, with goal of ensuring quality planar motion without rotation in hypomobile segments.
- If no pain with flexion and extension after 1 week of care, begin spinal side-bending and rotation, letting pain be the guide. Mobilization for these motions should also be grades I to II in hypomobile segments.
- Limit increase in motion to 30°/week.
- Grades I to IV segmental mobilization of cervical and thoracic spine may improve overall available spinal AROM and also assist in pain management.
- Initiate spinal mobilization for sacrum/pelvis as indicated by evaluation.

Soft Tissue Techniques

- Begin instrument assisted soft tissue mobilization (IASTM), such as Graston, ASTYM, or other manual soft tissue mobilizations and techniques.

Stretching and Flexibility Techniques for the Musculotendinous Unit

- Continue as in Phase I; ensure upper extremity and lower extremity AROM are within normal limits.

TIMELINE 20-1: **Nonoperative Rehabilitation of Spondylolysis** (Continued)

PHASE III (6 to 9 months)	PHASE IV (9 to 12 months)
• Protect healing segment • Maximize spinal mobility/full spinal mobility • No signs or symptoms of instability • Functional spinal movement mechanics • Increased quality of life and function • Begin sport-specific training	• Full function; ready to return to sport • Continue sport-specific training • No signs or symptoms of instability

- Patients may perform supine upper extremity and lower extremity AROM activities/mat activities to include straight leg raise (SLR) and shoulder AROM in spinal flexion/extension plane.
- Cervical spine AROM activities in all planes are encouraged.
- Check for purity of spinal motion and regard compensatory motion as pain and or segmental blocking. Avoidance or lack of motion at individual segments may prevent increase in overall motion and be the cause of pain.

Other Therapeutic Exercises

- Begin gentle mat activities to include pelvic tilts.
- Lower and upper extremity exercise without resistance may also be added during this phase.
- Lower extremity exercises during this phase may include higher level stationary cycling (slowly add resistance) and treadmill walking.

Activation of Primary Muscles Involved

- Stability plank and four-point unilateral leg and arm lifts, no pain.
  - Patients are reminded to avoid high level spine activities, (i.e., plyometric activity, sport-specific activities in this phase.)

Sensorimotor Exercises

Begin active replication exercises, such as yoga and movement patterns for motor control.

Techniques to Increase Muscle Strength, Power, and Endurance

- Overall strengthening exercise may be initiated to include therapeutic ball exercises.

Neuromuscular Dynamic Stability Exercises

- Lower extremity balance activities such as single leg standing, BOSU ball, star excursion

Functional Exercises

- Begin Phase I spinal core stability exercises, which include:
  - Upper body rolling patterns
  - Lower body rolling patterns
  - Dying bug: patient lying on back with lifting alternate arm and legs while maintaining core stability
  - Quadruped diagonals (i.e., bird dogs)
  - Double/single leg bridges
  - Active straight leg raise

Clinical Pearls

The introduction of Phase II activities/exercises coincides with limiting the use of the spinal brace until it is ultimately eliminated.

- A concerted phased approach to maximize effective rehabilitation must be used. The slow introduction of spine specific exercises is key in that the patient has been immobilized for up to 3 months.
- Techniques to increase spinal AROM include stretching and skilled manual therapy techniques. These are important tools to assist with proper spinal rhythm and restoring proper joint arthrokinematics.
- Often, patients are fearful of moving; this is to be expected. However, proper movement patterns play a large role in pain management.

Sport-Specific Exercises

- Patients may begin low level sport-specific exercises.
- If a training program is being used, a careful review should be initiated to decide which activities are appropriate at this time.
- Activities should not include maximum weightlifting.

Milestones for Progression to the Next Phase

- Spinal AROM is improving with no pain
- Able to walk aerobically without pain to patient tolerance for aerobic conditioning
- Begin walk to run program
  - Begin with 5 minutes of walking and 1 minute of running and continue until reaching a duration of 30 minutes (5 cycles).
  - Repeat twice with a day of rest in between workouts.
  - Progress by reducing walking to 4 minutes and increasing running to 2 minutes.
  - Repeat protocol above until running continuously for 30 minutes.
  - If any symptoms occur, digress to previous stage until symptoms resolve.

Phase III (6 to 9 months)

Goals

- Protect healing segment
- Maximize spinal mobility/full spinal mobility
- No signs or symptoms of instability (determined reassessment by a qualified healthcare provider)
- Functional spinal movement mechanics (quality of movement determined by reassessment by a qualified healthcare provider)
- Increased quality of life and function
- Begin with minimal repetitions to assess tolerance for exercise and progress dosage of sets and repetitions as tolerated
- Sensorimotor/proprioceptive activities are performed for 30 to 60 seconds daily. Repeat 2 to 3 times per week or as needed.

Protection

- Patient is out of the brace

Management of Pain and Swelling

- Oral NSAIDS and analgesic pain medicine should be on the decline or discontinued. May be used as needed.
- Cryotherapy is used posttherapy treatment for postexercise inflammation and soreness

Techniques for Progressive Increase in Range of Motion

Manual Therapy Techniques

- AROM precautions: None.
- Joint mobilizations: If adhesions are noted in lower spine, joint mobilizations may begin to be more aggressive, no thrust activities. Use oscillatory techniques grades II to IV. Care must be taken when assessing structures.
- Continued evaluation of all joint structures for maintenance and increasing level of function.

Soft Tissue Techniques

- We recommend continuing IASTM treatments over the course of this phase.
- Soft tissue techniques can include Graston, ASTYM, manual soft tissue mobilization or deep tissue massage.

Stretching and Flexibility Techniques for the Musculotendinous Unit

- Continue to maintain flexibility of upper extremity and lower extremity structures special attention to hip flexors and hamstrings
- Increase spinal AROM

Other Therapeutic Exercises

- Lower body strengthening is progressed and may include closed kinetic chain exercises (i.e., lunges, tubing resistance hip flex/extension/abduction, wall sits, body weight squats) and open chain resistance exercises.
- Treadmill walking and stationary biking with increased resistance.
- Add upper body ergometer (UBE) within pain free ranges without resistance. Performing the UBE in a standing position, if possible, provides an integrated conditioning exercise involving the trunk and hip girdle musculature.

Activation of Primary Muscles Involved

- Plank exercise with timed activities
- Four-point leg and arm exercises to progress to alternating arm/leg activities, again paying attention to quality versus quantity of motion.
- Stability ball: all activities on mat can advance to stability ball
- Wall squats
- Upper extremity and lower extremity strengthening with light resistance may begin.

Sensorimotor/Proprioceptive Exercises

- The Bodyblade is an effective tool to incorporate at this phase.
- Balance Master, proprioceptive neuromuscular facilitation (PNF) patterns (tall/half kneeling chops and lifts).
- Increase functional movement exercises.
- In addition, purity of motion will flow into sport-specific activities to restore successful movement patterns common to the athlete's sport of choice. This may be as simple as discussing these activities with your athlete.
- Successful movement patterns as this level will prepare the patient for more difficult functional patterns to be performed later as the treatment progresses. PNF patterns may be a way to integrate higher levels of sensory motor activities.

Clinical Pearl

> A key component to successful spinal rehabilitation is patient education for proper positioning during exercise; constant cueing is essential to maintain the purity of the designed activity.

Open and Closed Kinetic Chain Exercises

- Pool or aqua therapy is an effective method to get open chain activity and maximize training.
- Closed chain activities can include seated medicine ball flexion/extension and rotation progressing to standing medicine ball training.

Techniques to Increase Muscle Strength, Power, and Endurance

- Progress to all muscle groups as tolerated first in sitting, then in standing.
- Progress to lower extremity strength training exercises.
- Progress to elliptical and stair stepper for cardiovascular conditioning.

Neuromuscular Dynamic Stability Exercises

- Progress manual rhythmic stabilization drills for spine and advance to varying degrees of spinal motion as pain and ability allows.
- Performing these exercises in sitting first then standing will increase core recruitment.

Sport-Specific Exercises

- Can begin more sports specific training here. All should be performed without pain.

Milestones for Progression to the Next Phase

- No pain with activities
- Increased endurance
- Early participation in chosen sport activity/no competition

Phase IV (9 to 12 months)

Goals

- Full function; ready to return to sport
- Continue sports-specific training

- No signs or symptoms of instability
- Begin with minimal repetitions to assess tolerance for exercise and progress dosage of sets and repetitions as tolerated.

Management of Pain and Swelling

- Should be off all medication at this phase.
- Postexercise cryotherapy if needed.

Techniques for Progressive Increase in Range of Motion

Manual Therapy Techniques

- Should not need any hands-on treatment except for short-term care because patient has an acute condition that will respond to manual therapy/manipulation.

Soft Tissue Techniques

- Should not need any hands-on treatment except for short-term care.

Stretching and Flexibility Techniques for the Musculotendinous Unit

- Continue to maintain flexibility of all structures.
- At this phase, stretching is an important part of a sport-specific workout.

Other Therapeutic Exercises

- Continue and increase difficulty of Phase III exercises.

Activation of Primary Muscles Involved

- Continue with Phase III exercises.

Sensorimotor/Proprioceptive Exercises

- Continue Bodyblade
- Balance Master
- Side thrusts high speed crossover training
- Increase functional movement exercises

CLINICAL PEARL

A continuous increase in difficulty should be part of the treatment plan. At some point, it is more of a personal training session than a therapy session. When that becomes the case, the patient should be considered for a home self-paced program.

Open and Closed Kinetic Chain Exercises

- Continue with pool or aqua therapy
- Continue with high level closed chain activities.

Techniques to Increase Muscle Strength, Power, and Endurance

- Continue with increasing intensity

Neuromuscular Dynamic Stability Exercises

- Progress Phase III exercises

Plyometrics

- Continue progression of Phase III exercises

Milestones for Progression to Advanced Sport-Specific Training and Conditioning

- Sport specific training with team/coach
- No contact/competition until cleared by physician

Tips and Guidelines for Transitioning to Performance Enhancement

Once fundamental movement patterns are reestablished with no compensation observed with bodyweight, the athlete can progress to performance enhancement, as evaluated by a qualified rehabilitation heath care provider.

Performance Enhancement and Beyond Rehabilitation: Training/Trainer and Optimization of Athletic Performance

See Beyond Basic Rehabilitation: Return to Gymnastics after Surgical Repair of Spondylolysis later in this book.

Specific Criteria for Return to Sports Participation: Tests and Measurements

- The rehabilitation specialist should be able to analyze the demands on the spinal complex and create a sufficient series of tests and exercises to ensure readiness for return to preinjury levels of activity.
- Meets the demand/need for the chosen sport without symptoms.

After Return to Sport

- Continuing fitness or rehabilitation exercises including total body strengthening and fitness exercises.
- Exercises and other techniques for prevention of recurrent injury.

Evidence

Chou R, Qaseem A, Snow V, et al: Diagnosis and treatment of low back pain: A joint clinical practice guideline from the American College of Physicians and the American Pain Society. *Ann Inter Med* 147:478–491, 2007.

This review article discusses and lists seven recommendations to assist with the diagnosis and treatment of patients with low back pain. (Level II evidence).

Hu SS, Tribus CB, Diab M, et al: Spondylolisthesis and spondylolysis. *J Bone Joint Surg Am* 90:656–671, 2008.

This article reviews surgical and nonsurgical indications of spondylolisthesis and spondylolysis, and states that more than 80% of children treated nonsurgically have resolution of symptoms. The article stated that for patients requiring surgical treatment, fusion in situ may provide adequate treatment for young patients. (Level IV evidence).

Loghmani MT, Warden SJ: Instrument-assisted cross-fiber massage accelerates knee ligament healing. *J Orthop Sports Phys Ther* 39:506–514, 2009.

This article reviews the kinematics and lumbar compressive forces that occur when using the Bodyblade, a popular tool in physical medicine clinics. (Level III evidence).

Looney B, Srokose T, Fernández-de-las-Peñas C, et al: Graston instrument soft tissue mobilization and home stretching for the management of plantar heel pain: a case series. *J Manipulative Physiol Ther* 138–142, 2011.

This article reviews the outcome of a set of patients with plantar fasciitis treated with Graston instrument soft tissue mobilization techniques (GT) and a home stretching program. This article showed a clinically meaningful improvement (Level IV evidence).

Moreside JM, Vera-Garcia FJ, McGill SM: Trunk muscle activation patterns, lumbar compressive forces, and spine stability when using the Bodyblade. *Phys Ther* 87:153–163, 2007.

The article reviews to investigate the effects of instrument-assisted cross-fiber massage (IACFM) on tissue-level healing of knee medial collateral ligament (MCL) injuries. The article states that IACFM-accelerated ligament healing, possibly via favorable effects on collagen formation and organization, but had minimal effect on the final outcome of healing. (Level IV evidence).

Multiple-Choice Questions

QUESTION 1. The goals of Phase I rehabilitation include all but:

A. Protect healing segment.
B. Minimize effect of spinal immobilization
C. No signs or symptoms of instability
D. Return to sports

QUESTION 2. What are appropriate interventions for Phase III rehabilitation?

A. Manual therapy
B. Stretching exercises
C. Begin return to sport activity
D. All the above

QUESTION 3. What is the appropriate phase to discontinue full-time brace wear?

A. Phase I
B. Phase II
C. Phase III
D. Phase IV

QUESTION 4. During which phase is the slow introduction of spine-specific exercise key?

A. Phase I
B. Phase II
C. Phase III
D. Phase IV

QUESTION 5. What is not a criterion for progression of the patient to the next phase?

A. Increased AROM without pain
B. Able to perform sport-specific motion without pain
C. Able to tolerate improved activity without pain
D. Contact sports without physician clearance

Answer Key

QUESTION 1. Correct answer: **D** (see Phase I)

QUESTION 2. Correct answer: **D** (see Phase III)

QUESTION 3. Correct answer: **B** (see Phase II)

QUESTION 4. Correct answer: **B** (see Phase II, Clinical Pearl)

QUESTION 5. Correct answer: **D** (see Phases I to IV)

POSTOPERATIVE REHABILITATION AFTER REPAIR OF SPONDYLOLYSIS

Charles E. Rainey, PT, DSc, DPT, OCS, SCS, CSCS, FAAOMPT, Stewart M. Kerr, MD, Gregg Ziemke, PT, MS, MHA, OCS, and Leslie C. Hair, PT, DSc, OCS, FAAOMPT

Indications for Surgical Treatment

- Severe, refractory lumbosacral pain that has not responded in 6 to 9 months to nonoperative management.
- Imaging (i.e., SPECT and/or MRI) should also be active/positive at the pars defect. The SPECT study is used most commonly and typically is most helpful for localizing a pars defect.

Brief Summary of Surgical Treatment

Major Surgical Steps

- Exposure of defect
- Debridement of sclerotic/fibrous healing response to healthy bleeding bone at the pars
- Use of iliac crest autograft
- Consideration for stabilization/instrumentation for increased bone fusion
- Postoperative lumbosacral bracing
- The single lag screw fixation (Buck) approach has been widely studied in both athletes and nonathletes. Published outcomes have shown that >90% of patients return to their preoperative sports performance.

Factors That May Affect Rehabilitation

Anesthetic

- A general anesthetic is required for any surgical repair.

Presurgical

- Flexion and extension radiographs (A-P and lateral) are taken to observe the degree of vertebrate slippage or abnormal motion (Figure 20-5*A*, *B*)
- An MRI is performed to evaluate the disc, ruling out other various soft tissue causes of pain.

Surgical (Figure 20-6*A* to *F*)

- A lumbar spine standard midline approach is used, preserving the multifidus muscle attachments to the L4-S1 facet joints (keeping the interspinous and supraspinous ligaments intact).
- The pars defect and lamina bilaterally is exposed with the fascial tissue removed.
- Using a 3 cm window, cancellous bone is harvested from the iliac crest.
- The cephalad vertebra's inferior facet joints are resected 3 to 5 mm to decrease the likelihood of impingement occurring in the pars region during spine loading or standing postures (especially hyperextension).
- The lamina's inferior edge is squared off using a bar.
- A drill is used at this edge upward, forward, and slightly outward, passing through the pars and across the pars defect (creating a tunnel within the bone).
- A correct length screw is placed within this bone tunnel.
- The screw is partially withdrawn and the harvested cancellous bone from the iliac crest is placed in the pars defect.
- Screws are readvanced the pars defect stabilizing the bone graft.
- Instrumented arthrodesis alone results in acceptable outcomes for those with spondylolisthesis.

Postsurgical

- Plain radiographs for asymptomatic patients and CT or MR imaging studies only if symptoms persist or new symptoms appear. Surgical outcomes of those achieving bone healing and fibrous union remain similar.
- Lumbosacral bracing. This helps avoid the pathophysiology of spondylolysis which includes repetitive/mechanical flexion, extension and trunk rotation.

Before Surgery: Overview of Goals, Milestones, and Guidelines[1]

GUIDING PRINCIPLES OF POSTOPERATIVE REHABILITATION

- Understand type of surgical repair performed.
- Understanding of the anatomic structures and their rate of healing.
- Understand positions and activities that stress the healing structure.
- Proper selection of manual therapy and exercise interventions applied at the appropriate phase of healing.

[1]*Prehabilitation, if appropriate, is described in the Nonoperative Rehabilitation section of this chapter.*

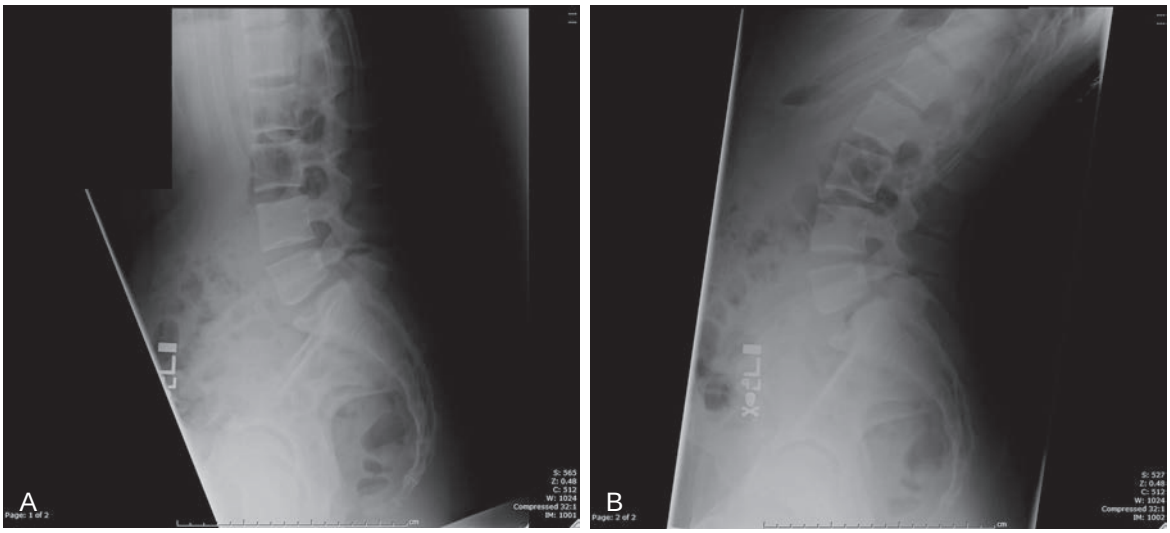

FIGURE 20-5. Spinal radiographs. **A,** Lateral view in flexion. **B,** Lateral view in extension.

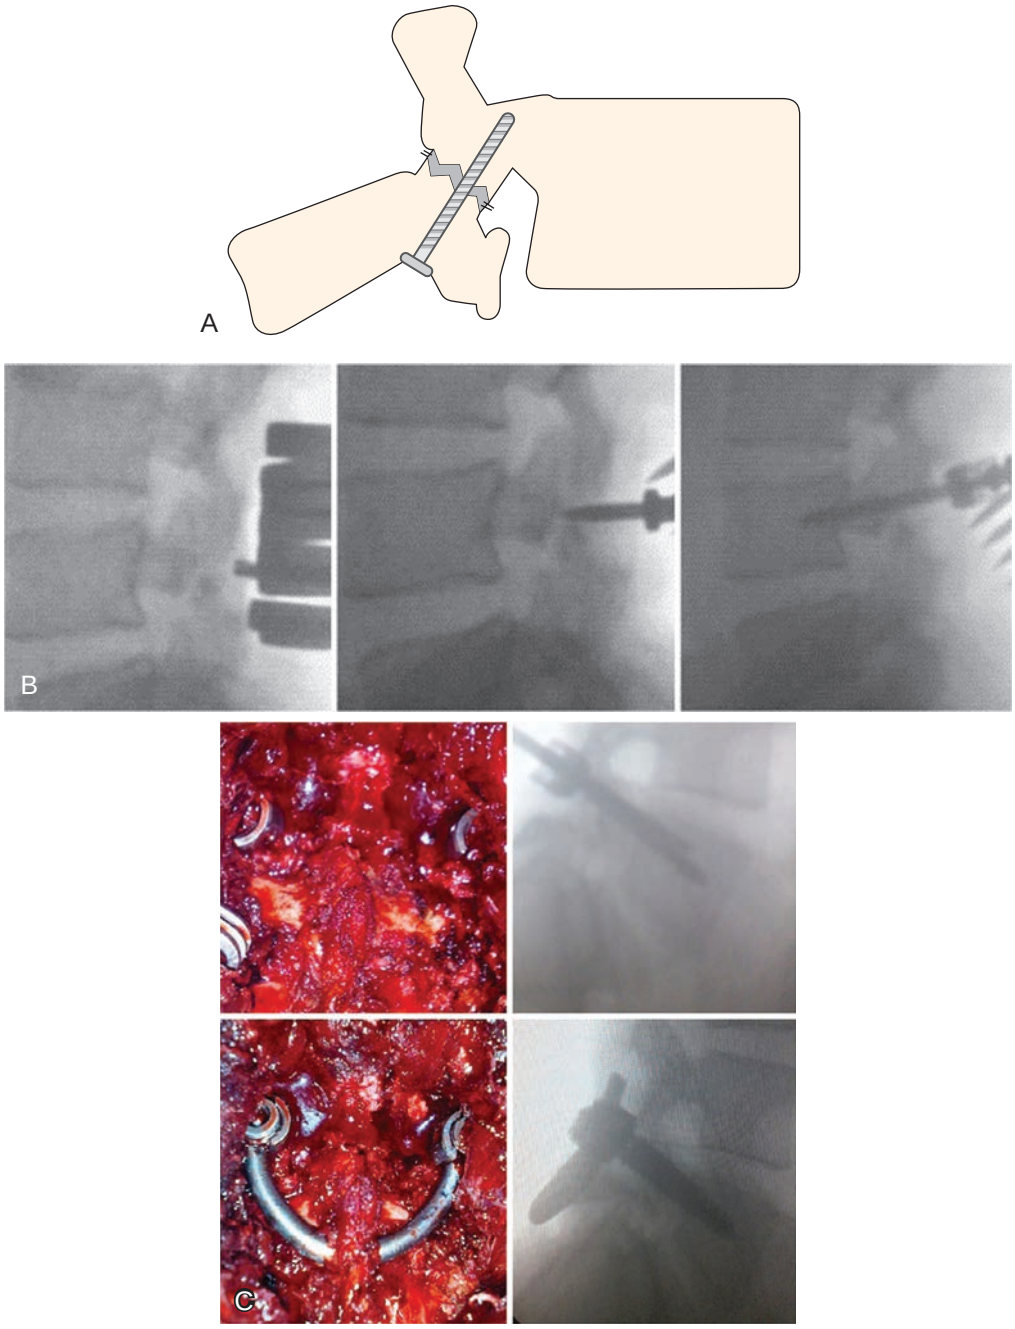

FIGURE 20-6. A, Single lag screw fixation as described by JE Buck in 1970. *(Redrawn from Drazin D, Shirzadi A, Jeswani S, et al: Direct surgical repair of spondylolysis in athletes: Indications, techniques, and outcomes. Neurosurg Focus 31(5):1-12, 2011.)* **B,** Intraoperative fluoroscopic images of the steps for a percutaneous technique of radiological guidance for screw insertion, without violating the facet joint. **C,** Intraoperative view of the construct (left) and lateral fluoroscopic images depicting screws insertion into the L4 pedicles (right).

Phase I Immediate Postoperative Period (days 0 to 7)

Goals

- Protect the surgical site to promote wound healing
- Decrease pain and inflammation
- Establish good body mechanics for safe, independent self-care and activities of daily living (ADLs) such as donning/doffing clothing, transfers, and gait.
- Educate on proper bed mobility and positioning

Protection

- Soft bracing (corset) or hard bracing (thoracolumbosacral orthosis [TLSO]) is optional per surgeon. Should never be required, but may be worn for comfort.
- Good body mechanics to promote patient comfort and proper positioning to prevent stress to the healing posterior structures (see body mechanics/positioning section below).

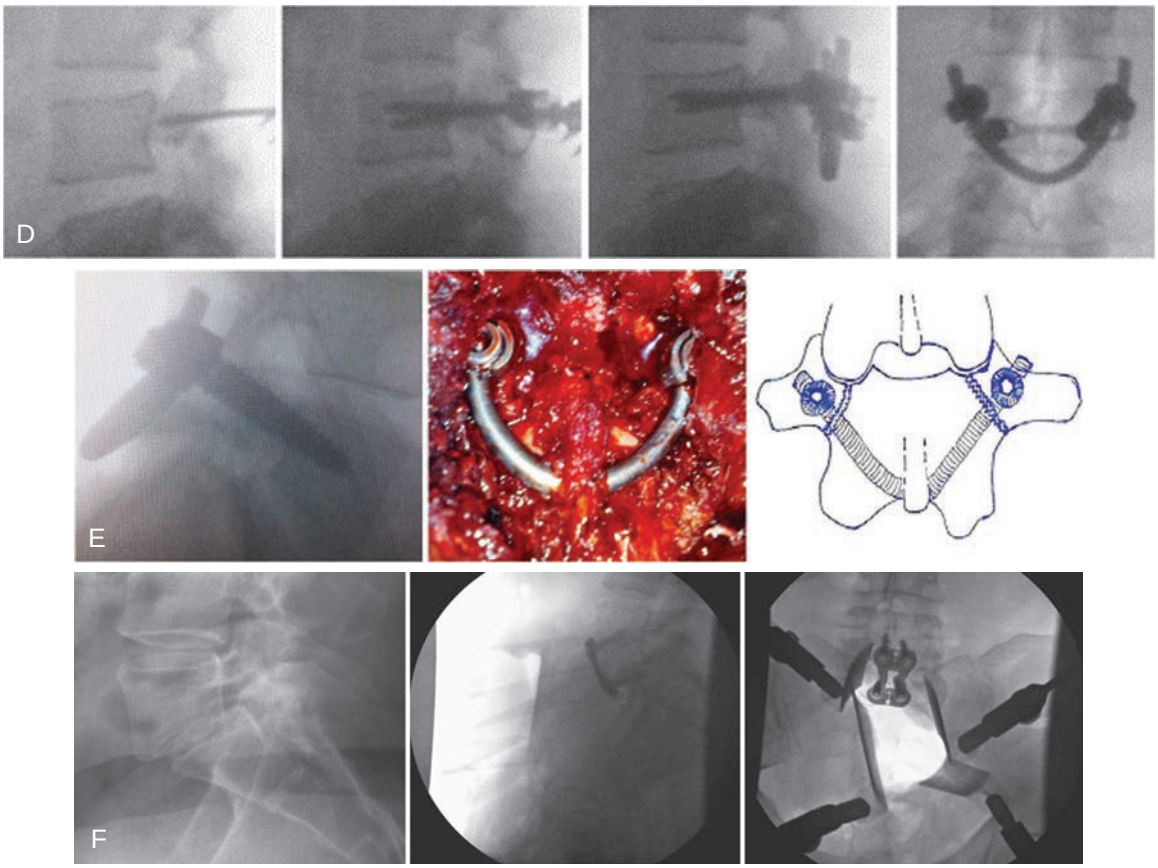

FIGURE 20-6. cont'd D, Intraoperative fluoroscopic images of the steps of the procedure (left to right), showing the defect (left) and screw insertion into the L4 pedicles with intraoperative posteroanterior view of the construct (right). **E,** Intraoperative fluoroscopic lateral image (left), operative view of the construct (center) and a graphic representation of the procedure (right). **F,** Fluoroscopic lateral image preoperative (left), lateral image intraoperative (center) and anterior image intraoperative. *(B to F from Eldin MM. Minimal: Access direct spondylolysis repair using a pedicle screw-rod system: A case series. J Med Case Rep 6:396, 2012.)*

Management of Pain and Swelling

- Oral pain medications
- Cryotherapy to decrease pain and inflammation

Proper Body Mechanics and Positioning

- Using pillows or bolsters to find a position of comfort to reduce stress on repaired structures.
- Instructions to avoid driving, prolonged sitting, lifting, bending, and twisting.
- Use lumbar roll when sitting
  - Maintain neutral posture
- Bed mobility/positioning
  - Log rolling, instruct in proper transfers
  - Pillow between knees when side lying
  - Pillow under knees when supine

Therapeutic Exercises

- Gentle nerve gliding
- Deep breathing exercises
- Ambulation progression daily as tolerated
  - Use assistive device as needed

Milestones for Progression to the Next Phase

- Assuming the athlete is progressing without complications (signs of infection, signs and symptoms of repair failure, and intractable pain limiting AROM tolerance) they are progressed to the next phase.

Phase II (weeks 1 to 6)

Goals

- Protect the surgical site to promote wound healing
- Decrease pain and inflammation
- Maintain nerve root mobility
- Establish good body mechanics for safe, independent self-care
- Educate on proper bed mobility and positioning
- Assuming the athlete is progressing without complications (signs of infection, signs and symptoms of repair failure, and intractable pain limiting AROM tolerance) they can progress to the next phase.

Protection

- Soft bracing (corset) or hard bracing (TLSO) is optional per surgeon. Should never be required, but may be worn for comfort.
- Good body mechanics to promote patient comfort and proper positioning to prevent stress to the healing posterior structures (see body mechanics/positioning section below).

Management of Pain and Swelling

- Oral pain medications is continued as needed
- Electro-therapy such as: transcutaneous electrical nerve stimulation (TENS), high voltage pulsed current (HVPC), or interferential current (IFC)
- Cryotherapy to decrease pain and inflammation

Proper Body Mechanics and Positioning

- Using pillows or bolsters to find a position of comfort to reduce stress on repaired structures
- Instructions to avoid driving, prolonged sitting, lifting, bending, and twisting
- Use lumbar roll when sitting
  - Maintain neutral posture
- Bed mobility/positioning
  - Log rolling, instruct in proper transfers
  - Pillow between knees when side lying
  - Pillow under knees when supine

Therapeutic Exercises

- Deep breathing exercises (supine/prone)
  - Crocodile breathing (Figure 20-7)
- Ambulation progression as tolerated
  - Use assistive device as needed
  - Progress to treadmill when independent
- Nerve mobilizations (Figure 20-8)
- Glute sets, quad sets, pelvic tilts, short arc quads, ankle pumps

Milestones for Progression to the Next Phase

- Assuming the athlete is progressing without complications (signs of infection, signs and symptoms of repair failure, and intractable pain limiting AROM tolerance) they are progressed to the next phase.

Phase III (weeks 6 to 11)

Goals

- Continue to protect surgical site
- Control pain and inflammation
- Improve nerve root mobility
- Improve lower extremity and thoracic mobility
- Improve core stability
- Increase walking tolerance and cardiovascular conditioning

Protection

- Continue good body mechanics to promote patient comfort and proper positioning to prevent stress to the healing structures.

FIGURE 20-7. Crocodile breathing.

FIGURE 20-8. Nerve mobilizations. **A,** Start. **B,** Finish.

TIMELINE 20-2: **Postsurgical Rehabilitation after Lumbar Spinal Fusion for Spondylolysis**

PHASE I (days 1 to 7)	PHASE II (weeks 1 to 6)	PHASE III (weeks 7 to 11)

• Bracing is optional
• Gentle nerve gliding
• Protection of incision
• Cryotherapy/oral pain meds
• Gentle nerve gliding
• Deep breathing exercises
• Ambulation daily as tolerated
• Avoid driving, prolonged sitting, lifting, bending, and twisting.
• Use lumbar roll when sitting
  • Maintain neutral posture
• Bed mobility /positioning
  • Log rolling, instruct in proper transfers
  • Pillow between knees when side lying
  • Pillow under knees when supine
	• Continue bracing if instructed
	• PT modalities (cryotherapy, e-stim)/oral meds
	• Continue proper body mechanics
	• Deep breathing exercises, crocodile breathing
	• Nerve gliding
	• Gait training
	  • Progress to treadmill when independent
	• Bed mobility, positioning
	  • Log rolling, instruct in proper transfers (bed to chair/car)
	  • Pillow between knees when side lying
	  • Pillow under knees when supine
	• Glute sets
	• Quad sets
	• Ankle pumps
	• Short arc quads
	• Pelvic tilts
	• Sit in chair for all meals
	  • Sit at 30+ minute intervals throughout the day
	  • Bending, twisting, lifting per patient tolerance
	• Posture education: use lumbar roll when sitting
	  • Maintain neutral posture
		• Continue with Phase II activities focusing on individual impairments
		• PT modalities as needed (cryotherapy, e-stim)
		• Scar mobilizations once incisions are closed
		• Lumbar spine/hip ROM
		  • Knee to chest, supine rotation, prone extension
		• Nerve mobilizations
		• Manual therapy techniques:
		  • Thoracic spine joint mobilizations
		  • Hip joint mobilizations
		• Therapeutic exercises: isometrics
		  • Glute squeezes
		  • Heel lifts
		• Lower body rolling
		• Lumbar/core stabilization exercises
		  • Dying bug (after Week 8)
		  • Quadruped diagonals
		  • Superman (after Week 8)
		  • Bridging (single/double leg)
		• Push-up progression: wall to table to chair
		• Abdominal crunches beginning at 9 weeks postop; NO sit-ups
		• Treadmill: walking progression program
		• Elliptical trainer
		• StairMaster
		• Pool therapy
		  • Hip flex/ext, int/ext rotation, and abduction/adduction
		• Lower extremity flexibility/stretches
		  • Quad stretches
		  • Glutes/hip Rotators
		  • Gastroc-soleus stretches
		  • Hip flexors stretches
		  • Hamstring stretches
		• Half-kneeling in-line posture
		• Walking progression program
		  • Treadmill
		• Elliptical trainer
		• StairMaster
		• Lower extremity balance activities
		• Wall squats with abdominal bracing
		• Forward lunges
		• May begin lifting and bending using proper biomechanics

TIMELINE 20-2 Postsurgical Rehabilitation after Lumbar Spinal Fusion for Spondylolysis (Continued)

PHASE IV (weeks 12 to 20)

- Continue appropriate previous exercises from Phase III
- Continue lumbar spine AROM
  - Quadruped heel rocking
  - Tall kneeling heel sits
  - Prone press-ups
- Continue thoracic spine joint mobilizations (P-A, transverse)
- Continue hip joint mobilizations (A-P, P-A, lateral)
  - Graded joint mobilizations progressing to include grades III to IV
- Continue scar mobilization as needed
- Foam rolling over thoracolumbar paraspinals
- PROM focusing on gentle end-range stretching.
- Thermotherapy may be used prior to stretching
- Continue lower extremity flexibility/stretches
  - Hamstrings
  - Quads
  - Glutes
  - Glutes/hip Rotators/piriformis
  - Adductors
  - Gastroc-soleus
- Nerve mobilizations as needed
- Continue lumbar/core stabilization exercises
  - Upper body rolling
  - Lower body rolling
  - Active SLR
    - Quadruped diagonals
    - Half/tall kneeling chops
    - Half/tall kneeling lifts
- Sit-up progression
- Lat pulldowns
- Seated rows
- Chest press
- Dips
- Calf raises (seated/standing)
- Progression of lower extremity strength training exercises
  - Progress to jogging/running for cardiovascular conditioning at week 12.
  - Front squats may be initiated with medicine ball hugs instead of bar.
- Cardiovascular endurance
  - Jogging to running
  - Elliptical trainer
  - StairMaster
- Neuromuscular dynamic stability exercises:
  - Lower extremity balance activities (i.e., single leg balance, BOSU ball, etc.)
  - Lower extremity single-leg balance activities are progressed
  - Progressed with decreased base of support, open chain or unstable surface
- Axial compression drills: closed chain on unstable surface (i.e., Airex pad, weighted ball, tilt boards)
- Manual perturbation to the trunk while in dynamic closed chain loaded position, such as half or tall kneeling.
- Cardiovascular endurance:
  - Treadmill jogging
  - StairMaster
  - Elliptical trainer
- Lower body strengthening
  - Closed kinetic chain exercises and open chain resistance exercises
- Functional exercises
  - Deadlifts/hip hinging progression
  - Front squats
  - Forward and side lunges
  - Step-ups
  - Pushups progression – knees to regular
- Plyometrics
  - Lower extremity plyometric drills (i.e., multidirectional lunges, side hops, etc.)
- Sport-specific exercises
  - Lower extremity sports-specific drills in a controlled environment at 12 to 16 weeks postoperatively (i.e., hopping, jumping, changes in direction/agility drills)

PHASE V (weeks 21 to 52)

- Continue appropriate previous exercises from Phase IV
- Continue to increase lumbar AROM
- Manual therapy techniques
  - Continue as above to achieve full thoracolumbar and hip mobility.
  - Joint mobilization grades III to IV as indicated.
- Soft tissue techniques
  - Scar mobilizations as necessary
- Full lumbo-pelvic-hip stretching techniques
  - Continued use of sustained end range stretching
- Progress lower extremity, gluteal and hip strength exercises.
- Multijoint movements
  - Front squats, power cleans, military press, etc.
- Continue Phase IV resistance exercises with progression
- Sensorimotor exercises (proprioception, kinesthesia)
  - Ball toss exercises in standing
  - D1/D2 movements with cables
  - Medicine ball trunk rotations
  - Rapid repositioning drills and reaction movement drills
- Open (OKC) and closed (CKC) kinetic chain exercises
- Advancing the Phase IV exercises in accordance with sport-specific demands
  - OKC: Kettle bell swings and snatches, lower and upper extremity PNF patterns OKC/CKC: Tall or half-kneeling with diagonal lift and chop resistance
  - CKC: Side planks, front planks, and weight shifts on stable and progress to unstable surfaces.
- Advance endurance sets to strength exercises (repetitions of 10-15 per set).
- Neuromuscular dynamic stability exercises:
  - Push-up progression then leads to dynamic floor pushups.
  - Resistance exercises in standing progress from double- to single-leg stance, asymmetrical resistance, and unstable surfaces as necessary
- Plyometrics
  - Begin with chest pass motions into a rebounder and progressing to single arm tosses
  - Overhead bilateral medicine ball slams and overhead medicine ball catching
  - Continue lower extremity plyometric drills (i.e., multidirectional lunges, side hops, etc.)
- Functional exercises
  - Continue deadlifts, front squats, and lunges
  - Overhead strengthening is incorporated as well as lower extremity agility drills including ladder and hurdle drills, and running progression (intervals, sprints).
  - Resistance exercises in standing progress from double-leg to single-leg stance, asymmetrical resistance, and unstable surfaces.
- Begin lower extremity agility program
- Sport-specific exercises
- Lower and upper extremity sports specific drills
  - Progression to formal strength and conditioning commences once full gross strength, AROM, and are pain-free with activity.

Management of Pain and Swelling

- Electrotherapy (TENS, HVPC, and IFC) is continued for pain and muscle guarding as needed
- Cryotherapy as needed

Proper Body Mechanics and Positioning

- May begin lifting and bending with proper body mechanics

Techniques for Progressive Increase in Range of Motion

- Lumbar spine/hip AROM
  - Knee to chest, supine rotation, prone extension

Manual Therapy Techniques

- Thoracic spine joint mobilizations
- Hip joint mobilizations

Soft Tissue Techniques

- Scar mobilization to postsurgical incisions once closed to minimize incisional adhesions.
  - Cross-friction is performed to assist with full tissue mobility in lumbar region.

Stretching and Flexibility Techniques for the Musculotendinous Unit

- Lower extremity stretches
  - Hamstrings
  - Quads
  - Glutes/hip rotators
  - Adductors
  - Gastroc-Soleus

Other Therapeutic Exercises

- Isometrics
  - Glute squeezes
  - Heel lifts
- Nerve mobilizations
- Lumbar/core stabilization exercises
  - Lower body rolling
  - Bridging (double leg/double leg with leg ext/single leg) (Figures 20-9 to 20-11)
  - Superman (after Week 8)
  - Dying bug (after Week 8)
  - Quadruped diagonals (Figure 20-12)
- Pool therapy
  - Pool-based exercises using the water for resistance may be incorporated during this phase if the incisions are well healed. Exercises should include reciprocal motions of Hip flex/ext, int/ext rotation, and abduction/adduction.

Activation of Primary Muscles Involved in Injury Area or Surgical Structures

- Abdominal crunches beginning 9 weeks postoperatively
- NO sit-ups

Sensorimotor Exercises

- Half-kneeling in-line balance (Figure 20-13)
- Active straight leg raise with core activation (Figure 20-14)

Techniques to Increase Cardiovascular Endurance

- Treadmill: walking progression program
- Elliptical trainer
- StairMaster

Neuromuscular Dynamic Stability Exercises

- Lower extremity balance activities (i.e. single-leg balance, BOSU ball, etc.)

FIGURE 20-10. Double-leg bridge with leg extention.

FIGURE 20-9. Double-leg bridge.

FIGURE 20-11. Single-leg bridge.

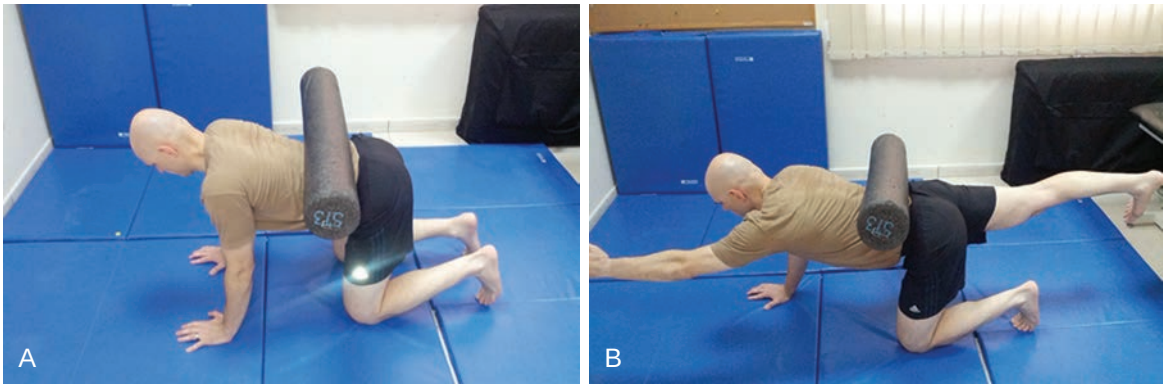

FIGURE 20-12. Quadruped diagonals. **A,** Start. **B,** Finish.

FIGURE 20-13. Half-kneeling in-line balance. *(From Rainey CE: The use of trigger point dry needling and intramuscular electrical stimulation for a patient with chronic low back pain: A case report. Int J Sports Phys Ther 8:145-161, 2013.)*

FIGURE 20-14. Straight leg raise with core activation. *(From Rainey CE: the use of trigger point dry needling and intramuscular electrical stimulation for a patient with chronic low back pain: A case report. Int J Sports Phys Ther 8:145-161, 2013.)*

Functional Exercises

- Wall squats with abdominal bracing
- Forward lunges

Phase IV (weeks 12 to 20)

Goals

- Independent with ADLs
- Increased trunk and extremity strength
- Maintenance of a neutral spine during corrective exercises
- No episodes of lumbar instability

Protection

- Continue good body mechanics to promote patient comfort and proper positioning to prevent stress to the healing structures.

Management of Pain and Swelling

- Oral NSAID therapy as needed
- IFC electrical stimulation for pain control as needed
- Cryotherapy or thermotherapy is used posttherapy to mitigate postexercise inflammation and soreness or exercise-induced inflammation.

Techniques for Progressive Increase in Range of Motion

- Continue lumbar spine AROM
  - Quadruped heel sits (Figure 20-15)
  - Tall kneeling heel sits (Figure 20-16)
  - Prone press-ups

Manual Therapy Techniques

- Continue thoracic spine joint mobilizations (P-A, transverse)
- Continue hip joint mobilizations (A-P, P-A, lateral)
  - Graded joint mobilizations progressing to include grades III to IV may be incorporated.

FIGURE 20-15. Quadruped heel sit. **A,** Start. **B,** Finish.

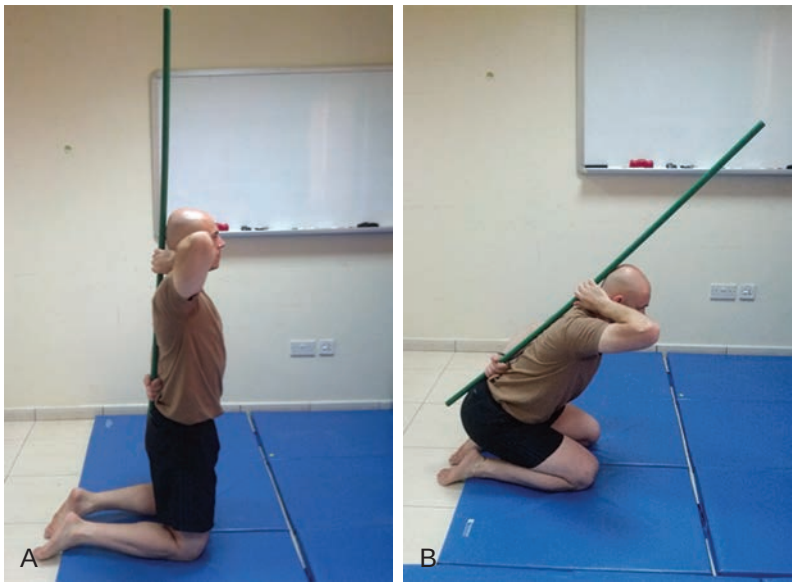

FIGURE 20-16. Tall kneeling heel sit. (**A**) Start. (**B**) Finish.

Soft Tissue Techniques

- Continue scar mobilization as needed
- Foam rolling over thoracolumbar paraspinals (Figure 20-17)

Stretching/Flexibility Techniques for the Musculotendinous Unit

- Passive range of motion (PROM) focusing on gentle end-range stretching.
- Thermotherapy may be used prior to stretching and tissue flexibility to facilitate muscle relaxation
- Continue lower extremity stretches
  - Hamstrings
  - Quads
  - Glutes/hip rotators/piriformis
  - Adductors
  - Gastroc-soleus

FIGURE 20-17. Foam rolling over paraspinals.

FIGURE 20-18. Half-kneeling chop. **A,** Start. **B,** Finish.

FIGURE 20-19. Half-kneeling lift. **A,** Start. **B,** Finish.

Therapeutic Exercises

- Nerve mobilizations as needed
- Continue lumbar/core stabilization exercises
  - Upper body rolling
  - Lower body rolling
  - Quadruped diagonals
  - Half/tall kneeling chops (Figure 20-18)
  - Half/tall kneeling lifts (Figure 20-19)

Activation of Primary Muscles Involved in Injury Area or Surgical Structures

- Spinal flexion progression

Techniques to Increase Muscle Strength, Power, and Endurance

- Lat pulldowns
- Seated rows
- Chest press
- Dips
- Calf raises (seated/standing)
- Progression of lower extremity strength training exercises
- Progress to jogging/running for cardiovascular conditioning at week 12
- Front squats may be initiated with medicine ball hugs instead of bar

Techniques to Increase Cardiovascular Endurance

- Jogging to running
- Elliptical trainer
- StairMaster

Neuromuscular Dynamic Stability Exercises

- Lower extremity balance activities (i.e., single leg balance, BOSU ball, etc.).
  - Lower extremity single-leg balance activities are progressed.
  - Deadlift repatterning to single-leg deadlifts with neutral spine (Figure 20-20).
- Positions progressed with decreased base of support, open chain or unstable surface.
- Axial compression drills: closed chain on unstable surface (i.e. Airex pad, weighted ball, tilt boards).
- Manual perturbation to the trunk while in dynamic closed chain loaded position, such as half or tall kneeling.

Other Therapeutic Exercises

- Cardiovascular: treadmill jogging, StairMaster, and elliptical trainer with increased resistance.
- Lower body strengthening is progressed and may include closed kinetic chain exercises and open chain resistance exercises.

Functional Exercises

- Deadlifts/hip hinging progression (Figure 20-21)
- Front squats

- Forward and side lunges
- Step-ups
- Pushups
  - Closed-chain activities progress to include a pushup progression beginning with wall pushups, advancing to table height pushups and pushups on knees, to finally floor pushups.

Plyometrics

- Lower extremity plyometric drills (i.e., multidirectional lunges, side hops, etc.).

Sport-Specific Exercises

- Lower extremity sports-specific drills in a supervised/controlled environment at 12 to 16 weeks postoperatively (i.e., hopping, jumping, changes in direction/agility drills).

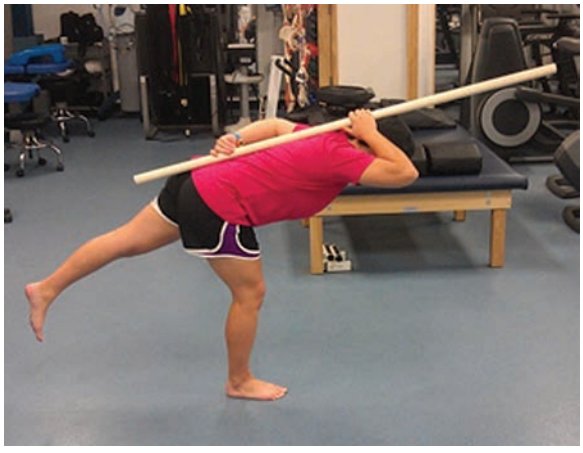

FIGURE 20-20. Single-leg deadlift with neutral spine. *(From Rainey CE: The use of trigger point dry needling and intramuscular electrical stimulation for a patient with chronic low back pain: A case report. Int J Sports Phys Ther 8:145-161, 2013.)*

Outcome Measures

- Patient reported outcome measures can be implemented at 12 weeks and administered at month 3, 6, 9, and 12. Outcome measures that have been used in the literature for lumbar spinal fusion include Oswestry Disability Index (ODI).

Phase V (weeks 21 to 52)

Goals

- Return to sport activities
- Improve trunk and extremity strength
- Improve muscular endurance
- Thoracic spine and hip full PROM

Management of Pain and Swelling

- Oral NSAIDs as needed.
- IFC electrical stimulation for pain control as needed.
- Cryotherapy or thermotherapy is used posttherapy to mitigate postexercise inflammation and soreness or exercise-induced inflammation.

Techniques for Progressive Increase in Lumbar Range of Motion

Manual Therapy Techniques

- Continue as above to achieve full thoracolumbar and hip mobility.
- Joint mobilization grades III to IV as indicated (use caution on surgical site).

Soft Tissue Techniques

- Scar mobilizations as necessary.

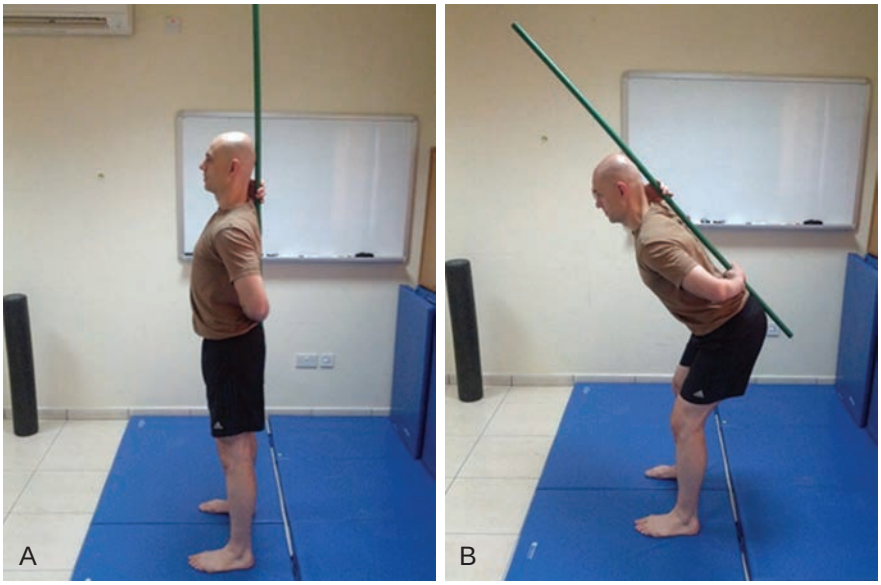

FIGURE 20-21. Deadlift. **A,** Start. **B,** Finish.

Stretching/Flexibility Techniques for the Musculotendinous Unit

- Athletes are instructed in full lumbo-pelvic-hip stretching techniques.
- Continued use of sustained end range stretching to achieve desired symmetrical or required mobility.
- Preperformance/exercise stretching should focus on functional movement patterns, then prepare the athlete for return to sport activity.

Other Therapeutic Exercises

- Progress lower extremity, gluteal, and hip strength exercises.
- Integrated training activities at this stage should include multijoint movements (i.e., front squats, power cleans, military press, etc.)

Activation of Primary Muscles Involved in Injury Area or Surgical Structures

- Previous exercises with progressive resistance.
- Focus in the late stage of recovery is on establishing preinjury levels of function.

Sensorimotor Exercises

- Ball toss exercises in standing
- D1/D2 movements with cables
- Medicine ball trunk rotations
- Rapid repositioning drills and reaction movement drills

Open and Closed Kinetic Chain Exercises

- Advancing the previous exercises in accordance with sport-specific demands
- OKC: Kettle bell swings and snatches, lower and upper extremity PNF patterns (Figure 20-22)
- OKC/CKC: Tall or half-kneeling with diagonal lift and chop resistance exercises
- CKC: Side planks, front planks, and weight shifts on stable and progress to unstable surfaces.
  - BOSU ball can be used for progression of pushups to uneven surfaces for CKC activities.

Techniques to Increase Muscle Strength, Power, and Endurance

- Advance endurance sets to strength exercises (repetitions of 10 to 15 per set).
- Implement an undulating periodization model for strength training

Neuromuscular Dynamic Stability Exercises

- Pushup progression then leads to dynamic floor pushups.
- Resistance exercises in standing progress from double- to single-leg stance, asymmetrical resistance, and unstable surfaces as necessary to replicate anticipated performance demands.

Plyometrics

- Plyometrics are initiated with chest pass motions into a rebounder and progressing to single arm tosses.
- Overhead bilateral medicine ball slams and overhead medicine ball catching.
- Continue lower extremity plyometric drills (i.e., multidirectional lunges, side hops, etc.).
- Advanced to increasing level of difficulty.

Functional Exercises

- Continue deadlifts, front squats, and lunges.
- Overhead strengthening is incorporated as well as lower extremity agility drills including ladder and hurdle drills as well as running progression (intervals, sprints).
- Resistance exercises in standing progress from double-leg to single-leg stance, asymmetrical resistance and unstable surfaces.
- Begin lower extremity agility program.

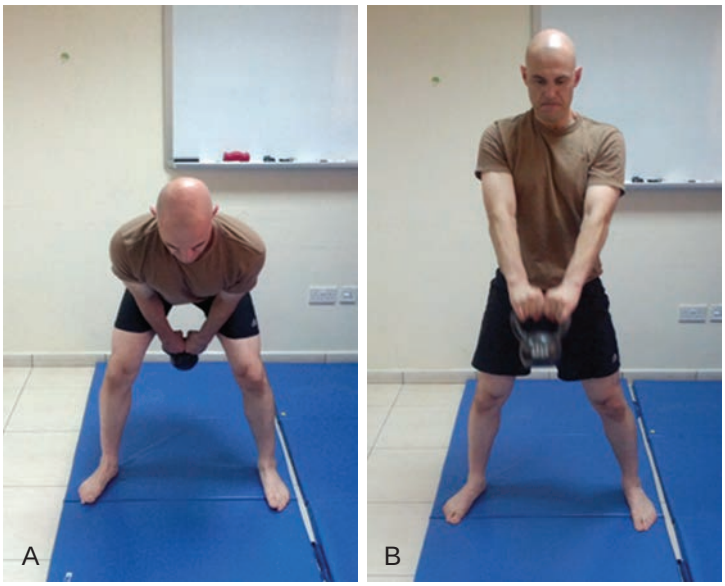

FIGURE 20-22. Kettlebell swings. **A,** Start. **B,** Finish.

Sport-Specific Exercises

- Lower and upper extremity sport-specific drills
- Progression to formal strength and conditioning commences once athletes have full gross strength, AROM and are pain-free with activity.

Outcome Measures

- Patient reported outcome measures (see Phase IV).

Milestones/Criterion-Based Rehabilitation Guidelines for Progression to the Next Stage

- CKC testing may include the CKC upper and lower extremity Y-balance test
- Power tests may include the vertical jump, standing backward overhead medicine ball throw, and standing rotational medicine ball throw. Preinjury test values would provide the best measure of functional recovery as sport/position-specific normative data is limited.

Criteria for Return to Sport

General

- Normal lumbar-pelvic-hip body mechanics.
- Full thoracic and hip mobility without instability.
- CKC testing and integrated functional movement tests with good quality of motion, maintenance of core stability throughout the tests with no report of lumbar pain or instability.

Sport-Specific

- Implementation of return to sport criteria must include a demand/needs analysis of the chosen sport. The rehabilitation specialist should be able to analyze the demands on the lumbar-pelvic-hip complex and create a sufficient series of tests and exercises to ensure readiness for return to preinjury levels of activity.

After Return to Sport

Continuing Fitness or Rehabilitation Exercises

- Total body strengthening exercises.

Exercises and Other Techniques for Prevention of Recurrent Injury

- Prevention of recurrence requires continued maintenance of dynamic neuromuscular control (strength, mobility, kinesthetic awareness, and proprioception). Degradation in any of these areas could put the athlete at risk for reinjury if they continue to place a high degree of physical demands on the hardware.
- While sport-specific training is essential to ensure readiness for return to sport, a training program that does not include reactive drills and a diversity of training modalities can result inability to adapt to the ever-changing demands of athletic competition.

Evidence

Drazin D, Shirzadi A, Jeswani S, et al: Direct surgical repair of spondylolysis in athletes: Indications, techniques, and outcomes. *Neurosurg Focus* 31:1–12, 2011.

This article reviews the surgical techniques of spondylolysis repairs in athletes. The authors' literature search found that the single lag screw fixation (Buck) outcomes for athletes was a >90% return to preoperative sports performance. (Level V evidence).

Micheli LJ, Wood R: Back pain in young athletes: Significant differences from adults in causes and patterns. *Arch Pediatr Adolesc Med* 149:15–18, 1995.

This article reviews the back pain in young athletes and the differences from adults in causes and patterns. The authors found that spondylolysis and spondylolisthesis are responsible for up to 47% of low back pain in adolescent athletes. (Level V evidence).

Radcliff KE, Kalantar SB, Reitman CA: Surgical management of spondylolysis and spondylolisthesis in athletes: Indications and return to play. *Curr Sports Med Rep* 8:35–40, 2009.

This article reviews the surgical indications of a spondylolysis and spondylolisthesis and the return to play in athletes. (Level V Evidence).

Rubery PT, Bradford DS: Athletic activity after spine surgery in children and adolescents: Results of a survey. *Spine (Phila Pa 1976)* 27:423–427, 2002.

The article reviewed 721 members of the Scoliosis Research Society via survey regarding their opinions and experience with athletic activity after spine surgery performed on children and adolescents. The article showed varying approaches to postoperative athletic activity. (Level V evidence).

Soler T, Calderon C: The prevalence of spondylolysis in the Spanish elite athlete. *Am J Sports Med* 28:57–62, 2000.

This article reviewed 3152 case histories of high-level athletes to determine which sports had a higher prevalence of spondylolysis. The article recommends systematic radiological examination of the lumbar spine in athletes considered to be at greater risk of developing spondylolysis. (Level V evidence).

Multiple-Choice Questions

QUESTION 1. In a symptomatic athlete, the diagnosis of spondylolysis (pars defect) as the etiology for lumbosacral pain is best confirmed with:

A. Computed tomography (CT)
B. Oblique lumbar radiographs
C. Magnetic resonance imaging (MRI)
D. Single-photon-emission computed tomography (SPECT)

QUESTION 2. The pathophysiology of spondylolysis is thought to be caused by:

A. Repetitive truncal twisting while loaded
B. Forceful hyperflexion with resistance
C. Multiple factors including repetitive lateral bending
D. Regular mechanical flexion, extension, and trunk rotation

QUESTION 3. The patient outcome results of pars fractures that have formed fibrous union vice nonunion are inferior to those that have healed with bony union.

A. False
B. True

QUESTION 4. Sport-specific exercises and drills are introduced:

A. At 5 to 6 weeks following surgery if the incision is well healing and without signs or symptoms of infection.
B. When the patient is able to effectively demonstrate grades III and IV mobilization.
C. Postoperatively in order to enhance osseous blood influx thereby facilitating more rapid bone healing rates.
D. In a supervised/controlled environment at 3 to 4 months following surgical management.

QUESTION 5. When considering surgical management of a pars interarticularis fracture that has progressed from spondylolysis to spondylolisthesis, current evidence shows:

A. That a properly performed Gill procedure to decompress the neural elements results in the most rapid return to unrestricted sport.
B. That even with radiculopathy, instrumented arthrodesis alone without decompression, will result in an acceptable outcome and resolve symptoms.
C. Improved outcomes with reduction of high grade slippage (Myerding grade III or higher) compared with in-situ arthrodesis.
D. Less intraoperative blood loss and more rapid return to unrestricted sport with percutaneous (minimally invasive instrumented) lumbar fusion surgical techniques.

Answer Key

QUESTION 1. Correct answer: **D** (see Indications for Surgical Treatment)

QUESTION 2. Correct answer: **D** (see Brief Summary of Surgical Treatment: Postsurgical)

QUESTION 3. Correct answer: **A** (see Brief Summary of Surgical Treatment: Postsurgical)

QUESTION 4. Correct answer: **D** (see Phase IV: Sport-Specific)

QUESTION 5. Correct answer: **B** (see Brief Summary of Surgical Treatment: Surgical)

BEYOND BASIC REHABILITATION: RETURN TO GYMNASTICS AFTER OPERATIVE REPAIR OF SPONDYLOLYSIS

Charles E. Rainey, PT, DSc, DPT, OCS, SCS, CSCS, FAAOMPT, Stewart M. Kerr, MD, Gregg Ziemke, PT, MS, MHA, OCS, and Leslie C. Hair, PT, DSc, OCS, FAAOMPT

Introduction

ASPECTS OF GYMNASTICS THAT REQUIRE SPECIAL ATTENTION IN REHABILITATION

- Range of motion/flexibility
- Lumbar/core stability
- Hyperextension movements
- Activities that require heavy spinal loads
- Spondylolysis and spondylolisthesis are responsible for up to 47% of low back pain in adolescent athletes.[1]
- Athletes who participate in sports that involve repetitive lumbar hyperextension, such as gymnastics, are at higher risk of developing these conditions (Figure 20-23*A* to *D*).[2]
- Soler and Calderon reviewed 3152 elite athletes and reported spondylolysis in 27% of throwing athletes, 17% of gymnasts, and 17% of rowers.[3]
- After a surgical repair of spondylolysis, rehabilitation is needed for return to function and sport. Rehabilitation for the athlete should begin quickly after surgery and consist of educating the patient regarding the proper way to transfer in/out of bed and to get dressed, ambulation and nerve mobilizations, and progression to core strengthening and low-impact cardiovascular activity at 2 weeks postoperatively.

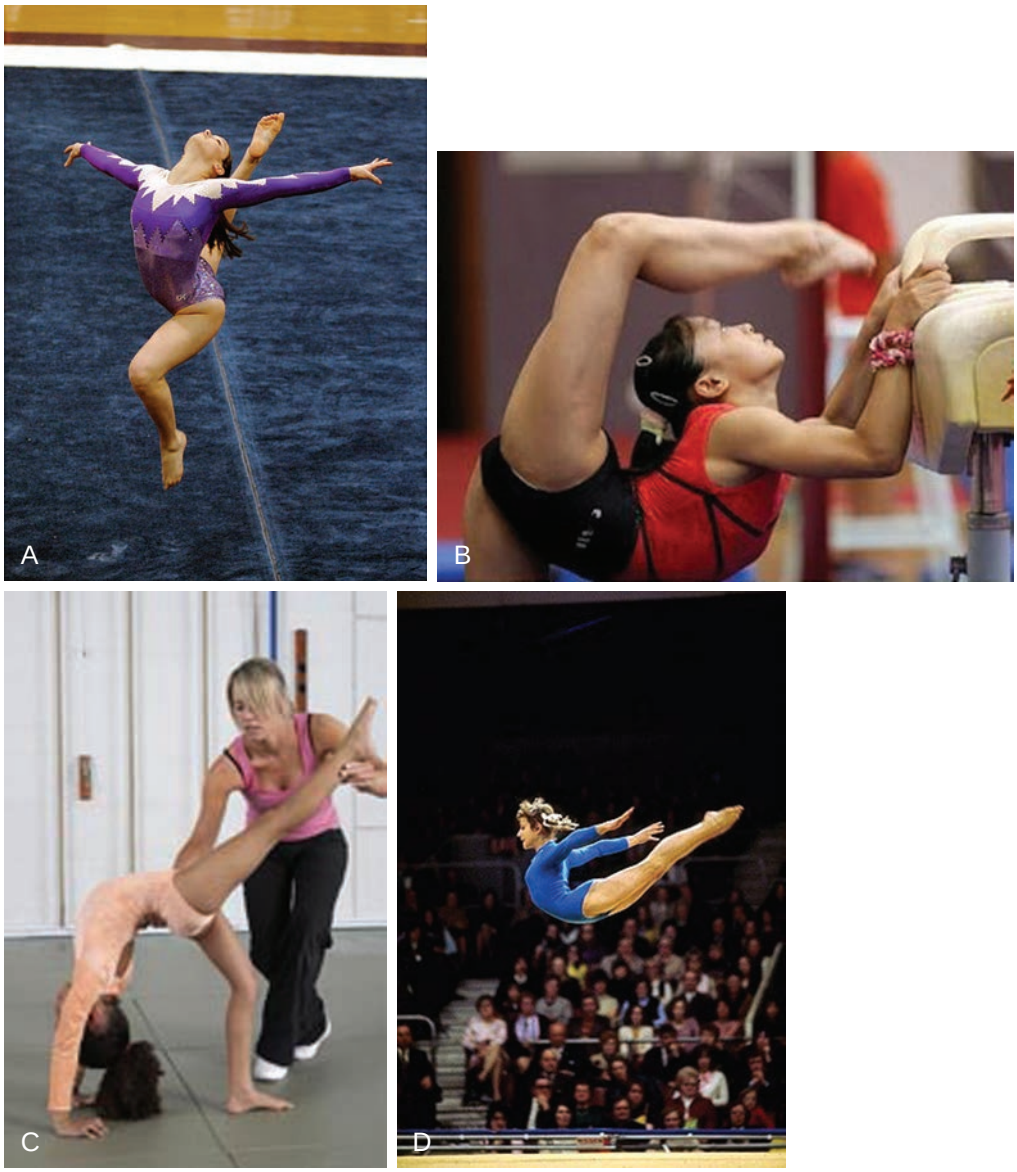

FIGURE 20-23A TO D. Gymnasts performing higher risk hyperextension movements/activities.

Literature

- There is no information on return to play (RTP) criteria after direct pars repair. Published recommendations for return to noncontact sports after fusion for spondylolisthesis are controversial.[4]
- Rubery and Bradford conducted a survey of 261 members of the Scoliosis Research Society who commonly treat spondylolisthesis.[5] They found that 62% to 66% of surgeons allowed return to low-impact, noncontact sports by 6 months postoperatively for both low-grade and high-grade slips.[5]
- Eck and Riley disagree and suggest delaying return to noncontact sports for 1 year.[6]
- The most common sports that surgeons forbade patients to resume after spondylolisthesis fusion were gymnastics, football, rugby, wrestling, weightlifting, skydiving, and bungee jumping.[5]
- Although some authors do not restrict return to contact sports after fusion for spondylolisthesis, they advise that athletes participating in activities that require extreme mobility or involve heavy loads may be limited after surgery.[4]
- Herman et al. allow unrestricted RTP in athletes who are asymptomatic, have achieved stable fusion, and are fully rehabilitated to their previous playing capacity.[7] This typically occurs within 1 year after surgery. The authors believe that a single-level lumbosacral fusion has minimal impact on spine function, whereas a multilevel fusion may impair mobility and performance.[7]
- Radcliff et al. caution that fusion may be a career-ending surgery for activities that require extreme lumbar hyperextension, such as gymnastics and dance. It was stated that athletes participating in sports that involve heavy loads may be reduced from highly competitive to recreational.[8]

Phase I: Advanced Strength and Conditioning Programs (weeks 1 to 4)

Program Design/Performance Training Program

Sport-Specific Concepts of Integrated Training

- Training continuum
- Flexibility/joint mobility
- Core stability/strengthening
- Low-impact cardiovascular training
- Training for optimum muscle balance
- Training for optimum muscle functional strength

Training Principles Used in the Design of the Program

- Principle of progression
- Principle of overload
- Principle of individualization

Application of Acute Training Variables

- Repetitions and sets may vary depending on where the patient is on the training continuum. Athletes should begin with spinal rehabilitation slowly, focusing on flexibility/range of motion and basic static stability exercises.
- Advance to dynamic stability exercises in a progressive manner, avoiding any pain during motor control activities. If pain occurs, exercises should be decreased to a less advanced stage of the rehabilitation program.
- The quality of exercises is far more important than the quantity.
- Rest periods should be at least 1 minute but can be as long as required to promote the highest exercise quality. This allows the muscle to have full recovery between sets and reinforces motor learning.
- Strengthening exercise sessions should be separated by at least one full day to allow the muscle to fully heal from any breakdown caused by training. This allows the muscle to fully recover between sets.
- Repetitions: 6 to 10
- Sets: 3 to 5
- Rest interval: 1 minute
- Intensity: submaximal (<50% one repetition maximum [1RM])
- Training frequency: 2 to 4 days per week (allow 2 to 4 days recovery)
- Training duration: 30 to 60 minutes
- Training volume: total number of repetitions completed in training session will vary
- Specific exercises used in the training:
  - Lower body rolling
  - Lumbar/core stabilization exercises
    - Dying bug
    - Quadruped diagonals (see Figure 20-7)
    - Superman
    - Bridging (double/single leg) (see Figures 20-4 to 20-6)
  - Pushup progression
  - Abdominal crunches
  - Cardiovascular endurance
    - Treadmill
    - Elliptical trainer
    - StairMaster
  - Lower extremity flexibility/stretches
    - Quad stretches
    - Glutes/hip rotators
    - Gastroc-soleus stretches
    - Hip flexors stretches
    - Hamstring stretches
  - Half-kneeling in-line balance (see Figure 20-8)
  - Lower extremity balance activities
  - Wall squats with abdominal bracing
  - Forward lunges

Phase II: Performance Enhancement Training Techniques (weeks 5 to 12)

Program Design/Performance Training Program

Sport-Specific Concepts of Integrated Training

- Multiplanar training activities
- Training for optimum functional movement
- Neuromuscular dynamic stability exercises
- Functional training

Training Principles Used in the Design of the Program

- Principle of progression
- Principle of overload
- Principle of variation
- Principle of individualization
- Principles of specificity: specific adaptation to imposed demands (SAID)

Application of Acute Training Variables

- Repetitions and sets for Phase II will again vary depending on the activity.
- For strengthening activities, 3 sets of 10 to 15 repetitions with increased intensity will work to progress to full strength.
- Intensity should still be kept to submaximal but progress as patients tolerates working towards full strength by the start of Phase III.
- Avoiding consecutive days of training will allow adequate amounts of rest, which is important to decrease the chance of re-rupture.
- Duration should last from 30 to 60 minutes, depending on endurance level of the athlete.
- Repetitions: varies depending on activity
- Sets: 3 to 5
- Rest interval: At least 1 minute between sets
- Intensity: moderate to high
- Training frequency: 1 to 3 times per week (no consecutive days)
- Training duration: 30 to 60 minutes
- Specific exercises used in the training:
  - Continue appropriate previous exercises from Phase I

TIMELINE 20-3: **Return to Gymnastics After Lumbar Fusion**

PHASE I (weeks 1 to 4)

- Lower body rolling
- Lumbar/core stabilization exercises
  - Dying bug
  - Quadruped diagonals
  - Superman
  - Bridging (single/double leg)
- Pushup progression
- Abdominal crunches
- Cardiovascular endurance
  - Treadmill
  - Elliptical trainer
  - StairMaster
- Lower extremity flexibility/stretches
  - Quad stretches
  - Glutes/hip rotators
  - Gastroc-soleus stretches
  - Hip flexors stretches
  - Hamstring stretches
- Half-kneeling in-line posture
- Lower extremity balance activities
- Wall squats with abdominal bracing
- Forward lunges

PHASE II (weeks 5 to 12)

- Continue appropriate previous exercises from Phase I
- Continue lower extremity flexibility/stretches
  - Hamstrings
  - Quads
  - Glutes
  - Glutes/hip rotators/piriformis
  - Adductors
  - Gastroc-soleus
- Continue lumbar/core stabilization exercises
  - Upper body rolling
  - Lower body rolling
  - Active SLR
  - Quadruped diagonals
  - Half/tall kneeling chops
  - Half/tall kneeling lifts
- Sit-up progression
- Lat pulldowns
- Seated rows
- Chest press
- Dips
- Calf raises (seated/standing)
- Progression of lower extremity strength training exercises
  - Front squats with bar or medicine ball hugs
- Cardiovascular endurance
  - Jogging to running
  - Elliptical trainer
  - StairMaster
- Neuromuscular dynamic stability exercises
  - Lower extremity balance activities (single-leg balance, BOSU ball, etc.)
  - Axial compression drills: closed chain on unstable surface (Airex pad, weighted ball, tilt boards)
  - Manual perturbation to the trunk while in dynamic closed chain loaded position
  - Half/tall kneeling
- Lower body strengthening
  - Closed kinetic chain exercises and open chain resistance exercises
- Functional exercises
  - Deadlifts/hip hinging progression
  - Front squats
  - Forward and side lunges
  - Step-ups
  - Pushup progression: knees to regular
- Plyometrics
  - Lower extremity plyometric drills (multidirectional lunges, side hops, etc.)
- Sport-specific exercises
  - Lower extremity sport-specific drills in a controlled environment (hopping, jumping, changes in direction/agility drills)

PHASE III (weeks 13 to 24)

- Continue appropriate previous exercises from Phase II
- Full lumbo-pelvic-hip stretching techniques
  - Continued use of sustained end range stretching
- Progress lower extremity, gluteal, and hip strength exercises.
- Multijoint movements
  - Front squats, power cleans, military press, etc.
- Continue Phase II resistance exercises with progression
- Sensorimotor exercises (proprioception, kinesthesia)
  - Ball toss exercises in standing
  - D1/D2 movements with cables
  - Medicine ball trunk rotations
  - Rapid repositioning drills and reaction movement drills
- Open (OKC) and closed (CKC) kinetic chain exercises
- Advancing the Phase II exercises in accordance with sport-specific demands
  - OKC: Kettle bell swings and snatches, lower and upper extremity PNF patterns
  - OKC/CKC: Half/tall kneeling with diagonal lift and chop resistance exercises
  - CKC: Side planks, front planks, and weight shifts on stable and progress to unstable surfaces.
- Advance endurance sets to strength exercises (repetitions of 10 to 15 per set)
- Neuromuscular dynamic stability exercises:
  - Pushup progression then leads to dynamic floor pushups
  - Resistance exercises in standing progress from double to single leg stance, asymmetrical resistance, and unstable surfaces as necessary
  - Kettle bell Turkish get-ups
- Plyometrics
  - Begin with chest pass motions into a rebounder and progressing to single arm tosses
  - Overhead bilateral medicine ball slams and overhead medicine ball catching
  - Continue lower extremity plyometric drills (i.e., multidirectional lunges, side hops, etc.)
- Functional exercises
  - Continue deadlifts, front squats, and lunges
  - Kettle bell swings
  - Overhead strengthening is incorporated as well as lower extremity agility drills including ladder and hurdle drills and running progression (intervals, sprints)
  - Resistance exercises in standing progress from double-leg to single-leg stance, asymmetrical resistance, and unstable surfaces
  - Begin lower extremity agility program
- Sport-specific exercises
- Lower and upper extremity sport-specific drills
  - Progression to formal strength and conditioning commences once full gross strength, AROM, and are pain-free with activity.

- Continue lower extremity flexibility/stretches
  - Hamstrings
  - Quads
  - Glutes
  - Glutes/hip rotators/piriformis
  - Adductors
  - Gastroc-soleus
- Continue lumbar/core stabilization exercises
  - Upper body rolling
  - Lower body rolling
  - Active straight leg raise with core activation (see Figure 20-10)
  - Quadruped diagonals
  - Half/tall kneeling chops (see Figure 20-13)
  - Half/tall kneeling lifts (see Figure 20-14)
- Sit-up progression
- Lat pulldowns
- Seated rows
- Chest press
- Dips
- Calf raises (seated/standing)
- Progression of lower extremity strength training exercises
  - Front squats with bar or medicine ball hugs
- Cardiovascular endurance
  - Jogging to running
  - Elliptical trainer
  - StairMaster
- Neuromuscular dynamic stability exercises
  - Lower extremity balance activities (i.e., single-leg balance, BOSU ball, etc.)
  - Deadlift repatterning to single-leg deadlifts with neutral spine (see Figure 20-24)
  - Lower extremity single-leg balance activities are progressed.
  - Progressed with decreased base of support, open chain, or unstable surface.
- Axial compression drills: closed chain on unstable surface (i.e., Airex pad, weighted ball, tilt boards)
- Manual perturbation to the trunk while in dynamic closed chain loaded position
  - Half or tall kneeling

FIGURE 20-24. Single-leg deadlift with neutral spine. *(From Rainey CE: The use of trigger point dry needling and intramuscular electrical stimulation for a patient with chronic low back pain: A case report. Int J Sports Phys Ther 8:145–161, 2013.)*

- Lower body strengthening
  - Closed kinetic chain exercises and open chain resistance exercises
- Functional exercises
  - Deadlifts/hip hinging progression (see Figure 20-16)
  - Front squats
  - Forward and side lunges
  - Step-ups
  - Push-ups progression: knees to regular
- Plyometrics
  - Lower extremity plyometric drills (i.e., multidirectional lunges, side hops, etc.)
- Sport-specific exercises
  - Lower extremity sport-specific drills in a controlled environment (i.e., hopping, jumping, changes in direction/agility drills)

Phase III: Sport-Specific Training (weeks 13 to 24)

Program Design/Performance Training Program

Sport-Specific Concepts of Integrated Training

- Low-impact plyometric training
- Functional training
- Sport-specific training

Training Principles Used in the Design of the Program

- Principle of progression
- Principle of overload
- Principle of variation
- Principle of individualization
- Principles of specificity; specific adaptation to imposed demands (SAID)

Application of Acute Training Variables

- The intensity for plyometrics varies depending on the activity and should start from relatively easy exercises, such as skipping, and progress to more difficult or higher intensity exercises like depth jumps.
- The frequency of plyometric training should range from 1 to 3 sessions per week allowing 48 to 72 hours of recovery between sessions.
- Rest between sets is generally 2 to 3 minutes allowing a work-to-rest ratio of 1:5 to 1:10.
- Training volume is determined by how many times the athlete's foot contacts the floor and should range between 100 to 140 contacts depending on the individual.
- Repetitions: varies depending on activity.
- Plyometrics: 100 to 140 contacts per session.
- Sets: 3 to 5
- Rest interval: work-to-rest ratio of 1:5 to 1:10 (2 to 4 minutes)
- Intensity: moderate to high
- Training frequency: 1 to 3 times per week (no consecutive days)

- Training duration: 30 to 60 minutes
- Specific exercises used in training:
  - Continue appropriate previous exercises from Phase II
  - Full lumbo-pelvic-hip stretching techniques
    - Continued use of sustained end range stretching
  - Progress lower extremity, gluteal, and hip strength exercises.
  - Multijoint movements
    - Front squats, power cleans, military press, etc.
  - Continue Phase II resistance exercises with progression
  - Sensorimotor exercises (proprioception, kinesthesia)
    - Ball toss exercises in standing
    - D1/D2 movements with cables
    - Medicine ball trunk rotations
    - Rapid repositioning drills and reaction movement drills
  - Open (OKC) and closed (CKC) kinetic chain exercises
  - Advancing the Phase II exercises in accordance with sport-specific demands
    - OKC: Kettle bell swings and snatches, lower and upper extremity proprioceptive neuromuscular facilitation (PNF) patterns
    - OKC/CKC: Tall or half-kneeling with diagonal lift and chop resistance exercises
    - CKC: Side planks, front planks, and weight shifts on stable and progress to unstable surfaces.
  - Advance endurance sets to strength exercises
  - Neuromuscular dynamic stability exercises
    - Pushup progression then leads to dynamic floor pushups
    - Resistance exercises in standing progress from double- to single-leg stance, asymmetrical resistance, and unstable surfaces as necessary
    - Kettle bell Turkish get-ups (Figure 20-25)
  - Plyometrics
    - Begin with chest pass motions into a rebounder and progressing to single arm tosses
    - Overhead bilateral medicine ball slams and overhead medicine ball catching
    - Continue lower extremity plyometric drills (i.e., multidirectional lunges, side hops, etc.)
  - Functional exercises
    - Continue deadlifts, front squats, and lunges
    - Kettle bell swings (see Figure 20-22)
    - Overhead strengthening is incorporated as well as lower extremity agility drills including ladder and hurdle drills and running progression (intervals, sprints).
    - Resistance exercises in standing progress from double-leg to single-leg stance, asymmetrical resistance and unstable surfaces
    - Begin lower extremity agility program
    - Sport-specific exercises
    - Lower and upper extremity sports specific drills
  - Progression to formal strength and conditioning commences once full gross strength, AROM, and are pain-free with activity.

Sports Performance Testing

General Information

- General patient history
- Subjective questionnaires: VAS, ODI, SF-36
- Medical history
- Sports injury history
- Surgical history
- Chronic conditions/medication

Objective Tests

- Movement performance screening: Functional Movement Screen (FMS). Studies have shown that FMS reliably predicts injury risk in many active populations/sports, including volleyball, soccer, basketball, football, and military.[9–11]
- Dynamic movement testing: upper/lower body Y Balance Test[12–13]

Specific Criteria for Progression to the Next Stage to Determine Readiness for Gymnastics

- The Functional Movement Screen and Y Balance Test can be used to determine the risk of injury and movement asymmetries when considering an athlete's return to sport.[9–13]
- Progress to advance stages per patient pain tolerance.
- Li and Hresko state athletes may return to sport when they demonstrate normal strength, normal ROM, and no pain with sport-specific activity.[3]

Specific Criteria for Release to Unsupervised Complete Participation in Gymnastics

- Complete resolution of symptoms and maintenance of all objective testing (normal strength, ROM, movement assessment, injury risk appraisal, etc.) used to determine readiness for gymnastics.

Recommended Ongoing Exercises

- Lumbar/core stabilization exercises, along with thoracic spine and hip mobility activities, are essential to be maintained and continued indefinitely while the athlete is participating in the sport.

Multiple-Choice Questions

QUESTION 1. Core strengthening and low-impact cardiovascular activity can begin at what week in the rehabilitation program?

A. Week 2
B. Week 6
C. Week 8
D. Week 12

QUESTION 2. Authors advise that athletes may be limited after surgery if they participate in activities that require:

A. Decreased mobility
B. Extreme mobility
C. Heavy loads
D. Both B and C

QUESTION 3. Authors caution that fusion may be a career-ending surgery for activities that require extreme:

A. Hyperflexion
B. Hyperextension
C. Excessive rotation
D. Decreased extension

QUESTION 4. Name a subjective questionnaire that can be used during lumbar fusion rehabilitation.

A. NDI
B. DASH
C. ODI
D. LEFS

QUESTION 5. At what percentage do surgeons allow return to low-impact, noncontact sports by 6 months postoperatively for both low-grade and high-grade slips?

A. 10% to 16%
B. 22% to 28%
C. 40% to 48%
D. 62% to 66%

Answer Key

QUESTION 1. Correct answer: **A** (See Phase I, Sport-specific concepts of integrated training)

QUESTION 2. Correct answer: **D** (See Literature)

QUESTION 3. Correct answer: **B** (See Literature)

QUESTION 4. Correct answer: **C** (See General information)

QUESTION 5. Correct answer: **D** (See Literature)

Chapter 21

Musculoskeletal Thoracic and Chest Injuries

INTRODUCTION

Paul F. Reuteman, PT, DPT, MHS, OCS, ATC, and Scott A. Escher, MD

Epidemiology

Age, Sex, Sport, and Position

Thoracic Pain

- Musculoskeletal thoracic pain is not as common as cervical or lumbar pain; however, it is typically more prevalent in the athletic population.
- Musculoskeletal sources of pain have been linked to both the costovertebral joints[1] and the facet joints of the thoracic vertebrae.[2] Little data exist on the frequency of pain associated with these structures.
- Thoracic disc injuries are quite rare because of the relative hypomobility of the thoracic spine. They account for only 0.15% to 4% of symptomatic disc herniations of the spine.[3,4]
- Even though thoracic pain is less prevalent, evolving evidence indicates that manual therapy interventions addressing impairments of the thoracic spine may be associated with enhanced outcomes of individuals with neck, shoulder, and upper extremity pain.[5–9]

Chest Wall Pain

- The anatomical structures that can cause chest wall pain are quite varied. A thorough examination is required to consider all the sources of pain.
- In athletes with chest pain, the first priority is to consider potentially life-threatening causes. Structures of the cardiovascular and gastrointestinal system must be considered.
- In the primary care setting, the cause of chest pain is benign in approximately 80% of cases, of which musculoskeletal chest pain accounts for almost 50%.[10]
- Musculoskeletal sources of chest wall pain in athletes can occur in the ribs, sternum, articulations of the ribs and sternum, and myofascial structures. Injury to these structures is commonly a result of direct trauma or overuse. The incidence of these conditions is 13% to 30% in patients seeking care in an emergency department with a primary complaint of chest pain.[11,12]
- Sports associated with musculoskeletal sources of chest pain include golf, baseball, and wrestling.
- Female rowers are especially susceptible to chest and rib injuries.[13]
- Overhead athletes participating in sports such as basketball, tennis, or weightlifting have been found to be susceptible to first rib injuries.[14]

Pathophysiology

Intrinsic Factors

Thoracic Pain

- An association between hypomobility of the thoracic spine and the presence of neck pain has been well documented in the literature.[5,6] It is generally accepted that a similar association exists between thoracic pain but, ironically, evidence is less compelling for this association.

- Postural conditions that create an accentuated thoracic kyphosis and forward head posture have been found to correlate with thoracic and periscapular pain.[15]
- A hyperkyphosis of the *nonpostural* type (nonreversible) is often associated with Scheuermann's disease.[16] To date, there has not been any correlation between pain and the presence of Scheuermann's disease. It has been hypothesized from a biomechanical perspective that intense athletic exercise and training regimens may lead to further progression of hyperkyphosis conditions of either postural or nonpostural types.[16]

Chest Wall Pain

- It is difficult to isolate common underlying impairments associated with pathologies such as costochondritis, stress fractures of the ribs or sternum, and strains of the intercostal muscles. Hypomobility of the thoracic spine and ribs may be associated with these conditions.[17–19] Muscle tightness, especially of the pectoralis minor and serratus anterior, may also contribute to abnormal mechanical stresses to the anterior-lateral structures.
- Athletes are especially susceptible to stress fractures of the rib. The first rib is the most common rib to sustain a stress fracture. It has a point of relative weakness where a deep groove exists for the subclavian artery. Strong contractions of the anterior scalene muscles while a traction force applied to the arm during forceful overhead motion may exceed the bone's loading capacity.[14,20]
- Ribs 4 through 8 are also susceptible to stress fractures. These stress fractures are commonly associated with a strong contraction of the serratus anterior as the athlete moves forcefully into a side-bending and flexion motion, as in golf and softball pitching.[14]

Extrinsic Factors

- A majority of extrinsic factors associated with musculoskeletal thoracic and chest wall pain deals with training errors. A study that sampled 2270 adolescents between 8 and 18 years of age found that increased angles of thoracic kyphosis were associated with greater cumulative training times. Of all the athletes studied, gymnasts trained the most each year and showed the largest thoracic curve. Lack of sports participation was associated with the smallest curve. Age and sex did not significantly have an effect on the degree of curvature.[21]
- Other correlations exist between muscle activity and the prevalence of rib stress fractures and costochondritis. Rowers and golfers are especially prone to rib stress fractures and costochondritis.[22,23]
- In rowers, the co-contraction of the serratus anterior and external obliques exerting opposite forces on the ribs may lead to rib failure.[22] In golfers, the swing mechanics appear to have an influence on the prevalence of stress fractures. Of 19 golfers diagnosed with a rib stress fracture, 16 had stress fractures on their leading side.[24] Electromyography of the serratus anterior on the lead side has shown the muscles to be active during the entire swing.[25]

Traumatic Factors

- As mentioned, musculoskeletal injury to the chest wall and thoracic region are commonly associated with overuse activity.
- However, trauma is also associated with injuries to the chest and thorax. Athletes participating in high collision sports such as football, rugby and wrestling are most susceptible to injuries such as rib fractures. Traumatic rib fractures are quite painful but commonly respond to rest and conservative management. The immediate concern associated with rib fractures is the potential for injury to the underlying tissue.
- Any trauma to the chest may result in a pneumothorax (puncture of the lung and pleura and deflating of the lung) or a laceration of the spleen, liver, or kidney. All of these are considered life-threatening emergencies.
- Complaints of shortness of breath, pain with deep breathing, severe chest or abdominal pain, and asymmetrical chest expansion associated with direct trauma to the chest requires immediate medical attention.
- Another indicator of injury is Kehr's sign, which is pain in the left scapular region referred from the peritoneal cavity. This is considered a classic sign of a ruptured spleen.
- Blood in the urine is considered a sign associated with trauma to the kidney.

Classic Pathological Findings

- It is uncommon for overuse conditions of the thoracic spine and chest wall to present with pathological findings.
- Costochondritis, rib stress fractures, and thoracic musculoskeletal pain rarely present with cardinal signs of inflammation (localized swelling, increased tissue temperature, redness).
- Traumatic fractures to the ribs, sternum or thoracic spine are often accompanied by localized swelling, increased tissue temperature, ecchymosis, and point tenderness.

Clinical Presentation

History

- A thorough subjective examination and history is critical for any person that has primary complaints of either thoracic or chest wall pain.
- Professional responsibilities require the practitioner to especially ask questions regarding the cardiovascular system. Specific concern is if the athlete complains of chest pain and tightness or shortness of breath with activity or a general decrease in exercise tolerance.
- Once cardiovascular conditions have been ruled out, common subjective complaints associated with musculoskeletal sources of thoracic and chest pain may be addressed.

Thoracic Pain

- Common complaints associated with musculoskeletal thoracic pain include pain along the spine, either bilaterally or unilaterally. Pain in the thoracic region

may be very specific to the level of the dysfunction or it may be vague because of the referral patterns associated with the thoracic facet joints.[2]
- The onset of pain may correlate with an increase in the athlete's training volume and intensity.
- Pain is commonly aggravated with movement of the thoracic spine, especially with rotation and/or extension. Deep breathing and coughing will often exacerbate the pain as well.

Chest Wall Pain

- As with thoracic pain, musculoskeletal causes of chest wall pain are often associated with a change in activity or from direct trauma.
- Pain is localized to the costosternal or costochondral joints or along the ribs. Pain is usually exacerbated with upper extremity motions such as horizontal adduction or trunk rotation and/or extension.
- Athletes may report symptoms with increased activity or repetitions of a specific motion (e.g., trunk rotation with flexion) or with deep breathing.
- In the presence of costochondritis, pain may be associated with a popping sensation in the vicinity of the costochondral joint.[17] This popping sensation may be quite painful when it occurs but may provide a temporary reduction of symptoms.
- In the presence of stress fractures, athletes commonly complain of specific pain at the region of the fracture. This pain may be present at rest but is certainly aggravated with activity.
- First rib stress fractures often produce dull, aching pain in the neck and shoulder complex.
- Stress fractures to the middle ribs (usually 4 to 8) are accompanied with complaints of mid-costal pain especially with deep breathing or rolling over in bed.[1]
- In the presence of a traumatic fracture of a rib, the athlete can usually recall a single event in which the chest wall suffered a direct blow.

Physical Examination

Abnormal Findings

- A standardized protocol to assess chest and thoracic pain has been proposed by several authors.[10,26] It consists of three parts: a structured interview, a general health examination, and a specific manual examination of the muscles and joints of the neck, thoracic spine, and chest wall. The use of a standardized protocol to evaluate for musculoskeletal chest pain has been found to have substantial interobserver reliability.[26]
- Once it has been deemed from the interview and general health examination that the source of pain is stemming from the musculoskeletal system, the examination attempts to reproduce the patient's pain by implying mechanical stresses to the anatomical structures.
- Assessment of the following is necessary: Active motion of the trunk, palpation, mobility assessment of the thoracic spine, and assessment of flexibility of the muscles in the thoracic region. A thorough examination will identify impairments necessary to address in the intervention plan.
- For musculoskeletal conditions of both the thorax and chest, common findings include pain and/or limited motion during active range of motion (ROM) of the thoracic region. Range of motion of the thoracic region is commonly assessed in standing and/or sitting and specific attention is paid to flexion, extension, and rotation (Figures 21-1 to 21-4). Provocation of symptoms is deemed a more valuable finding during motion assessment because it is challenging to measure exact degrees of motion. To further elicit symptoms, overpressure may be applied at the end range of motion (Figures 21-5 to 21-7).

FIGURE 21-1. Assessment of active thoracic flexion.

- Determination of palpable tenderness provides more specific detail of the location of the patient's symptoms. Palpation of posterior structures includes the erector spinae muscles, the spinous and transverse processes, and the posterior and lateral ribs. Palpation of anterior structures includes the sternum, sternocostal joints, costochondral joints, anterior ribs, pectoralis minor/major, subclavius, and intercostal muscles.
- Many authors have identified aberrant or decreased mobility of the thoracic spine as a contributing factor in many of the overuse injuries of the thorax and chest.[17–19,26]
- Assessment of thoracic mobility is commonly performed by applying a posterior to anterior (PA) pressure to different levels of the thoracic spine when the patient is in a prone position (Figure 21-8). The clinician assesses the magnitude of motion with respect to the force applied and qualitatively determines joint

FIGURE 21-2. Assessment of active thoracic extension.

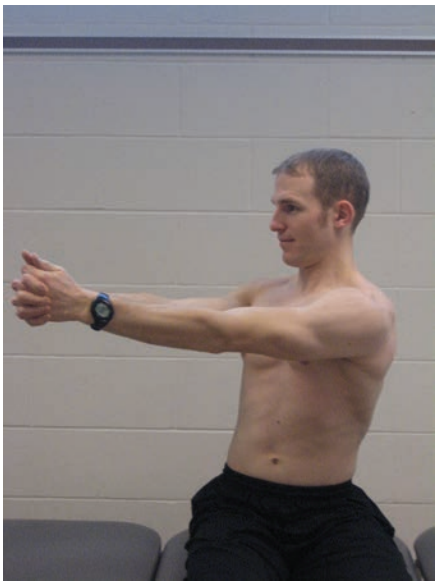

FIGURE 21-3. Assessment of active thoracic right rotation.

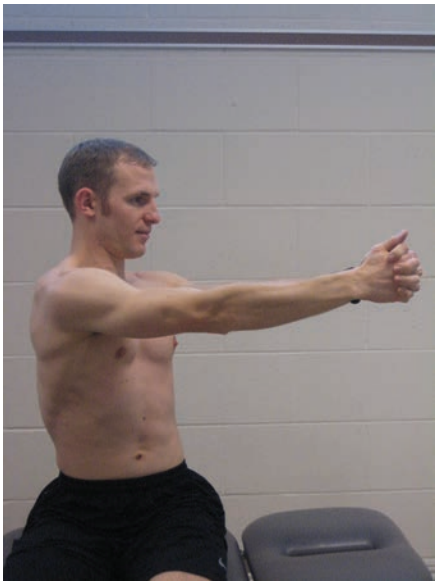

FIGURE 21-4. Assessment of active thoracic left rotation.

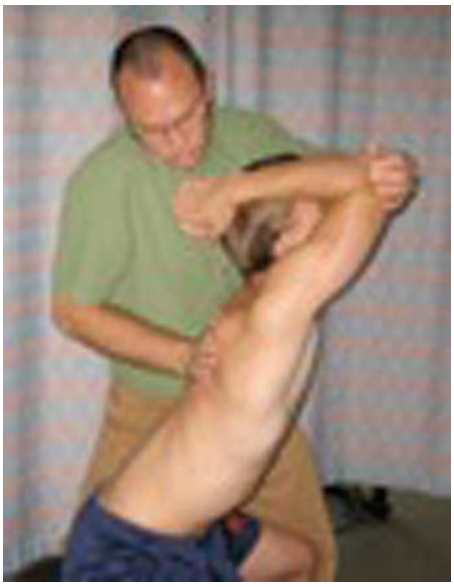

FIGURE 21-5. Assessment of thoracic extension with overpressure.

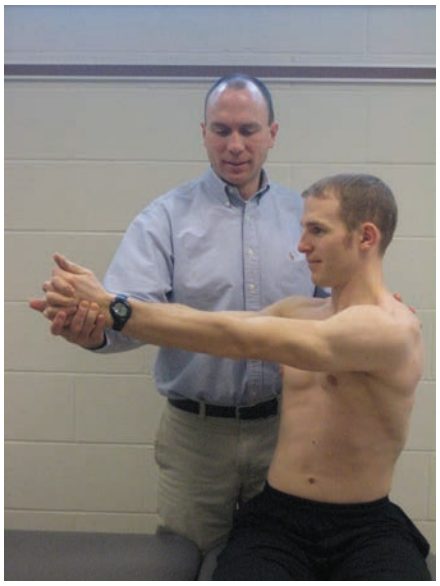

FIGURE 21-6. Assessment of thoracic right rotation with overpressure.

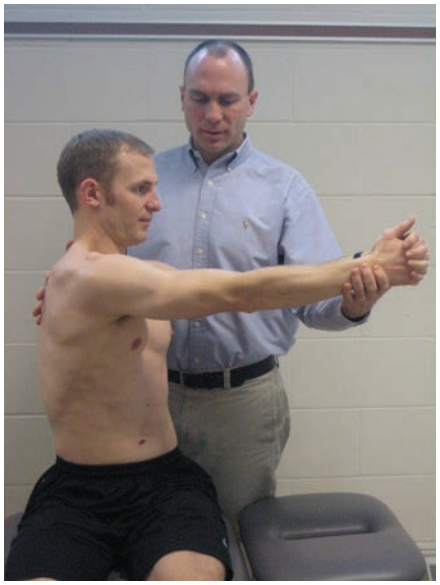

FIGURE 21-7. Assessment of thoracic left rotation with overpressure.

FIGURE 21-8. Assessment of posterior-anterior mobility of the thoracic spine.

stiffness.[27,28] In addition to assessing joint stiffness, the clinician also inquires about pain during the application of force. Both intra- and inter-assessment reliability was found to be moderate to very good for both joint mobility and pain provocation assessment.[27]

Pertinent Normal Findings

- As described, a thorough evaluation must be performed to rule out non-musculoskeletal causes of chest and thoracic pain. It is important to take a clear history of the present symptoms and a general health history of the athlete.
- In the presence of musculoskeletal pain, normal findings should be found during the assessment of vital signs, auscultation of the heart, lung, and neck, abdominal palpation, and a neurological examination of the extremities.
- If the patient does not present with any significant signs or symptoms associated with the gastrointestinal and cardiovascular system, the clinician should proceed onto assessment of the musculoskeletal structures.

Imaging

Thoracic Pain

- If the athlete has sustained a traumatic injury, it is standard practice to order a traditional series of radiographic films of the thoracic spine.
- Other imaging studies to assess for fractures in the thoracic region may include the use of a bone scan, CT scan, or MRI.
- In the absence of traumatic injuries of the thoracic region, imaging of the thoracic spine typically does not provide much benefit.

Chest Pain

- Again, if the athlete has sustained a traumatic injury, it is standard practice to order a traditional series of radiographic films of the chest.
- For overuse injuries, a bone scan may be used to diagnose the presence of a stress fracture. A CT scan or MRI may also be ordered for more detail of the bony structures. The MRI has an added benefit of visualization of the soft tissue structures of the thorax.

Differential Diagnosis

- Currently a diagnosis of musculoskeletal chest and thoracic pain can be difficult to establish because there is no reference standard to verify the diagnosis. Except for traumatic fractures or stress fractures of the thorax, there are no diagnostic tests to confirm a diagnosis of musculoskeletal pain.
- Therefore any musculoskeletal pain is often a diagnosis made when other conditions have been excluded.
- Some of the conditions that could be confused with chest and thoracic musculoskeletal pain include
  - Gastroesophageal reflux diseases (GERD): Athletes often present with burning retrosternal pain and may have a dry cough and sore throat.
  - Pancreatitis: Acute pancreatitis causes severe epigastric and lower chest pain, it may be associated with vomiting and can be life threatening. Blood tests are performed to rule out this condition.
  - Exercise-induced asthma (EIA): Symptoms of EIA include chest tightness/pain, dyspnea, wheezing, coughing, and fatigue. Diagnosis is confirmed by stress pulmonary function testing or methacholine challenge testing.
  - Lower respiratory infections: These can include bronchitis, influenza, and pneumonia. Inflammation of the pleura and overuse of the muscles around the chest wall from excessive coughing are often a cause of chest pain. These conditions can be accompanied by a fever and dyspnea.
  - Spontaneous pneumothorax: This is an uncommon condition associated with severe chest pain and shortness of breath. Diagnosis is confirmed by chest films. An association with Alpha-1 antitrypsin (AAT) deficiency has been identified with this condition.
  - Pericarditis: This is an inflammation of the pericardium usually caused by an infection. Chest pain is the primary symptom and is often worsened by lying down and relieved by sitting forward. It typically presents with characteristic ECG changes including upward-concave ST-segment elevation in all leads.[29] A complication of pericarditis may be pericardial effusion, which may be seen on an echocardiography.
  - Myocarditis: This is an inflammatory disease of the heart most commonly caused by a viral infection or noninfectious agents such as drugs (e.g., cocaine). Physical activity increases the inflammation seen in myocarditis and leads to complications of dilated cardiomyopathy, heart failures, arrhythmias, and death.[29] Symptoms include chest pain, fatigue, dyspnea, reduced exercise tolerance, and/or palpitations. Diagnostic studies include an ECG, echocardiography, cardiac MRI, or an endomyocardial biopsy.

Treatment

Nonoperative Management

- Because of the infrequent nature of musculoskeletal chest and thoracic pain in athletes, there is a lack of high-level randomized trials that assess best practice for intervention. Case reports dominate the literature on treatment options.
- Therefore a majority of the intervention, whether the pain is anterior or posterior, is intended to address underlying impairments of the cervical, thoracic, and lumbar region that have been identified during the examination of the athlete (e.g., thoracic hypomobility, muscular tightness, poor trunk strength and endurance, postural considerations).
- Special consideration must be made in the management of rib stress fractures. Treatment of first rib stress fractures involves immobilization of the upper extremity in a sling for 4 weeks with a gradual return to activity.
- Management of other rib stress fractures requires relative rest for 4 to 6 weeks. Light training and

cardiovascular conditioning may be undertaken during this time. Return to full competition is commonly allowed around 8 weeks.

Guidelines for Choosing Among Nonoperative Treatments

- Manual therapy options
  - Thoracic posterior-anterior (PA) and anterior-posterior (AP) mobilizations or thrust manipulations. Currently only one study, a nonrandomized trial with several limitations, has assessed the effectiveness of manual therapy directed at the thoracic spine to address chest and thoracic pain.[30] In this study, approximately 75% of the patients described a self-reported improvement in pain and general health following treatment involving thrust techniques to the thoracic region.
  - Several studies have identified a subset of patients with neck and shoulder pain that may benefit from these manual therapy interventions. It is believed that these techniques may enhance general mobility of the thoracic spine and costovertebral joints resulting in decreased pain and enhanced function.[5,6,9,31]
  - Soft tissue mobilizations to the tight and tender musculature of the thoracic and chest region
- Self-mobilization of the thoracic spine. These exercises are prescribed as a supplement to the manual therapy interventions described above.
- Stretching of musculature of the trunk with special attention to the pectoralis major/minor and the latissimus dorsi.
- Strengthening of the musculature of the trunk with special attention to the lower/middle trapezius and serratus anterior.

Surgical Indications

- There are no surgical indications for the pathologies discussed in this chapter.

Evidence

Coriss EE, Higgins HW: First rib stress fractures in throwing athletes. *Am J Sp Med* 33(9):1400–1404, 2005.

This report describes a unique case of a 20-year-old baseball player with a first rib stress fracture of the dominant arm. Differential diagnosis and intervention are discussed. (Level V evidence)

Davis BA, Finnoff JT: Diagnosis and management of thoracic rib pain in rowers. *Curr Sports Med Rep* 2:281–287, 2003.

This report reviews the literature and describes the various causes of rib pain in rowers and also provides insight into methods to make an appropriate diagnosis and develop an effective intervention plan. (Level V evidence)

Gregory PL, Biswas AC, Batt ME: Musculoskeletal problems of the chest wall in athletes. *Sports Med* 32(4):235–250, 2002.

This is a review intended to assist the clinician on diagnosing chest wall pain in athletes by identifying the possible causes as reported in the literature. (Level V evidence)

Rambey IM: Costochondritis: Are the symptoms and signs due to neurogenic inflammation? Two cases that responded to manual therapy directed towards posterior spinal structures. *Man Ther* 13:82–86, 2008.

This is a series of two case reports of individuals with musculoskeletal related chest pain that depicts the use of manual therapy to enhance outcomes. (Level IV evidence)

Sik EC, Batt ME, Heslop LM: Atypical chest pain in athletes. *Curr Sports Med Rep* 8(2):52–58, 2009.

This review looks at the possible causes of atypical chest pain in athletes, focusing on conditions that are more common in athletes than the general population or have a link to exercise. (Level V evidence)

Stochkendahl MJ, Christensen HW: Chest pain in focal musculoskeletal disorders. *Med Clin North Am* 94:259–273, 2010.

This is a review article that discusses the different sources of chest pain and differential diagnosis of different pathologies, and describes a systematic examination for chest pain that leads to appropriate intervention. (Level V evidence)

Multiple Choice Questions

QUESTION 1. Which of the following statements is true regarding kyphosis of the thoracic spine?

A. Thoracic manipulation has been found to decrease the kyphosis of the thoracic spine.
B. A strong correlation exists between thoracic pain and kyphosis angles of the thoracic spine.
C. Thoracic kyphosis angles were found to increase with greater training times and intensity.
D. Those participating in swimming were found to have the greatest kyphosis angles.

QUESTION 2. Which of the following is NOT a sign or symptom associated with a pneumothorax?

A. Shortness of breath
B. Bruising of the costal region
C. Asymmetrical chest expansion
D. Pain with deep breathing

QUESTION 3. Which of the following statements regarding assessment of thoracic mobility is true?

A. Thoracic mobility is assessed in a posterior to anterior direction while the athlete is prone. It has been found to have adequate reliability.
B. Thoracic mobility is assessed in a posterior to anterior direction while the athlete is supine. It has been found to have adequate reliability.
C. Thoracic mobility is assessed in a posterior to anterior direction while the athlete is prone. It has been found to have poor reliability.
B. Thoracic mobility is assessed in a posterior to anterior direction while the athlete is supine. It has been found to have poor reliability.

QUESTION 4. Which of the following statements is inaccurate regarding myocarditis?

A. There are very few symptoms associated with myocarditis.
B. Myocarditis may be caused by a viral infection or noninfectious agents (e.g., cocaine).
C. A complication associated with myocarditis may be potential death.
D. Diagnostic studies to confirm myocarditis include ECG, echocardiography, cardiac MRI, or an endomyocardial biopsy.

QUESTION 5. Which statement is true regarding the use of thoracic manipulations/mobilizations?

A. Thoracic manipulations have been found to be very specific to a segment of the thoracic spine.
B. Strong evidence exists for the use of thoracic manipulation for musculoskeletal pain of the thoracic region
C. A subset of patients has been identified in the literature that may benefit from these techniques.

Answer Key

QUESTION 1. Correct answer: **C** (see Pathophysiology)

QUESTION 2. Correct answer: **B** (see Pathophysiology)

QUESTION 3. Correct answer: **A** (see Clinical Presentation)

QUESTION 4. Correct answer: **A** (see Differential Diagnosis)

QUESTION 5. Correct answer: **C** (see Treatment)

NONOPERATIVE REHABILITATION OF MUSCULOSKELETAL THORACIC SPINE AND CHEST INJURIES

Paul F. Reuteman PT, DPT, MHS, OCS, ATC

GUIDING PRINCIPLES OF NONOPERATIVE REHABILITATION

- In the presence of acute traumatic fractures or stress fractures of the ribs or thoracic vertebrae, time must be allowed for adequate healing of the fracture. Typically, active rest is prescribed in the first 4 to 6 weeks of treatment. For the sake of this chapter, we will be focusing on pain and impairments not related to a confirmed fracture.
- Conservative management is guided by an impairment-based approach. Common impairments associated with musculoskeletal thoracic and chest pain include:
  - Postural considerations
  - Thoracic and cervical motion restrictions.
  - Thoracic and rib hypomobility
  - Muscular tightness, especially the pectoralis major/minor and the latissimus dorsi
  - Poor neuromuscular control, strength and endurance of muscles of the thoracic region, especially the serratus anterior, lower and middle trapezius and the spinal muscles

Phase I (weeks 2 to 4)

Protection

- In the presence of acute pain that is quite debilitating, early protection and "active rest" is advocated. Avoidance of provocative activities while still allowing the athlete to engage in tolerable cardiovascular conditioning and/or strengthening is recommended.

Techniques for Progressive Increase in Range of Motion

Manual Therapy Techniques

- Thoracic posterior-anterior (PA) and anterior-posterior (AP) mobilizations or thrust manipulations (Figs 21-9 to 21-11). Currently, only one study, a nonrandomized trial with several limitations, has assessed the effectiveness of manual therapy directed at the thoracic spine to address chest and thoracic musculoskeletal pain.[1] Approximately 75% of patients studied described a self-reported improvement in pain and general health after treatment involving thrust techniques to the thoracic region.
- Several studies have identified a subset of patients with neck and shoulder pain that may benefit from these manual therapy interventions. It is believed that these techniques may enhance general mobility of the thoracic spine and costovertebral joints and improve rehabilitation outcomes.[2–7] These techniques are thought to be quite general and are not intended to target one specific segment.[8] Mobilizations and thrust manipulations have been found to have no greater negative side effects than therapeutic exercise.[9]

Soft Tissue Techniques

- Soft tissue mobilization to musculature of the thoracic and chest region. Special attention is directed to the structures that are tight and/or tender (pectoralis minor, thoracic paraspinal muscles).

Stretching and Flexibility Techniques for the Musculotendinous Unit

- Self-mobilization of the thoracic spine performed by the patient to enhance extension and rotation range of motion (Figs. 21-12 to 21-15).

TIMELINE 21-1: **Nonoperative Rehabilitation of Musculoskeletal Thoracic and Chest Injuries**

PHASE I (weeks 0 to 4)	PHASE II (weeks 4 to 12)

• "Active rest": Engaging in activity that does not provoke pain
• Manual therapy interventions:
  • Thoracic mobilizations and thrust manipulations
  • Soft tissue mobilization
• Self-range of motion to the thoracic region with specific attention to extension and rotation
• Self-stretching with specific attention to the latissimus dorsi and pectoralis minor
• Strengthening with specific attention to the serratus anterior and the lower trapezius
	• Manual therapy interventions as stated earlier to address further pain and impairments.
	• Continued self-stretching and range of motion.
	• More advanced strengthening with specific attention to addressing core stability
	• Gradual return to athletic activity as the patient tolerates

FIGURE 21-9. Prone PA mobilization and thrust manipulation to the mid thoracic spine.

- Stretching of musculature of the trunk with special attention to the pectoralis major/minor and the latissimus dorsi

Other Therapeutic Exercises

- Appropriate muscle strength and balance of the primary muscles of the scapulothoracic region (trapezius, serratus anterior, rhomboids and pectoralis minor) is critical for coordinated movement of the shoulder complex and the thoracic region. These muscles attach distally on the scapula and have a significant proximal attachment on both the thoracic spine and ribs. Strengthening of these muscles enhances outcomes for shoulder rehabilitation but they must also be considered in the management of musculoskeletal chest and thoracic pain.
- Muscle activation and strengthening exercises are initiated in phase I of the rehabilitation with specific attention to the serratus anterior and middle and lower trapezius.
- A common progression of serratus anterior strengthening involves: Supine scapular protraction → pushups with a plus (scapular protraction) → dynamic hug with a Thera-Band → serratus punch at 120°[10] (Figs. 21-16 to 21-19).

FIGURE 21-10. Supine AP thrust manipulation to the mid thoracic spine.

FIGURE 21-11. Supine AP thrust manipulation to the upper thoracic spine.

FIGURE 21-12. Self mobilization of the thoracic spine into extension over a therapy ball.

FIGURE 21-13. Self mobilization of the thoracic spine into extension over the edge of a table.

FIGURE 21-14. Self mobilization of the thoracic spine into extension over the edge of a chair.

FIGURE 21-15. Self mobilization of the thoracic spine into rotation while side sitting in a chair.

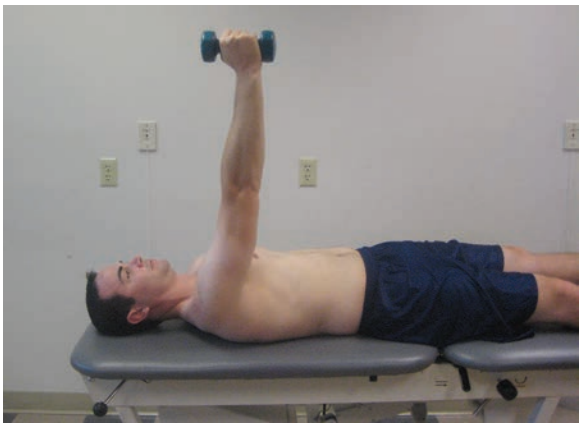

FIGURE 21-16. Supine scapular protraction.

FIGURE 21-17. Push up with a plus (scapular protraction).

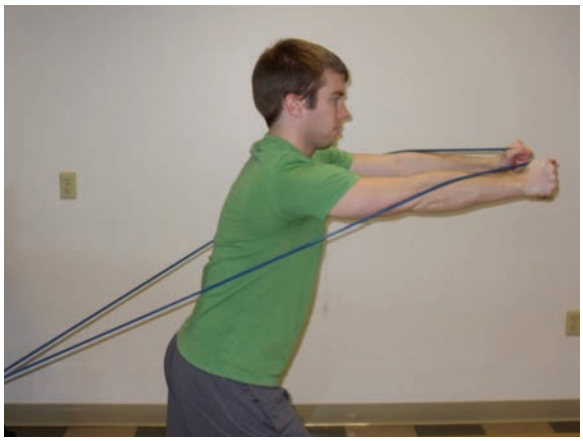

FIGURE 21-18. Dynamic hug with a Thera-Band.

- A common progression of lower trapezius strengthening exercises involves: Bilateral external rotation in standing with use of a Thera-Band → prone horizontal abduction with glenohumeral joint externally rotated at 90° → prone horizontal elevation with glenohumeral joint at 120°[10] (Figs. 21-20 to 21-22).

Milestones for Progression to the Next Phase

- Near pain-free range of motion of the thoracic spine noted, especially into extension and rotation.
- Improved mobility of the thoracic spine and little to no pain reported during assessment of mobility.
- Symmetrical flexibility of the pectoralis major/minor and serratus anterior muscles noted during standardized assessment of muscle length.
- Adequate neuromuscular control of the lower trapezius and serratus anterior as indicated during the exercises prescribed to effectively progress to activities that involve more functional strengthening and endurance.

FIGURE 21-19. Serratus punch at 120° with a Thera-Band.

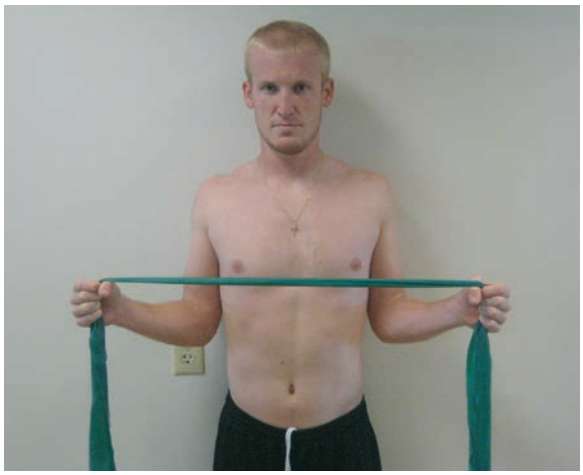

FIGURE 21-20. Bilateral external rotation in standing with use of a Thera-Band.

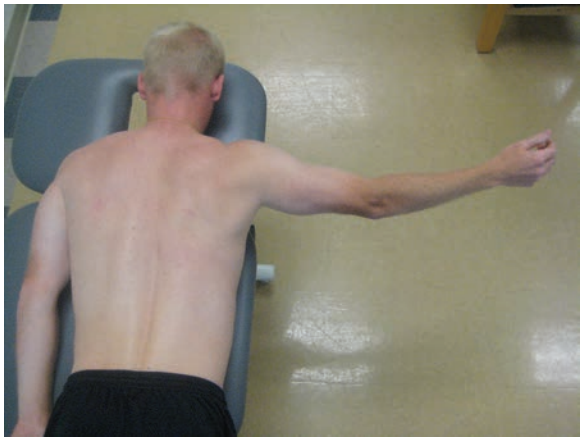

FIGURE 21-21. Prone horizontal extension with glenohumeral joint externally rotated at 90°.

FIGURE 21-22. Prone horizontal extension with glenohumeral joint at 120°.

FIGURE 21-23. Prone planks on a therapy ball with scapular protraction.

Phase II (weeks 4 to 12)

Techniques for Progressive Increase in Range of Motion

Manual Therapy Techniques

- In the presence of persistent pain that has less effect on overall function but still limits the athlete from competing in their sport, continued manual therapy interventions are considered but more advanced strengthening exercise are recommended.
- The manual therapy, soft tissue, and stretching techniques explained above are continued as needed to address remaining impairments of the thoracic spine and ribs.

Other Therapeutic Exercises

- For Phase II, other therapeutic exercises are prescribed involving advanced core stability with specific attention to the following:
  - Deep abdominal strengthening activities in a plank position on a therapeutic ball where the patient can also focus on serratus activation (prone planks on a therapy ball) (Fig. 21-23). Further challenges are imposed to facilitate transverse trunk stability (Figs. 21-24 to 21-25).

FIGURE 21-24. Prone planks on a therapy ball with hip extension.

FIGURE 21-25. Prone planks on a therapy ball with hip flexion and trunk rotation.

FIGURE 21-27. Prone on a therapy ball, bilateral glenohumeral extension.

- Bridging activities with resisted upper extremity motion (ex: PNF lift and chop) (Fig. 21-26).
- Prone exercises over a therapy ball involving active glenohumeral extension, horizontal abduction and elevation to further challenge the posterior scapulothoracic muscles (Figs. 21-27 to 21-29).
- Other exercises may be initiated that replicate the motion of the athlete during their sport activity.

Evidence

Christensen HW, Vach W, Gichangi A: Manual therapy for patients with stable angina pectoris: A nonrandomized open prospective trial. *J Manipulative Physiol Ther* 28:654–661, 2005.

This prospective, nonrandomized study of 50 patients with musculoskeletal chest pain assessed the effectiveness of manual therapy approaches to manage the patients' symptoms. At a 4-week follow up, 75% of subjects reported an improvement in pain and function assessed by an 11-point pain scale and a SF-36 form respectively. (Level IIc evidence)

FIGURE 21-29. Prone on a therapy ball, bilateral glenohumeral elevation.

the thoracic spine in patients with neck pain: A randomized clinical trial. *Phys Ther* 87(4):431–440, 2007.

This prospective randomized clinical trial of 60 patients compared the use of thoracic non-thrust mobilization to thrust manipulation in the treatment of their neck pain. Subjects in the thrust manipulation group exhibited significantly higher scores on the GROC Scale and reduction in pain four days following treatment. No difference in the frequency, duration, and types of side effects existed between the two groups. (Level Ic evidence)

Cleland JA, Mintken PE, Carpenter K, et al: Examination of a clinical prediction rule to identify patients with neck pain likely to benefit from thoracic spine thrust manipulation and a general cervical range of motion exercise: multi-center randomized clinical trial. *Phys Ther* 90(9):1239–1250, 2010.

This multicenter randomized clinical trial of 140 patients with a primary complaint of neck pain compared therapeutic exercise to therapeutic exercise and manipulation in the treatment of their pain. Subjects were randomly assigned to two groups. Those who received thoracic spine manipulation exhibited significantly greater improvements in disability at both 4 weeks and 6 months and in pain at 1-week follow-up. (Level Ib evidence)

Grindsaff TL, Beazell JR, Saliba EN, et al: Treatment of a female collegiate rower with costochondritis: A case report. *J Man Manip Ther* 18(2):64–68, 2010.

This case report provides insight into the characteristics, examination, clinical impressions and intervention of a 21-year-old female collegiate rower with multiple episodes of costochondritis over a one year period. (Level IV evidence)

Ian Rabey M: Costochondritis: Are the symptoms and signs due to neurogenic inflammation. Two cases that responded to manual therapy directed towards posterior spinal structures. *Man Ther* 13:82–86, 2008.

This study reviewed two patients who were diagnosed with costochondritis. Both patients were managed with manual therapy approaches, including oscillatory joint mobilizations and thrust manipulations, to enhance upper and mid thoracic spinal mobility and improve motor control of the scapulothoracic muscles. Both subjects had favorable outcomes of care. (Level IV evidence)

Multiple-Choice Questions

QUESTION 1. Which muscles should be strengthened in the early phase of rehabilitation for patients with musculoskeletal thoracic and chest pain?

A. Pectoralis minor and latissimus dorsi
B. Lower trapezius and serratus anterior
C. Upper trapezius and levator scapulae
D. Deep abdominals and gluteus maximus

QUESTION 2. Which of the following statements are true regarding joint mobilizations/manipulations of the thoracic region?

A. Thrust manipulations should be avoided in the thoracic region.
B. Thrust manipulations have been found to have greater side effects than mobilizations.
C. Thrust manipulations of the thoracic spine have been found to be helpful in decreasing pain and improving function.

QUESTION 3. "Active rest" is defined by which of the following?

A. The athlete may engage in cardiovascular conditioning and general strengthening as long as it does not reproduce their symptoms.
B. The athlete should rest for the first 4 weeks of rehabilitation and not engage in any cardiovascular or strengthening activities.
C. The athlete visualizes self-performing the sport-specific activity.

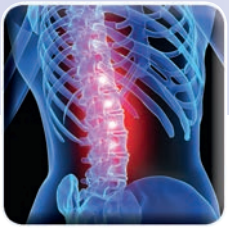
Answer Key

QUESTION 1. Correct answer: **B** (see Phase I)

QUESTION 2. Correct answer: **C** (see phase I)

QUESTION 3. Correct answer: **A** (see phase I)

Chapter 22



Cervical Spine Strains, Sprains, and Burners

INTRODUCTION

Nelson S. Saldua, MD

Epidemiology

- Cervical injuries often occur in contact sports. Approximately 1.4 million athletes play tackle football annually at the high school, collegiate, or professional levels.
- Cervical injuries occur in 10% to 15% of football players. Although these injuries can occur in a player of any position, there does seem to be a predilection for linemen, defensive ends, and linebackers.

Pathophysiology

Intrinsic Factors

- Cervical ligament sprains can occur with any forced neck motion that results in stretching or tearing of the cervical ligaments.
- Athletes with preexisting cervical stenosis are predisposed to some cervical injuries during the collisions inherent to contact sports.
- The Pavlov-Torg ratio is a radiographic measurement for detecting the presence of cervical stenosis (or tight cervical spine canal). Using a lateral cervical radiograph, it is determined by measuring the anterior-posterior width of the spinal canal and dividing that by the anterior-posterior length of the cervical vertebral body. Cervical stenosis is present if this ratio is less than 0.8 (Figure 22-1).
- "Burners" or "stingers" usually occur after a direct blow to the neck and/or shoulder resulting in downward displacement of the ipsilateral shoulder with concomitant lateral neck flexion to the contralateral shoulder. This results in a traction injury to the ipsilateral brachial plexus. Another mechanism of injury includes an extension-compression model. In this case, the cervical spine is extended and then lateral flexion results in a compression injury of the brachial plexus (Figure 22-2).

Extrinsic Factors

- Use of helmets in tackle football has decreased the incidence of head injuries but may have led to more cervical spine injuries. The postulated reason for this

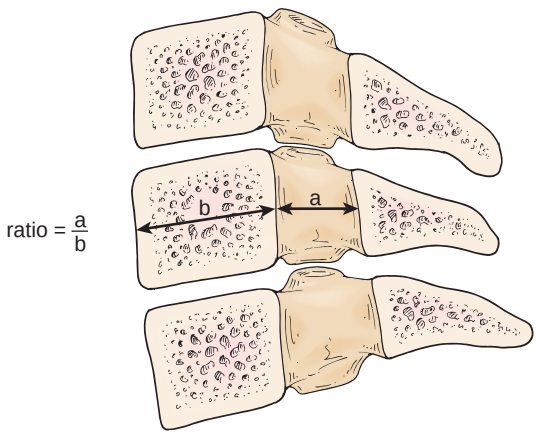


FIGURE 22-1. The Pavlov-Torg ratio is determined by dividing the anterior-posterior diameter of the spinal canal by the anterior-posterior length of the adjacent vertebral body.

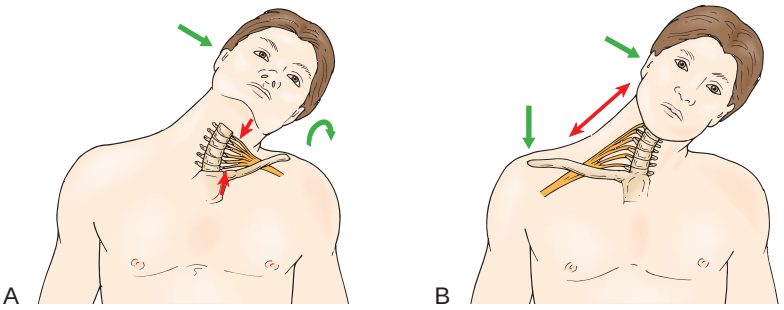

FIGURE 22-2. The two proposed mechanisms for stingers/burners are either traction to the brachial plexus or compression of the brachial plexus.

increase is the tackling technique of using the crown of the head as the initial point of contact with the opposing player (Figure 22-3).
- The postulated reason for this increase is using the tackling technique of using the crown of the head as the initial point of contact with the opposing player.

Traumatic Factors

- Axial loading of the head and neck can lead to bony and ligamentous injuries to the cervical spine.
- Because of the normal lordosis of the cervical spine, when the cervical spine is flexed to approximately 30° the cervical spinal vertebral bodies become a straight column. Axial loading of this straight column does not allow the force applied to be dissipated by the paraspinal muscles and is therefore applied directly to the spinal column.

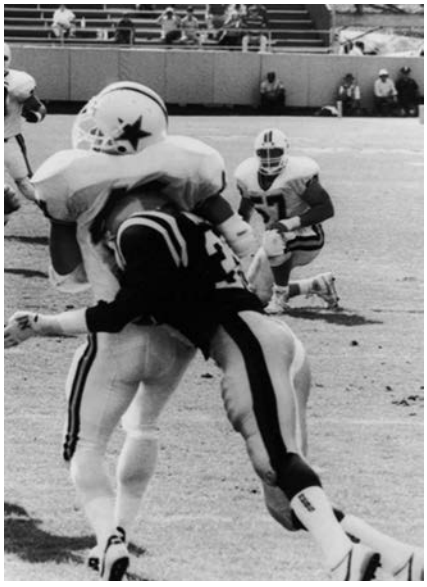

FIGURE 22-3. Use of the helmet as the initial point of contact is a risk factor for cervical injuries. In this position, the cervical vertebral column is straight, and this loss of normal lordosis is postulated to transmit more energy to the vertebral column directly rather than allowing the energy to be dissipated by the paraspinal muscles.

- Enforcement of tackling rules (spearing, helmet-to-helmet contact) may also continue to decrease the risk, although the data are still lacking.

Classic Pathological Findings

- A cervical sprain is a ligamentous injury that often results from a direct collision. The athlete will usually complain of pain localized to the neck without upper extremity radiation. This pain can be provoked or worsened with direct palpation.
- Because of the pain associated with a cervical sprain, the athlete will often guard against active or passive range of motion of the cervical spine.
- The neurologic exam after a cervical sprain is nonfocal, with full and symmetric strength in both upper and lower extremities as well as lack of sensory deficits.
- A "burner" or a "stinger" is a transient neurologic event that affects one single upper extremity. The athlete often describes tingling, burning, or numbness in a nondermatomal pattern. Because this condition is usually caused by either a traction injury or a compression injury to the brachial plexus and not an individual nerve root, the patient's symptoms rarely follow a single dermatomal distribution.

Clinical Presentation

History

- A cervical sprain is a ligamentous injury that often results from a direct collision. The athlete will usually complain of pain localized to the neck without upper extremity radiation.
- A "burner" or a "stinger" is a transient neurologic event that affects one single upper extremity. The athlete often describes tingling, burning, or numbness in a nondermatomal pattern. Because this condition is usually caused by either a compression or a traction injury to the brachial plexus and not an individual nerve root, the patient's symptoms rarely follow a single dermatomal distribution.
- In the compression mechanism of injury, the cervical spine is extended and laterally flexed toward the ipsilateral side of symptoms. This extension and lateral

bending of the cervical spine results in compression of the brachial plexus.
- In the brachial plexus traction mechanism of injury, the cervical spine is a lateral bend toward the contralateral side, and concomitantly the ipsilateral upper extremity or shoulder is pushed downward. This results in a traction injury to the brachial plexus caused by the opposing directions of force applied.

Physical Examination

Abnormal Findings

- Cervical sprain: focal tenderness to palpation at maximum site of reported pain
- Burner/stinger: tingling, burning, or numbness of a single upper extremity in a nondermatomal pattern
- Transient quadriplegia/cervical cord neuropraxia (CCN): there is a focal neurologic deficit. Sensory symptoms can range from burning pain to tingling to loss of sensation.
- Motor symptoms can vary from mild weakness to complete paralysis. These abnormal neurologic exam findings can last from 10 minutes to 48 hours to resolve.

Pertinent Normal Findings

- The neurologic exam in cervical sprains and burners/stingers is generally nonfocal. There is full (5/5) and symmetric motor strength in both upper and lower extremities as well as lack of sensory deficits.
- In contrast, the neurologic exam in an athlete with transient quadriplegia with CCN will show a focal neurologic deficit that lasts from 10 minutes but can take up to 48 hours to resolve.

Imaging

- In a neurologically intact patient without cervical pain and without cervical tenderness to palpation, radiographic imaging may not be necessary. However, because almost all cervical sprains result in cervical pain and/or tenderness to palpation, this injury warrants further workup.
- Cervical fractures and dislocations can result in irreversible and permanent neurologic injury, there-by making cervical sprains and strains a diagnosis of exclusion. Cervical fractures and dislocations, as well as acute disc herniations, have potentially disastrous implications for the patient, so they must be ruled out when making the diagnosis of a cervical sprain.
- Plain radiographs of the cervical spine should include anterior-posterior, lateral, open mouth odontoid. A swimmer's view is sometimes necessary to view the cervicothoracic junction.
- Patients with decreased Torg ratios and with decreased foraminal height have been found in patients with chronic, recurrent stingers.
- If not evident on plain radiographs, a computed tomography scan of the cervical spine can be done to rule out any fracture or dislocation of the cervical spine.
- Magnetic resonance imaging (MRI) of the cervical spine can help to identify any compression of the neural elements, to include the spinal cord as well as the nerve roots. In addition, an MRI can occasionally show some increased signal within the spinal cord itself. This increased signal, also called myelomalacia, implies the presence of edema or trauma to the spinal cord.

Differential Diagnosis

- Stinger or burner
  - Pain and/or paresthesia in a single upper extremity
- Central cord syndrome
  - Extremity weakness that affects the upper extremities more than the lower extremities. Often seen after a cervical hyperextension injury in a patient with preexisting cervical stenosis.
- CNN, also known as transient quadriplegia
  - This results in deficits in motor and/or sensory function caudal to the level of the injury.

Treatment

Nonoperative Management

- Cervical spine immobilization in cervical orthosis
- Restriction from returning to contact sports
- No activity restrictions to include full return to participation in contact sports

Guidelines for Choosing Among Nonoperative Treatments

- If there is any suspicion of unstable cervical spine injury, the patient must not return to play. The cervical spine should be immobilized and the patient transferred to an appropriate facility to complete the imaging workup.
- Relative contraindications to return to participation in contact sports
  - Stinger that results in residual muscle weakness
  - Torg ratio less than 0.8 with one episode of CCN
  - MRI with degenerative disc disease after one episode of CCN
  - MRI with presence of cord deformation after one episode of CCN
- Absolute contraindications to return to participation in contact sports
  - MRI with cord edema or myelomalacia after one episode of CCN
  - Ligamentous instability after one episode of CCN
  - CCN lasting longer than 36 hours
  - Multiple episodes of CCN
- Some authors recommend that spear-tacklers' spine is a contraindication to return to contact sports. This is a clinical entity that includes:
  - Congenital narrowing of the spinal cord with Torg ratio less than 0.8
  - Loss of cervical lordosis or the presence of cervical kyphosis

- Posttraumatic radiographic abnormalities
- Prior history of using spear-tackling or helmet-to-helmet hitting techniques

Surgical Indications

- Absolute
  - Any fracture or dislocation that is etiology for abnormal neurologic exam finding
  - Any injury that results in instability of the cervical spine
- Relative
  - Recurrent episodes of transient quadriplegia/CCN that can be attributed to a compressive lesion on the spinal cord. The goal of any surgical intervention in this case would be to decrease the likelihood of further neurologic injury, not to return to competitive play.

Aspects of History, Demographics, or Exam Findings that Affect Choice of Treatment

- Cervical sprains are injuries to the ligaments of the cervical spine. In the absence of concomitant cervical fracture of injury of the intervertebral disc, these ligamentous sprains are rarely sufficient to cause instability of the cervical spine.
- Burners or stingers are by definition transient events and therefore require no surgical intervention.

Aspects of Clinical Decision Making When Surgery Is Indicated

- The goal of any surgical intervention in this case would be for preservation of neurologic function. Sprains and burners/stingers rarely warrant surgical intervention. Often a restriction from return to sport is sufficient to prevent future symptoms.
- The sporting injury can be the antecedent event that leads to radiographic workup, which then reveals a compressive lesion on the spinal cord. This can be from a large cervical disc herniation or from congenital cervical stenosis. In this case, surgical intervention can be performed with the goal of preservation of neurological function.

Evidence

Castro FP, Jr, Ricciardi J, Brunet ME, et al: Stingers, the Torg ratio, and the cervical spine. *Am J Sports Med* 25:603–608, 1997.

This prospective study of college football athletes showed that patients with recurrent stingers had smaller Torg ratio (0.75) than athletes who experienced only one stinger (0.87). (Level X evidence)

Kelly JD, Aliquo D, Sitler MR, et al: Association of burners with cervical canal and foraminal stenosis. *Am J Sports Med* 28:214–217, 2000.

This case series of patients who experienced upper extremity stingers/burners showed that on lateral radiographs, there was decreased foraminal height compared with asymptomatic control participants. (Level X evidence)

Meyer SA, Schulte KR, Callaghan JJ, et al: Cervical spinal stenosis and stingers in collegiate football players. *Am J Sports Med* 22:158–166, 1994.

This case series of 266 collegiate football players revealed 40 with at least one episode of an upper extremity stinger/burner. The authors proposed two mechanisms of injury, traction injury of the brachial plexus traction, and cervical extension/lateral bending. (Level X evidence)

Murone I: The importance of the sagittal diameters of the cervical spinal canal in relation to spondylosis and myelopathy. *J Bone Joint Surg Br* 56:30–36, 1974.

This clinical and radiographic study showed the correlation between sagittal diameter of the cervical spinal canal and the clinical symptoms associated with myelopathy. (Level X evidence)

Pavlov H, Torg JS: Roentgen examination of cervical spine injuries in the athlete. *Clin Sports Med* 6:751–766, 1987.

This original description of the Pavlov-Torg ratio proposed a radiographic determination of cervical stenosis that took into account the magnification of the radiograph itself. By relying on a ratio, rather than one measurement of distance, any potential magnification was eliminated. (Level X evidence)

Torg JS, Sennett B, Pavlov H, et al: Spear tackler's spine. An entity precluding participation in tackle football and collision activities that expose the cervical spine to axial energy inputs. *Am J Sports Med* 21:640–649, 1993.

Spear tacklers spine is defined, and 15 cases are reported by the authors. Of these 15, four sustained injuries that resulted in permanent neurologic deficits. The authors conclude that spear tackler's spine is a contraindication to return to contact sports. (Level X evidence)

Torg JS, Vegso JJ, O'Neill MJ, et al: The epidemiologic, pathologic, biomechanical, and cinematographic analysis of football-induced cervical spine trauma. *Am J Sports Med* 18:50–57, 1990.

In addition to defining the epidemiology of cervical injuries in tackle football, the authors were able to review game films of 60 cervical spine injuries. In 51 of these, the mechanism of injury was able to be determined, and axial loading was the mechanism in all 51 cases. (Level X evidence)

Multiple-Choice Questions

QUESTION 1. The Pavlov-Torg ratio is

A. the proportion of athletes who will sustain a cervical spine injury per season.
B. the anterior-posterior diameter of the spinal canal divided by the anterior-posterior length of the vertebral body.
C. abnormal when it is less than 0.8.
D. Both b and c

QUESTION 2. All of the following apply to the diagnosis of a cervical stinger/burner EXCEPT for:

A. unilateral upper extremity symptoms.
B. caused by a traction injury to the brachial plexus.
C. symptoms follow a specific dermatomal pattern.
D. symptoms are usually transient.

QUESTION 3. All of the following are contraindications to return to participation in contact sports EXCEPT for:

A. single episode of stinger/burner without residual muscle weakness.
B. single episode of stinger/burner with residual muscle weakness.
C. cervical injury in a neurologically intact patient with focal posterior midline tenderness to palpation and palpable stepoff.
D. single episode of cervical cord neuropraxia with a Pavlov-Torg ratio of less than 0.8.

QUESTION 4. A cervical sprain is a diagnosis of exclusion because

A. the workup, to include radiographs/CT scan/MRI, makes it impossible for the athlete to return to play in the same game.
B. cervical sprains happen infrequently.
C. the consequences of missing a cervical fracture or dislocation can include incomplete spinal cord injury or even paralysis.
D. cervical sprains are a common injury in contact sports.

Answer Key

QUESTION 1. Correct answer: **D** (see Pathophysiology)

QUESTION 2. Correct answer: **C** (see Clinical Presentation)

QUESTION 3. Correct answer: **A** (see Treatment)

QUESTION 4. Correct answer: **C** (see Clinical Presentation)

NONOPERATIVE REHABILITATION OF CERVICAL SPINE STRAINS, SPRAINS, AND BURNERS

Bradley S. Wells, DPT, CSCS, LT

GUIDING PRINCIPLES OF NONOPERATIVE REHABILITATION

- Restore cervical active range of motion early.
- After full cervical range of motion is established, progress to strength and postural training.
- Return to practice is prohibited until patient is completely asymptomatic with full range of motion, strength, and sensation.
- Return to game is prohibited until patient remains asymptomatic during practice.

Phase I (weeks 0 to 1)

Protection

- Soft cervical collar may be used as needed for protection and support but should be limited to avoid dependency and muscle deactivation.
- Borchgrevink et al. found that patients with neck sprains experienced better outcomes when they continued to engage in their normal, preinjury activities than those who were immobilized during the first 14 days after injury.

Management of Pain and Swelling

- Nonsteroidal antiinflammatory drugs (NSAIDs) and ice for decreased pain and inflammation.

Techniques for Progressive Increase in Range of Motion

Manual Therapy Techniques

- No passive range of motion in the acute phase to prevent excessive motion and stretching to injured segments

Stretching and Flexibility Techniques for the Musculotendinous Unit

- No passive range of motion in the acute phase to prevent excessive motion and stretching to injured segments

Other Therapeutic Exercises

- Isometric cervical muscle strengthening starting in neutral cervical position and progressing through full range of motion for initiation of cervical muscular strengthening

Activation of Primary Muscles Involved

- Muscle activation exercises for the trapezius, sternocleidomastoid, scalenes, levator scapulae, splenius capitis, and deep neck flexors

Techniques to Increase Muscle Strength, Power, and Endurance

- Isometric exercises are introduced and progressed as patient tolerates.

Milestones for Progression to the Next Phase

- No vestibular or visual dysfunctions
- No fracture or dislocations of cervical segments
- No extreme amounts of pain that would limit patient's ability to participate in rehabilitative program

Phase II (weeks 2 to 4)

Management of Pain and Swelling

- Moist heat pack with interferential current using electrical stimulation prior to mobility training may decrease stiffness and patient guarding prior to treatment.

Techniques for Progressive Increase in Range of Motion

Manual Therapy Techniques

- Cervical mobilizations using multidirectional glides and posterior to anterior directed forces, starting with Grades I and II and progressing to Grades III and IV as patient tolerates for improved segmental mobility

Soft Tissue Techniques

- Soft tissue massage to cervical muscles and upper trapezius as needed for reduction in muscle tone, trigger point release, and improved cervical mobility

Stretching and Flexibility Techniques for the Musculotendinous Unit

- Upper trapezius, scalene, and levator scapulae stretching, adding overpressure as tolerated

Other Therapeutic Exercises

- Chin tucks in supine position with towel behind head. The patient will lie flat on her/his back to help eliminate gravity and actively engage the deep neck flexors by gently nodding the head forward as if saying "yes" and slowly flattening out the lordotic curve of the cervical spine. Verbal cues and manual cues should be given to the patient to ensure proper form.
- Supine chin tucks with biofeedback cuff. Perform the previous exercise using biofeedback cuff in the lordotic curve of the cervical spine. Start with increasing the pressure 2 mm Hg above baseline and increase pressure in increments of 2 mm Hg until reaching 10 mm Hg and hold for 10 seconds. Perform 10 reps with 10-second holds.
- Progress to the performing chin tucks in seated position, allowing for patient to work against gravity in more functional position. Have patients maintain holds for up 30 seconds without the use of the biofeedback cuff. Be sure to monitor for correct form and give manual cues as needed.
- Upper extremity strengthening using progressive resistive exercises (PREs)
- Cervical muscle strengthening using PREs: Resisted cervical flexion, extension, and sidebending using light resistance with Thera-Band.
- Scapular strengthening using PREs

Activation of Primary Muscles Involved

- Deep neck flexors (longus capitis and longus colli)
  - The patient is first taught to perform a slow and controlled chin tuck, creating craniocervical flexion while flattening out the lordotic curve of the cervical spine.
  - The patient is then trained to increased control and endurance with the use of a biofeedback cuff.
  - Training then progresses into postural correction exercises in the sitting position, which is a more functional daily position.
  - The patient should be instructed to sit with a natural lordosis in the lumbar spine, gently retract the scapulae, and perform a slow chin tuck activating the longus capitis and longus colli.

Techniques to Increase Muscle Strength, Power, and Endurance

- Resisted cervical flexion, extension, and sidebending using Thera-Band and progressing resistance as tolerated.

TIMELINE 22-1: **Nonoperative Rehabilitation of Cervical Spine Strains/Sprains/Burners**

PHASE I (week 0 to 1)	PHASE II (weeks 2 to 4)	PHASE III (weeks 5 to 6)
• Gentle cervical AROM: All directions w/o overpressure • Cervical isometrics • Interferential current • Ice	• AROM/ AAROM/ PROM for full cervical ROM • Manual cervical mobilizations: Grade I/II → III/IV • Cervical PREs • Shoulder PREs • Scapular PREs • Deep neck flexor strengthening/ endurance training • Introduce throwing exercises using rebounder • Introduce light jogging program as tolerated	• Gym program • Plyometrics • Running

Plyometrics

- Throwing progression using weighted Theraballs and a rebounding trampoline for introduction of throwing and critique of throwing mechanics in preparation for sport-specific throwing

Functional Exercises

- Performing upper extremity proprioceptive neuromuscular facilitation training in the D1/D2 patterns will allow for strengthening in functional moments patterns with the incorporation of the scapula.
- Resistance should be progressive by starting with Thera-Band and progressing to the cable column as the athlete tolerates.

Milestones for Progression to the Next Phase

- Establish full pain-free cervical range of motion.
- Full pain-free shoulder range of motion
- No neurologic symptoms (radiculopathy, paresthesia)

Phase III (weeks 5 to 6)

Management of Pain and Swelling

- Ice as needed

Techniques for Progressive Increase in Range of Motion

Soft Tissue Techniques

- Soft tissue massage as needed to upper trapezius, sternocleidomastoid, scalene, and deep neck flexors

Stretching and Flexibility Techniques for the Musculotendinous Unit

- Scalene, levator scapulae, upper trapezius stretching as needed

Activation of Primary Muscles Involved

- Strengthening exercises for trapezius, deltoids, pectoralis major, and rhomboids

Techniques to Increase Muscle Strength, Power, and Endurance

- Gym-based upper body strengthening program should be started focusing on muscles of the shoulders, chest, and back.
- Bench press, military press, power cleans, kettle bell swings, rows, burpees, pullups, and pushups should be incorporated in the gym and progressed slowly to make sure the athlete allows his or her body to adapt to increased training demands.

Plyometrics

- Box jumps and bounding exercise may be performed to train for control impact and landing for proper shock absorption and explosive moments.

Sport-Specific Exercises

- Sport-specific throwing program should begin, increasing distance and throw count as tolerated.

Milestones for Progression to Advanced Sport-Specific Training and Conditioning

- Full pain-free cervical range of motion
- Full pain-free shoulder range of motion
- No neurologic symptoms (radiculopathy, paresthesia)
- No functional limitations

Criteria for Abandoning Nonoperative Treatment and Proceeding to Surgery or More Intensive Intervention

- Persistent radiculopathies or paresthesias leading to muscle weakness or functional limitations

Performance Enhancement and Beyond Rehabilitation: Training/Trainer and Optimization of Athletic Performance

- Proper flexibility and strength of the neck and shoulders continue to be a focus for desired performance enhancement and injury prevention because stiffness and weakness are predisposing factors for burners.
- For football players, protective equipment such as raised shoulder pads, a cowboy collar, or a neck roll can reduce pressure on the neck and help augment shock absorption.
- Work with coaches and trainers on proper safe tackling technique to avoid further injury, keeping a more vertical and upright position to prevent dropping the shoulder and rotating the head and neck, which can result in lateral bending and extension of the cervical spine.
- Avoid hitting with the crown of the head to avoid axial compressive loading to the cervical spine.

Specific Criteria for Return to Sports Participation: Tests and Measurements

- Return to painfree cervical and shoulder range of motion
- Full strength and function

- Symptom free with no exacerbations with training or practice
- Normal upper extremity reflexes

Evidence

Borchgrevink G: Acute treatment of whiplash neck sprain injuries: A randomized trial of treatment during the first 14 days after a car accident. *Spine* 23:25–31, 1998.

This randomized study assessed the long-term consequences of whiplash cervical sprain in patients treated with two different rehabilitation programs during the first 14 days after injury. There was a significantly better outcome for patients in the act-as-usual group than those who took sick leave from work and were immobilized. (Level I evidence)

Feinberg J: Burners and stingers. *Phys Med Rehabil Clin North Am* 11:771–784, 2000.

This article defines stinger syndrome and the symptoms that are most commonly reported. Management, rehabilitation, and prevention guidelines are set for injury and return to sport. (Level III evidence)

Kelly J: Association of burners with cervical canal and foraminal stenosis. *Am J Sports Med* 28:214–217, 2000.

This retrospective study examined the images of 64 patients who sustained cervical burners. Significant differences were found between the burner and control groups for the mean minimum and mean average Pavlov ratios and foramen/vertebral body ratios. Scholastic athletes sustaining the burner phenomenon have an increased risk of cervical canal and foraminal stenosis as measured by the Pavlov and foramen/vertebral body ratios, respectively. (Level II-2 evidence)

Kuhlman G: The "Burner": A common nerve injury in contact sports. *Am Fam physician* 60:2035–2040, 1999.

This article reviews the pathophysiology, diagnostic testing, and management of athletes who sustain nerve injury from contact sports. Guidelines are reviewed for return to sport, prognosis, and steps that should be taken for future prevention of repeated injury. (Level II-3 evidence)

Safran M: Nerve injury about the shoulder in athletes, part 2. *Am J Sports Med* 32:1063–1076, 2004.

This two-part article is a review and an overview of the current state of knowledge regarding some of the more common nerve injuries seen about the shoulder in athletes, including long thoracic nerve, spinal accessory nerve, burners and stingers, and thoracic outlet syndrome. Each of these clinical entities is discussed independently, reviewing the anatomy, mechanism of injury, patient presentation (history and examination), the role of additional diagnostic studies, differential diagnosis, and management. (Level II-3 evidence)

Multiple-Choice Questions

QUESTION 1. Immediately following cervical sprain, patients should _____.

A. be immobilized
B. perform active range of motion
C. return to contact sports
D. be instructed to limit cervical range of motion

QUESTION 2. What type of strengthening should be introduced first following cervical sprain?

A. Isometric
B. Isotonic
C. Isokinetic
D. Plyometric

QUESTION 3. What criteria must be met for the athlete to return to sports?

A. Full cervical range of motion
B. No neurologic symptoms
C. Full strength
D. All of the above

QUESTION 4. Why is passive stretching avoided in the acute phase of a cervical sprain?

A. To prevent muscle tearing
B. To avoid headaches
C. To prevent paraspinal muscle spasms
D. This is not a requirement in the acute phase

QUESTION 5. What protective measures should be taken for football players who have sustained burners and are ready to return to sport?

A. Raised shoulder pads
B. Instruction on proper tackling technique
C. Cowboy collar
D. All of the above

Answer Key

QUESTION 1. Correct answer: **B** (see Phase I)

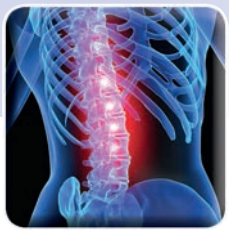
QUESTION 2. Correct answer: **A** (see Phase I)

QUESTION 3. Correct answer: **D** (see Phase III)

QUESTION 4. Correct answer: **C** (see Phase I)

QUESTION 5. Correct answer: **D** (see Phase III)

Chapter 23



Cervical Spine Disc Injuries

INTRODUCTION

Christopher K. Kepler, MD, MBA, Nikolaus S. Hjelm, MD, Gursukhmandeep S. Sidhu, MBBS, David Gendelberg, MD, and Alexander R. Vaccaro, MD, PhD

Epidemiology

- Disc degeneration is exceedingly common although only a small percentage of individuals with disc degeneration will need surgical intervention to address axial neck pain or a symptomatic herniated disc causing radiculopathy or myelopathy.
- In this sense, although athletic participation and subsequent injury may accelerate disc degeneration, this injury is by no means exclusively sport related.

Age

- Late twenties, early thirties, mean age of approximately 28 in series of professional rugby and American football players who underwent surgery for disc herniation

Sex

- Although disc degeneration occurs in both males and females, sports that require axial loading where disc herniation and return to play has been characterized in the literature are predominantly played at the professional level by men (rugby, American football).

Sport

- Rugby, American football

Position

- Rugby—heavy predominance of forward, especially first row (Figure 23-1); American football—most common in defensive players although also common in offensive lineman, running backs, and quarterbacks.

Pathophysiology

Intrinsic Factors

- Genetic factors account for approximately 70% of individual susceptibility.
- Many environmental factors have been proposed (occupational loading, tobacco, traumatic injury) and likely contribute but to a lesser degree than genetics.
- Congenital stenosis may contribute to susceptibility to radiculopathy or myelopathy related to a herniated disc (Figure 23-2).

Extrinsic Factors

- No extrinsic factors have been rigorously proved to be associated although predominance of defensive

FIGURE 23-1. Rugby scrum in which the players in the front line on each side push forward with their shoulders, head, and neck to gain an advantage. This tendency for high impact, repetitive load is thought to contribute to the high incidence of symptomatic cervical spine pathology in this group of players.

FIGURE 23-2. Lateral cervical spine radiograph of a patient with congenital stenosis. This diagnosis is made based on a ratio of the width of the spinal canal (**A**) to the width of the vertebral body (**B**) which is less than 0.8, a threshold suggesting the patient has congenital stenosis.

players in American football and front row players in rugby strongly suggests that repetitive axial loading is a risk factor.

Traumatic Factors

- Axial load

Classic Pathological Findings

- Radiculopathy
  - Myotomal weakness
- Myelopathy
  - Gait instability
  - Difficulty with fine motor control (e.g., buttoning shirt)
  - Difficulty performing repetitive tasks rapidly (Figure 23-3)
- Disc degeneration
  - None

Clinical Presentation

History

- Radiculopathy
  - May present with or without neck pain
  - Dermatomal pain, paresthesias or dysesthesias
- Myelopathy
  - May present with or without neck pain
  - Gait instability
  - Difficulty with buttons or handwriting
- Axial neck pain
  - Waxing-waning course
  - Pain may include any region of posterior head/neck from occiput to periscapular area

Physical Examination

Abnormal Findings

- Radiculopathy
  - Pain, paresthesias or dysesthesias found in dermatomal pattern
  - Myotomal weakness
  - Muscle atrophy in myotome possible but rare
  - Skeletal reflexes may be attenuated or absent compared with contralateral side
- Myelopathy
  - May have symptoms consistent with radiculopathy
  - Positive Hoffman's sign (Figure 23-4), Babinski's sign
  - Positive Romberg's sign, difficulty with tandem walk
  - Cannot perform repetitive activities rapidly (alternating hand slap on other hand) (see Figure 23-3)
  - Skeletal reflexes may be hyperactive, patient may demonstrate clonus
- Axial neck pain
  - None

Pertinent Normal Findings

- Radiculopathy
  - No Hoffman's reflex or Babinski's sign
- Axial neck pain
  - Normal neurological examination

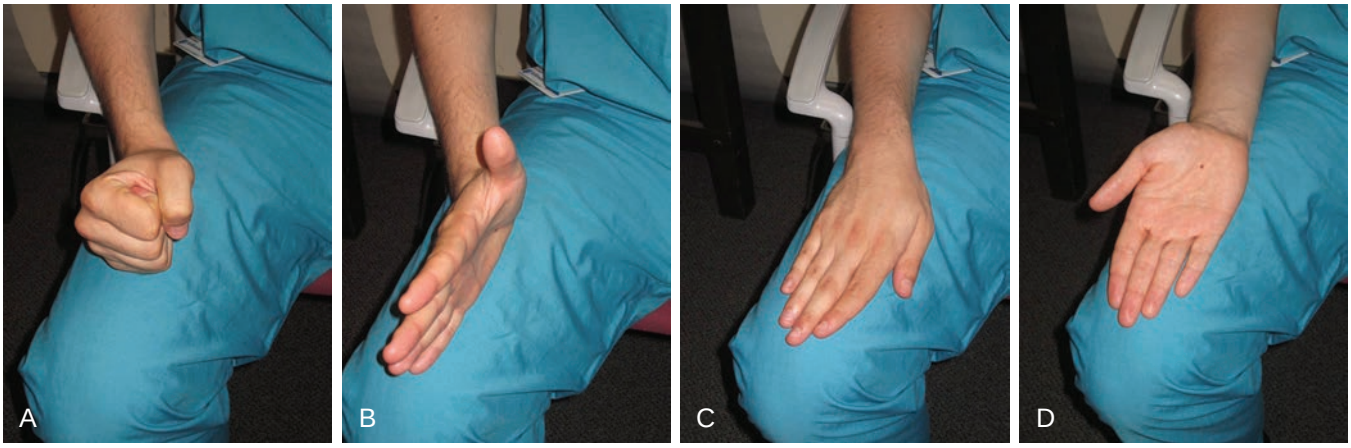


FIGURE 23-3. Players with cervical myelopathy due to spinal cord compression often have difficulty performing repetitive tasks quickly, such as closing (**A**) and opening (**B**) closing a clenched fist rapidly or slapping the palm (**C**) and then dorsum (**D**) of their hand on their anterior thigh.

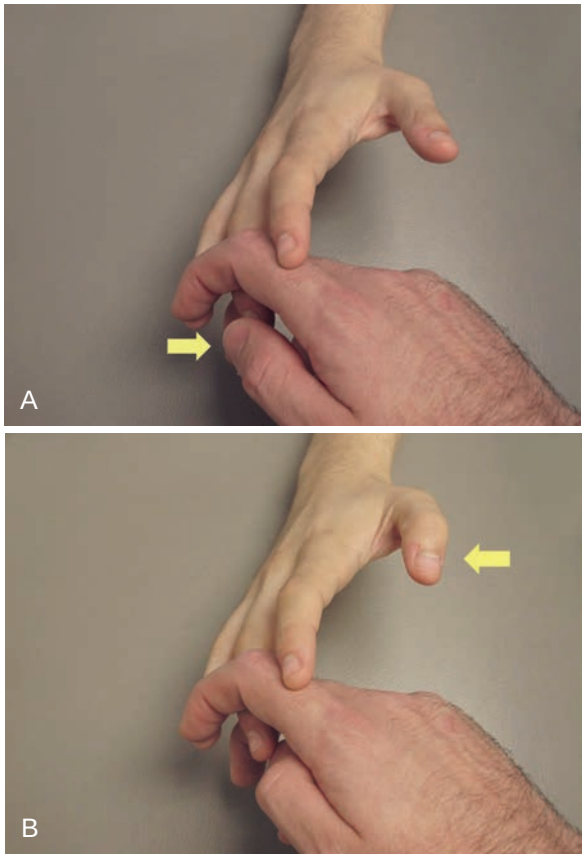

FIGURE 23-4. A, Hoffman's test is performed by stabilizing the middle phalanx of the third finger and flicking (*arrow*) or tapping the distal phalanx of the third finger. **B,** The test is positive when this action results in a reflexive flexion of the interphalangeal joint of the thumb (*arrow*), a finding suggestive of spinal cord compression.

Imaging

- Radiographs—to evaluate canal anteroposterior diameter to rule out congenital stenosis. Significant stenosis may be contraindication to contact sports participation.
- MRI—to evaluate disc degeneration, neural element compromise.
- CT occasionally helpful for further anatomic detail regarding congenital stenosis

Differential Diagnosis

- Peripheral nerve entrapment—median and ulnar neuropathy may mimic C6 and C8 radiculopathy, respectively (Figure 23-5). Differentiated by electromyogram (EMG).
- Neurological disease such as amyotrophic lateral sclerosis (ALS) or multiple sclerosis (MS). ALS diagnosed by EMG and findings that do not localize to cervical spine nerve roots, such as tongue fasciculations, MS differentiated by EMG and MRI and by discordant symptoms (e.g., cranial nerve involvement).
- Fibromyalgia—trigger points near cervical spine but also common over lower back, buttocks, and greater trochanter (Figure 23-6). Associated sleep disturbance nearly universal on history.

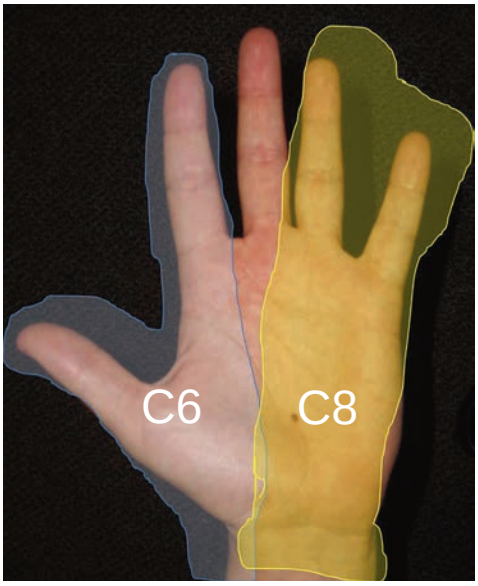

FIGURE 23-5. Dermatomes of the hand. C6 and C8 radiculopathy can be confused with peripheral compression of the median nerve and ulnar nerve, respectively, which have a similar distribution in the hand.

Treatment

Nonoperative Management

- Radiculopathy
  - Activity avoidance, nonsteroidal antiinflammatory medications, possible brief period of immobilization using soft collar, avoid narcotic use
  - Epidural steroid injections to nerve root at which symptoms localize
- Myelopathy
  - No role for nonsurgical treatment in young athlete
- Axial neck pain
  - Primarily nonsurgical treatment because the surgical result is often poor. Maintain range of motion (ROM), avoid prolonged immobilization.

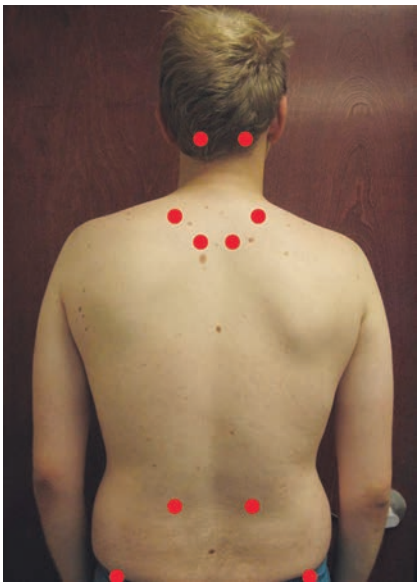

FIGURE 23-6. Stereotypic locations (*red circles*) of trigger points in patients with fibromyalgia.

- Nonsteroidal antiinflammatory medications useful, role of steroid injection unclear
- Avoid exacerbating activities.
- Pain management as necessary

Guidelines for Choosing Among Nonoperative Treatments

- Radiculopathy
  - Begin with activity avoidance and antiinflammatory medications and progress to epidural injections if the patient fails less invasive treatment.
- Myelopathy
  - N/A
- Axial neck pain
  - Initial treatment should focus on avoiding immobilization, maintaining range of motion with use of nonsteroidal antiinflammatory medication as necessary.
  - If pain cannot be managed otherwise, referral to pain management specialist may be useful.

Surgical Indications

- Radiculopathy
  - Incapacitating pain with failure of nonsurgical treatment
  - Progressive neurological deficit
  - Neurological deficit that fails to improve
- Myelopathy
  - Should be treated surgically in all young patients
- Axial neck pain
  - Surgical indications are failure of nonsurgical modalities, although indications for neck pain operations are heavily surgeon-dependent.

Aspects of History, Demographics, or Exam Findings That Affect Choice of Treatment

- History of improving radicular or axial neck pain symptoms may encourage longer trial of nonsurgical treatment as radiculopathy often resolves spontaneously, allowing the athlete to avoid surgery, and axial neck pain commonly has a waxing-waning course.
- Multiple affected levels (>2) in athletes with radiculopathy will preclude return to play if treated using spine fusion; athletes may elect for longer nonsurgical course rather than face career-ending surgery.
- Any signs or symptoms of myelopathy are an absolute indication for decompression and fusion.
- Patients with symptomatic disc herniation in the setting of congenital stenosis may be more likely to be treated with multilevel posterior surgery or anteroposterior surgery, which will often end the athlete's career.

Aspects of Clinical Decision Making When Surgery Is Indicated

- Kyphotic alignment of the cervical spine is a contraindication for posterior-only decompression and fusion.
- Athletes undergoing surgery for more than three affected levels will usually be treated with posterior decompression and fusion.
- Athletes with severe axial neck pain who elect to undergo surgery should be counseled that results are less predictable and, in general, inferior to surgery for radiculopathy or myelopathy.
- Motion-preserving surgery such as cervical disc replacement is contraindicated for contact athletes owing to the potential risk of component dislocation and spinal cord injury.

Evidence

Andrews J, Jones A, Davies PR, et al: Is return to professional rugby union likely after anterior cervical spinal surgery. *J Bone Joint Surg Br* 90(5):619–621, 2008.

This study reports the success of return to play in professional rugby players after surgical treatment for cervical disc herniation. (Level IV evidence)

Battie MC, Videman T, Kaprio J, et al: The Twin Spine Study: Contributions to a changing view of disc degeneration. *Spine J* 9:47–59, 2009.

This multinational study of a large cohort of twins establishes genetics as a major contributor to pathological disc degeneration and suggests a much smaller role for other environmental factors previously thought to play a significant role in disc degeneration, such as smoking and occupational hazards.

Hsu WH: Outcomes following nonoperative and operative treatment for cervical disc herniations in National Football League athletes. *Spine* 36(10):800–805, 2011.

This retrospective cohort study reports the success of return to play in NFL players after surgical treatment for cervical disc herniation. (Level IV evidence)

Rihn JA, Anderson DT, Lamb K, et al: Cervical spine injuries in American football. *Sports Med* 39(9):697–708, 2009.

This review article describes commonly seen cervical spine injuries and treatment strategies associated with American football, the most common sporting mechanism of cervical spine injury seen in the United States. (Review)

Torg JS, Ramsey-Emrhein JA: Management guidelines for participation in collision activities with congenital, developmental, or postinjury lesions involving the cervical spine. *Clin J Sport Med* 7(4):273–291, 1997.

This article outlines management guidelines for many cervical spine injuries, including those related to disc injury. (Review)

Multiple Choice Questions

QUESTION 1. Based on current evidence, approximately what percentage of individual susceptibility to disc degeneration is owing to genetic influences?

A. 15%
B. 40%
C. 70%
D. 90%

QUESTION 2. For which of the following ailments on the differential diagnosis for cervical radiculopathy or myelopathy is sleep disturbance nearly universally found on taking a thorough history?

A. Multiple sclerosis
B. Amyotrophic lateral sclerosis
C. Axial neck pain
D. Fibromyalgia

QUESTION 3. Which of the following treatment strategies is most appropriate for a young athlete presenting with signs of myelopathy?

A. Observation as long as the athlete can compete without limitations
B. Surgery
C. Initial use of aggressive PT with traction and core strengthening.
D. Expectant observation with surgery if the athlete has neurological decline

QUESTION 4. What is the likelihood of return to play of a football lineman treated with four level anterior cervical fusion?

A. Zero—return to play is contraindicated.
B. Unlikely—patients treated with four level fusion rarely are asymptomatic after surgery.
C. Likely provided that the player has painless range of motion after surgery
D. Likely, although the player will likely not attain the same level of competitiveness after surgery

Answer Key

QUESTION 1. Correct answer: **C** (see Pathophysiology)

QUESTION 2. Correct answer: **D** (see Differential Diagnosis)

QUESTION 3. Correct answer: **B** (see Treatment)

QUESTION 4. Correct answer: **A** (see Aspects of History, Demographics, or Exam Findings That Affect Choice of Treatment)

NONOPERATIVE REHABILITATION OF CERVICAL SPINE DISC INJURIES

Christopher K. Kepler, MD, MBA, Michael J. Ross, MD, Christopher Peduzzi, MA, ATC, Rick Burkholder, MS, ATC, and Alexander R. Vaccaro, MD, PhD

Guiding Principles of Nonoperative Rehabilitation

- Allow acute symptoms to resolve. Although cervical spine should be protected from secondary injury, prolonged use of a cervical collar is discouraged.
- Gradually, range of motion must be resumed once axial pain has decreased and radicular pain is absent.
- Return to play is possible only when full, painless range of motion is possible.

Phase I: Acute Injury Phase (weeks 0 to 3)

Protection

- Cervical collar *may* be used if necessary to reduce painful muscle splinting, but its use should be minimized to prevent muscle atrophy and excessive stiffness caused by immobility.

Management of Pain and Swelling

- Nonsteroidal antiinflammatory drugs (NSAIDs) as necessary. The use of narcotics is discouraged but may be necessary for an acute radiculopathy.

Techniques for Progressive Increase in Range of Motion

- Little range of motion should be pursued during the period of acute radicular or axial pain if such range of motion exacerbates pain. Gentle passive range of motion may be pursued as the acute pain phase begins to abate.

Soft Tissue Techniques

- Although recommended by some, the benefit of manual traction for cervical disc degeneration or radiculopathy is uncertain and not recommended. Modalities, such as heat, electrical stimulation, ultrasound, and others may be used based on personal preferences of the treating physician. Little data are available regarding the long-term efficacy of these modalities in treating patients with cervical spine injuries.

Stretching and Flexibility Techniques for the Musculotendinous Unit

- None in Phase I other than gentle passive range of motion.

Other Therapeutic Exercises

- Upper extremity activities that could potentially exacerbate cervical radiculopathy via nerve root traction should be avoided during the acute phase.

- Depending on axial pain distribution, periscapular strengthening exercises may also exacerbate pain and should be delayed until pain is improving.

Activation of Primary Muscles Involved

- Paraspinal musculature involved in cervical extension, superficial and deep flexors involved in cervical flexion, which are exercised in short arc range of motion.

Sensorimotor Exercises

- Postural training should commence to encourage long-term training of core neck musculature, including include neck retraction and scapular stabilizer retraction exercises.

Functional Exercises

- None other than postural training

Milestones for Progression to the Next Phase

- Axial pain becomes tolerable without narcotic analgesics, radiculopathy is substantially diminished or absent.
- Patient can tolerate 15 to 30 minutes of nonimpact exercise such as on an elliptical machine from a cardiovascular standpoint.

Phase II (weeks 1 to 8): Range of Motion Recovery Phase

Management of Pain and Swelling

- NSAIDs as necessary

Techniques for Progressive Increase in Range of Motion

- Any stretching activities such as slow passive movement to limits of range of motion (extension, flexion, side bending, rotation) that result in worsening of symptoms, especially radicular symptoms, should be immediately eased and attempted again with decreased amplitude after a cool-off period of several days.

Manual Therapy Techniques

- Joint mobilizations and manipulation to maintain range of motion and modulate associated pain (Figure 23-7), manually assisted flexion, extension, and side bending cervical stretches.

Soft Tissue Techniques

- Massage, heat for muscle relaxation, other modalities per physician preference may provide temporary relief of muscular discomfort although there is little evidence that these modalities have any long-term benefit.

Stretching/Flexibility Techniques for the Musculotendinous Unit

- Passive and active cervical flexion, extension, and side bending stretching

Other Therapeutic Exercises

- Scapular movement therapy should be initiated—shoulder shrugs, shoulder rolls, and scapular retraction and depression exercises designed to stretch and begin to strengthen (Figure 23-8).
- Longus colli strengthening and re-education can be initiated via neck retraction exercises, which can be done first without resistance then against resistance using a weighted headpiece or headband in the prone position.
- Limited upper extremity exercises can be initiated with light weights. Provided light weights are used and the trunk is stabilized during lifting, there are no limitations with respect to the type of lifts that can be performed.

Activation of Primary Muscles Involved

- Until the athlete has regained full, painless range of motion, strengthening of paraspinal muscles and anterior flexors is deferred. What constitutes full range of motion varies from athlete to athlete and ultimately must be subjectively determined by the athletes themselves.

TIMELINE 23-1: **Postsurgical Rehabilitation of Cervical Spine Disc Injuries**

PHASE I (weeks 0 to 3)	PHASE II (weeks 1 to 8)	PHASE III (weeks 8+)
• Cervical collar • Antiinflammatory medications • Full ROM avoided until painless • Short arc ROM for strengthening paraspinal musculature • Heat, ultrasound used per physician preference	• Discontinue collar • Gentle passive ROM—extension, flexion, side bend, rotation • Heat, ultrasound, massage per physician preference • Scapular exercises • Longus colli strengthening, re-education • Upper extremity exercise based on sport-specific demands • Proprioceptive exercise for neck	• Manual joint and soft tissue mobilization, manipulation • Aggressive A+PROM • Isometric, antigravity and resisted exercises through full ROM • Antiinflammatory medications • Cardiovascular exercise • Continue scapular, longus colli, upper extremity strengthening • Strengthening of deep cervical flexors • Proprioceptive exercise for neck • Performance of all exercise wearing helmet for helmeted athletes • Weighted helmet for supraphysiological exercise as tolerated • Simulated game environment to assess readiness for return to play

FIGURE 23-7. Cervical mobilizations and manipulation by a therapist increases passive range of motion in a controlled setting and may also identify directions of motion in which the player continues to have difficulty. Cervical mobilizations and manipulation starting in the neutral position (**A**), may include side bend (**B**), rotation (**C**), and traction (**D**).

Sensorimotor Exercises

- A proprioceptive component can be added to postural exercises though the integration of isometric or isotonic resistance exercise with the use of a balance ball or unstable surface (Figure 23-9).

Open and Closed Kinetic Chain Exercises

- Gentle open kinetic chain exercises can be used for scapular strengthening although aggressive strengthening is deferred until the next stage.

Techniques to Increase Muscle Strength, Power, and Endurance

- Because of the risk of symptom recurrence with increased loading of the cervical spine because of the discogenic nature of the symptoms, muscle strengthening is deferred until a full, painless range of motion is established.

Functional Exercises

- Postural training and re-establishment of full range of motion to facilitate both activities of daily living as well as return to play.

Milestones for Progression to the Next Phase

- Full, painless range of motion. As in the preceding, the baseline range of motion will vary between individuals and must be judged by the athlete.
- No residual radiculopathic symptoms, minimal or absent axial pain symptoms

Phase III (weeks 8+): Strengthening Phase

Management of Pain and Swelling

- NSAIDs as necessary

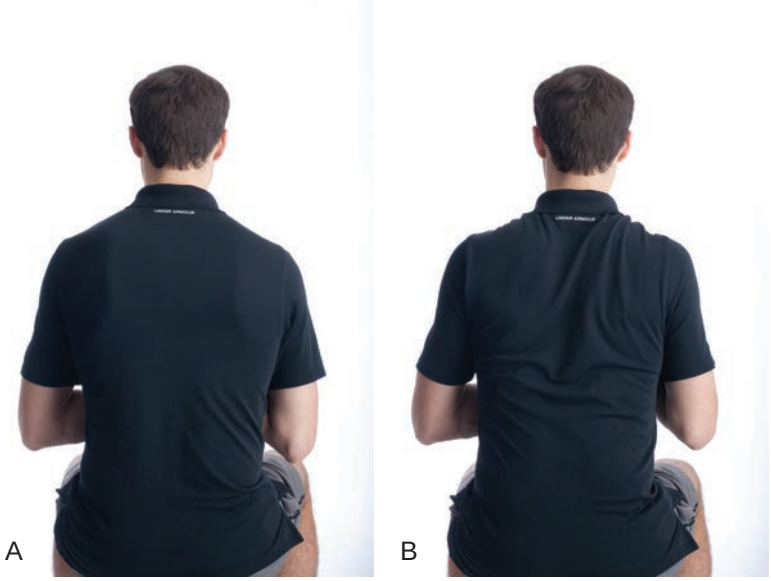

FIGURE 23-8. Neutral scapular position (**A**) and scapular retraction (**B**) are demonstrated. As players establish periscapular strength, resistance can be added with either resistance bands or weights.

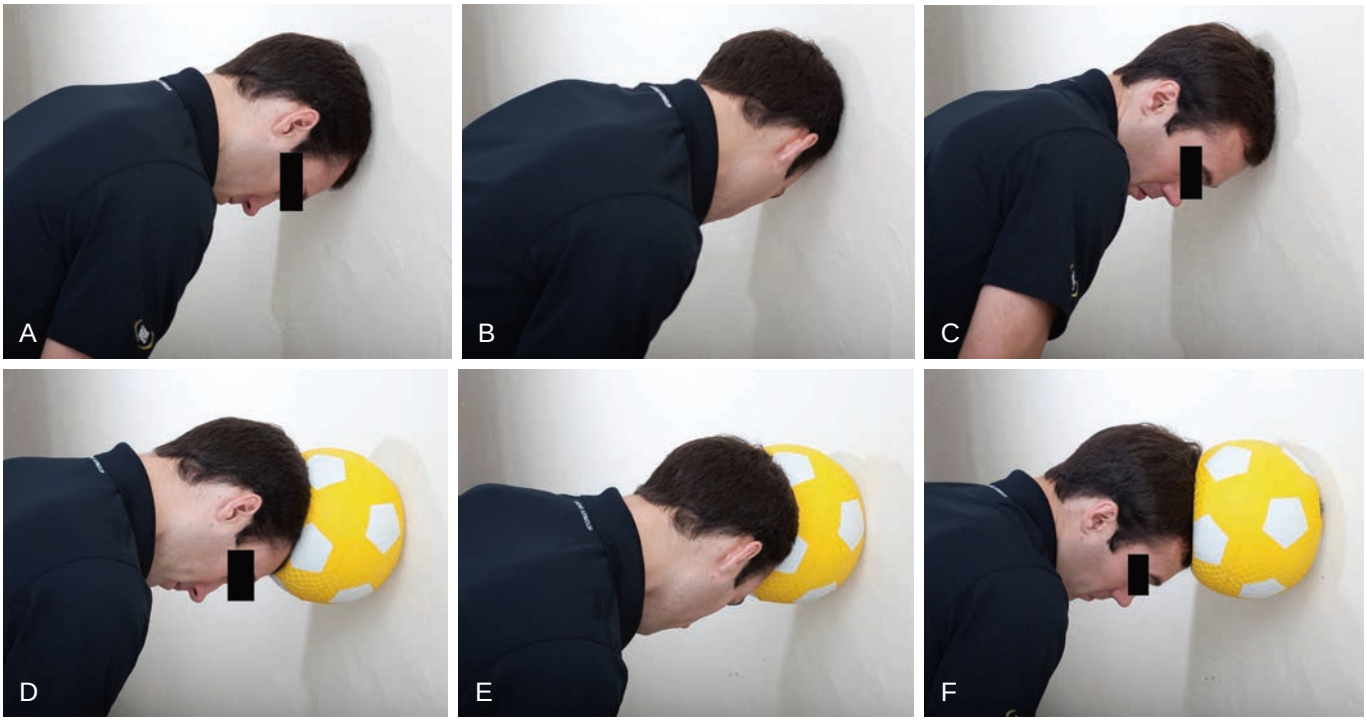

FIGURE 23-9. Progression that simultaneously works on both range of motion and proprioception against the wall (**A–C**) and using a ball (**D–F**).

Techniques for Progressive Increase in Range of Motion

Manual Therapy Techniques

- Joint mobilizations and manipulation to maintain range of motion and modulate associated pain, more aggressive manually assisted flexion, extension, and side bending cervical stretches

Soft Tissue Techniques

- Soft tissue mobilization to decrease apprehension, modalities as in the preceding

Stretching and Flexibility Techniques for the Musculotendinous Unit

- Continue stretching exercises as outlined in Phase II.

Other Therapeutic Exercises

- Cardiovascular exercise and core strengthening should commence to facilitate a return to competition.
- Upper extremity and periscapular muscle open chain strengthening should be increased in preparation for resuming competition. Upper extremity exercises will be almost entirely sport-specific and will vary widely but are important because periods of neck immobilization during early recovery often indirectly result in limitation of upper extremity activity and associated loss of strength.
- Continue strengthening of longus colli and other paraspinal musculature progressing from isometric exercises to exercises bearing body weight. As described, the longus colli can be strengthened through neck retraction exercises. Additional exercises to build paraspinal strength include scapular stabilizer retraction and neck extension in the prone position to lift both the head and shoulders off the floor.

Activation of Primary Muscles Involved

- Core paraspinal muscles, such as longus colli, should be strengthened as described above to provide assistance to the superficial cervical flexors. The work load of the superficial cervical flexors should be decreased as these often tend to assume a disproportionate amount of post-injury work load.

Sensorimotor Exercises

- Proprioception training continues as in Phase II.

Open and Closed Kinetic Chain Exercises

- Although the focus of Phase III should be on strengthening of the cervical musculature, open kinetic chain exercises should be used for scapular and upper extremity strengthening and will vary widely by sport.

Techniques to Increase Muscle Strength, Power, and Endurance

- The tendency to preferentially recruit superficial flexors should be addressed. This can be accomplished by encouraging strengthening of the deep flexors using a chin tuck exercise (Figure 23-10).
- Flexion, extension, and side bending strength should be increased by progressing through a combination of isometric, antigravity and resisted exercises.

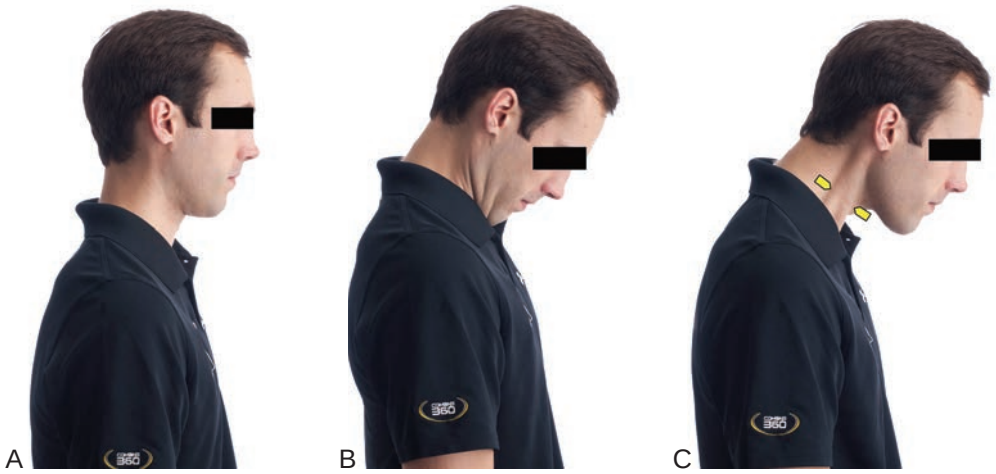

FIGURE 23-10. Chin tuck exercise. From the neutral position (**A**), the therapist must ensure that the player tightly tucks the chin to recruit the deep cervical flexors (**B**) and not allow the player to move their head too far forward (**C**), which preferentially recruits the sternocleidomastoid muscles (*arrowheads*).

Resistance can be provided through the use of rubber tubing, pulleys, or manual methods. When an increase in resistance results in recurrent symptoms, the amount of resistance should be decreased to continue strengthening. Loading can be advanced as tolerated.

Functional Exercises

- Continued stretching exercise to maintain full range of motion for sporting and everyday activities.

Sport-Specific Exercises

- Strengthening and stretching exercises can be done with helmet in place to simulate game time loading.
- Athletes should not return to sport wearing a collar. Players who require a collar to be able to perform athletically should not be playing, and there are no orthoses designed to provide the combination of mobility and stabilization which would be necessary in many sports.
- The principle of overload may be used to strengthen using a weighted helmet to increase muscle strength in a controlled environment.
- Simulated game situations may be helpful for assessing readiness to return to competition.

Milestones for Progression to Advanced Sport-Specific Training and Conditioning

- Full, painless range of motion with evidence of normal strength on manual muscle testing
- Before the contact athlete is allowed to return to play, the training staff should put the athlete through simulated gamelike activities emphasizing cervical flexion, extension and rotation activities that may provoke residual symptoms to ensure the athlete is ready to return to full contact activity.

Criteria for Abandoning Nonoperative Treatment and Proceeding to Surgery or More Intensive Intervention

- Progressive neurological symptoms or evidence of myelopathy
- Unrelenting pain which prohibits return to range of motion and strengthening

Tips and Guidelines for Transitioning to Performance Enhancement

- During the period in which an athlete is transitioned from a rehabilitation scheme to gradually return to play, the full complement of strengthening and stretching exercises should continue until the athlete is fully integrated into a normal training schedule.
- Even then, core strengthening and stretching should continue as an adjunct to customary sport-specific training to minimize the likelihood of symptom recurrence.

Performance Enhancement and Beyond Rehabilitation: Training/Trainer and Optimization of Athletic Performance

- Initial efforts should attempt to identify the mechanism of injury if known and evaluation the player for any underlying contributing weakness that can be addressed through targeted exercise to prevent recurrent injury.
- A period of transition to full training for the injured helmeted athlete may involve continuing all rehabilitation exercises with the helmet in place to increase the

load seen by cervical musculature and more closely simulate physiologic demands of competition.
- Before the contact athlete is allowed to return to play, the training staff should put the athlete through simulated gamelike activities emphasizing cervical flexion, extension, and rotation activities, which may provoke residual symptoms to ensure the athlete is ready to return to full contact activity.

Specific Criteria for Return to Sports Participation: Tests and Measurements

- Athlete is able to perform all sport-specific activities at full speed without pain.
- Athlete demonstrates no hesitation or compensatory movement when performing cervical flexion, extension or rotation in game simulations. As the contributions of cervical spine range of motion to most sporting activities is indirect, this must be assessed subjectively by the athlete and trainers or coaches who are observing the player at full speed practice.

Evidence

There are little published data exploring the use of rehabilitation techniques after cervical injury. The only available literature consists of review articles that communicate guidelines based on the experience of experts in the field.

Torg JS, Ramsey-Emrhein JA: Suggested management guidelines for participation in collision activities with congenital, developmental, or postinjury lesions involving the cervical spine. *Med Sci Sports Exerc* 29(7 suppl):S256–S272, 1997.

This article outlines management guidelines for many cervical spine injuries, including those related to disc injury. (Level IV evidence)

Vaccaro AR, Klein GR, Ciccoti M, et al: Return to play criteria for the athlete with cervical spine injuries resulting in stinger and transient quadriplegia/paresis. *Spine J* 2:351–356, 2002.

In addition to highlighting return to play criteria, this review article outlines the diagnostic workup necessary for patients with neurological symptoms after sporting injuries. (Level IV evidence)

Multiple Choice Questions

QUESTION 1. What is the principal goal of Phase II?

A. Resolution of acute pain
B. Strengthening of core muscles
C. Return to play
D. Restoration of range of motion

QUESTION 2. What is the role of a cervical orthosis in Phase I?

A. A soft cervical orthosis may be used but should be discontinued as quickly as symptoms allow.
B. A hard cervical orthosis should be used for 2 weeks to provide support followed by a transition to a soft collar for another 2 weeks.
C. Use of a cervical orthosis should be strongly discouraged.
D. A cervical orthosis (soft or hard) should be used for the entirety of Phase I to facilitate reduction in pain.

QUESTION 3. Which of the following indicates an injury not amenable to a course of nonsurgical treatment?

A. C5 radiculopathy
B. Axial neck pain which is severe on initial presentation
C. Bilateral symptoms of radiculopathy
D. Left arm pain in the C6 distribution accompanied by difficulty manipulating small objects and buttoning shirts.

QUESTION 4. What rehabilitation technique for helmeted athletes may ensure that the athlete can return to the supraphysiological demands placed on the neck during competition?

A. Strength training using resistance bands
B. Game simulation
C. Game simulation wearing a helmet
D. Endurance training using a linear periodization

Answer Key

QUESTION 1. Correct answer: **D** (see Phase II)

QUESTION 2. Correct answer: **A** (see Phase I)

QUESTION 3. Correct answer: **D** (see Criteria for Abandoning Nonoperative Treatment and Proceeding to Surgery or Other More Invasive Intervention)

QUESTION 4. Correct answer: **C** (see Performance Enhancement and Beyond Rehab: Training/Trainer, and Optimization of Athletic Performance)

BEYOND BASIC REHABILITATION: RETURN TO CONTACT SPORTS AFTER CERVICAL SPINE INJURY

Christopher K. Kepler, MD, MBA, Michael J. Ross, MD, Christopher Peduzzi, MA, ATC, Rick Burkholder, MS, ATC, and Alexander R. Vaccaro, MD, PhD

Aspects of Contact Sports That Require Special Attention in Rehabilitation

- Athletes are susceptible to secondary injury in contact sports secondary to loss of structural integrity related to the primary injury.
- Athletes are also susceptible to secondary injury in contact sports owing to impaired self-protection mechanisms related to decreased range of motion and muscle strength.
- Specific risks vary widely with the nature of individual contact sports, the use of a helmet or other protective devices and the level of competition.

Introduction

- Although serious cervical spine injuries are relatively rare in contact sports, the potential for catastrophic career-ending and life-altering consequences demands strict adherence to return to play criteria.
- The spectrum of severity of cervical spine injury is wide. Although some conditions, such as a stinger, will result in rapid abatement of symptoms and return to play, other more serious injuries or chronic conditions may require surgery that will substantially delay, or even preclude, return to play.
- For this reason, this chapter focuses on return to play after either a stable cervical spine fracture which does not preclude return to play or after one- or two-level spinal fusion in athletes without a contraindication to return to play.
- No guidance in the literature is available on rate of return to play in athletes after minor cervical fractures, likely because of the clinical insignificance of the most common injury patterns, such as spinous process fractures or nondisplaced compression fractures and the relative rarity that prevents any one clinician from assembling a series to report outcome.
- In contrast, chronic cervical disc injury leading to herniation or degeneration is much more common in sports that result in axial loading of the head and neck such as American football and rugby.
- In series describing outcomes after anterior cervical discectomy and fusion in professional football and rugby players, return to play at the same level of competition was remarkably similar at about 70%.

Phase I: Advanced Strength and Conditioning Programs

Periodization

- Undulating periodization is ideal for strength building and recommended during rehabilitation of the cervical spine after surgery or injury. Undulating periodization uses weekly cycles of increasing resistance. The cycle repeats: Hard, Harder, Hardest, Rest, Hard, Harder, and Hardest.

TIMELINE 23-2: **Postsurgical Rehabilitation of Cervical Spine Disc Injuries**

PHASE I (weeks 8 to 12 post injury/ postoperative)	PHASE II (weeks 12 to 15)	PHASE III (15+ weeks)
• Removal of collar after 2 weeks in case of 1 or 2 level spinal fusion, 8 weeks for fracture to allow for healing • Antiinflammatory medications avoided until 3 months post op or post injury • Full ROM avoided until painless • Short arc ROM for strengthening paraspinal musculature • Heat, ultrasound used per physician preference	• Discontinue collar • Aggressive cardiovascular training to regain fitness level • Gentle passive ROM—extension, flexion, side bend, rotation • Heat, ultrasound, massage per physician preference • Antiinflammatory medications • Scapular exercises • Longus colli strengthening, re-education • Upper extremity exercise based on sport-specific demands • Proprioceptive exercise for neck • Strengthening exercises using sport-specific training parameters	• Manual joint and soft tissue mobilization, manipulation • Aggressive A+PROM achieved before strengthening begins • Isometric, antigravity and resisted exercises through full ROM • Sport-specific training and strengthening depending on sport type: Tracking, Momentum Generator, or Support Sports • Weighted helmet for supraphysiological exercise as tolerated • Simulated game environment to assess readiness for return to play • Released to competition when full-speed simulation produces no pain, excess fatigue or loss of head/neck control even in simulation exceeding game length

Program Design/Performance Training Program

Sport-Specific Concepts of Integrated Training

1. Flexibility/joint mobility for joint stability is essential to rehabilitation of the neck after a spinal injury or surgery. For most sports, the neck is primarily used to position the head in space and does not play a direct role in competition with the exception of striking a ball with the head in soccer, which uses neck motion to transfer momentum to the ball and front row rugby players, who push in part with their neck to gain advantages during the scrum (see Figure 23-1 in the Introduction).
2. Training with optimum posture is important for all sports because of the importance of head position to integrate visual and auditory stimulation and for balance.
3. Sensorimotor and balance training
4. Core training is essential. Most of the paraspinal musculature can be considered core muscles.
5. Cardiorespiratory training helps maximize cervical musculature endurance to maintain head control even when fatigued.
6. Multiplanar training activities
7. Training for optimum muscle functional strength, to control the position of the head should it be subject to rapidly applied external force or when the body accelerates or decelerates quickly and the neck must accommodate to control the effect on the mass of the head.
8. Training for speed, agility, quickness (SAQ), again in the context of positioning the head in space to allow for integration of situational information and muscle coordination.
9. Plyometric training is not typically used for the neck in isolation but the neck must be able to accommodate to control head momentum when plyometric exercise are used in the rest of the body.
10. Functional training includes achieving a full range of motion to allow for activities of daily living.
11. Sport-specific training is particularly important for helmeted athletes where the neck bears a greater-than-physiological load and for sports such as cycling, which require a particular, somewhat unnatural neck position (neck extension with the body in the "tuck" position in order to visualize the road ahead, oftentimes, for extended periods of time) (Figure 23-11).

Olympic Lifts Used in the Training Program

- No specific lifts are typically used to rehabilitate the neck but good posture of the neck should be maintained during lifting to strengthen other parts of the body.

Training Principles Used in the Design of the Program

- Principle of specificity: specific adaptation to imposed demands (SAID) should be used to address sport specific demands considering variables, such as requirements for range of motion, endurance, speed and power.

FIGURE 23-11. The tuck position in cycling places the rider's head and neck in the hyperextended position necessary to see the road and other riders ahead.

Application of Acute Training Variables

- These training variables are applied differently depending on the sport-specific requirements. In general, because of the limited positions in space that the neck can occupy, exercises are typically limited to resisted flexion, extension, side bend, and rotation. Flexion, extension, and side bends are strengthened first by positioning the body such that each motion occurs against gravity and continues in the same manner as head weights or exercise bands are added to increase resistance. Rotational muscles are more difficult to strengthen but typically done with exercise bands held to the chin. Specific recommendations for specific sports follow.
- Sports that require endurance should arrange exercises into four sets of 15 to 20 repetitions with repetition tempo varying with the sport-specific demands. For instance, cyclists who require holding an extended neck position for "tuck" riding would use a slow repetition tempo of extension exercises to mimic long periods of isometric contraction.
- Sports requiring neck strength should perform exercises in three sets with 8 to 12 repetitions and should vary repetition tempo to accommodate sport-specific demands.
- Finally, sports requiring neck power should perform three sets of six to eight repetitions with rapid tempo.

Phase II: Performance Enhancement Training Techniques

- Rehabilitation of the neck after cervical spine injury is somewhat different from extremity musculoskeletal injuries in that the neck is primarily important in sport in an indirect manner.
- In this sense, general performance optimization will include identification and treatment of specific

structural or medical problems contributing to susceptibility to the index injury.
- Generalized performance enhancement training is not typically part of cervical spine rehabilitation, which focuses much more on sport-specific training once pain has subsided and range of motion has returned to normal.

Phase III: Sport-Specific Training

- For sport-specific training guidelines, sports will be broken up into three types depending on the contribution of the cervical spine to the sport. The three types we will use throughout this section include Tracking sports, Momentum Generator sports, and Support sports.
- Tracking sport examples include ball sports such as basketball, in which the neck is used primarily to position the head to follow the ball, see other players, or the field.
- In contrast, Momentum Generator sports primarily include soccer, in which the neck is important in imparting force to the ball when heading the ball.
- Finally, Support sports include helmeted sports in which a supraphysiological load is supported by the neck or sports such as martial arts, in which the neck must routinely respond to sudden acceleration or deceleration moments.

Periodization

- Undulating periodization is ideal for strength building and recommended during rehabilitation of the cervical spine after surgery or injury.

Program Design/Performance Training Program

Sport-Specific Concepts of Integrated Training

- All sport types should utilize training with optimum posture, core training, cardiorespiratory training, training for optimal muscle balance, and neuromuscular dynamic stability exercises.
- These concepts as applied to rehabilitation of the neck, however, will mostly be used indirectly during exercises for the rest of the body with the exception of postural and core training, which are of primary importance to the neck itself.
- Flexibility and joint mobility are a requisite for even beginning sport-specific training for the neck, and athletes should not be considered for return to intensive training unless flexibility and mobility have returned to baseline after injury. Range of motion will vary from athlete to athlete and must ultimately be judged by the athletes themselves
- For Tracking sports, joint mobility and flexibility training incorporating multiplanar exercises are particularly important. Athletes must optimize functional power for sport-specific tasks, and rehabilitation should incorporate speed, agility, and quickness (SAQ) drills for sport-specific situations, such as quickly turning the head to visualize players or incoming balls during fast break drills in basketball, for example.
- For Momentum Generator sports, training should also focus on developing optimum functional power from sport-specific tasks, and SAQ drills are similarly important for coordinating the head-strike on a moving soccer ball.
- Finally, Support sports require the development of optimal functional strength and should focus on eccentric exercises, a rehabilitation strategy used to re-build strength as quickly as possible.

Training Principles Used in the Design of the Program

- The principle of variation is essential because of the often subconscious movement of the neck in many different activities, but this will be accomplished often unintentionally through routine sport-specific training with an overt focus on the neck, although appropriate posture must always be emphasized.
- The principle of progression should be employed in particular for Momentum Generator sports in order not to overburden the recovering and rebuilding neck musculature before adequate recovery has restored sufficient strength.
- As described in the preceding, the concept of specific adaptation to imposed demands is the largest determinant of rehabilitation protocol as neck function varies widely across different sports but is essential in nearly all sport.

Application of Acute Training Variables

- As described in Phase I, designing rehabilitation protocols for the neck depends heavily on the sport-specific demands and unique positional requirements.
- Sports that require endurance and have prolonged postural requirements such as cycling should arrange exercises into four sets of 15 to 20 repetitions with repetition tempo varying with the sport-specific demands but with a tendency toward slower repetition tempo.
- Sports requiring neck strength should perform exercises in three sets with 8 to 12 repetitions and also should vary repetition tempo to accommodate sport-specific demands.
- Finally, sports requiring neck power should perform three sets of six to eight repetitions with rapid tempo.
- Specific exercises for Tracking sports will emphasize complete recovery of range of motion and muscle stretching to accommodate restoration of the extremes of motion. Range of motion will vary from athlete to athlete and must ultimately be judged by the athletes themselves.
- Building strength is important for Momentum Generation sports and may use exercises with elastic exercise bands and a head harness.
- Finally, Support sports should focus on integrating eccentric exercises and exercises performed with the helmet in place when appropriate to optimize control of the head, especially during unpredictable acceleration and deceleration periods that are likely in sports like martial arts as well as helmeted contact supports like American football and hockey.

Sports Performance Testing

General Information

- Information about the injury history and mechanism of injury are important to identify potential weak or injured muscle groups that should be strengthened before return to play.
- Medical history should explore whether unsteadiness or imbalance may have contributed to the injury, especially as these can be associated with cervical spine pathology.
- Finally, the timing and nature of any prior cervical spine or neck surgery is important to learn about appropriate timing of return to play and any associated muscular deficits that may have resulted from surgical intervention (Figure 23-12).

Specific Tests

- Physiological assessments in the way of restoration of full, active range of motion are necessary not only before the athlete returns to play but full range of motion should be restored before high-level training starts. Range of motion will vary from athlete to athlete and must ultimately be judged by the athletes themselves.
- As the player returns to full training but before return to competition, the training staff should evaluation whether the player is able to demonstrate sport-specific neck control during explosive efforts in full-speed game situations and simulations. Range of motion will vary from athlete to athlete and must ultimately be judged by the athletes themselves; functional return of full range of motion in game situations can also be judged to some extent by coaches and trainers observing simulated game environments.
- Movement performance testing will vary from sport to sport. Examples include achievement of sufficient neck extension to see the horizon in cyclists in the "tuck" position, 180° of side to side head rotation in the supine position without lifting the shoulder blades from the ground (Figure 23-13) and painless chin-on-chest and vertical gaze in Tracking athletes (Figure 23-14).

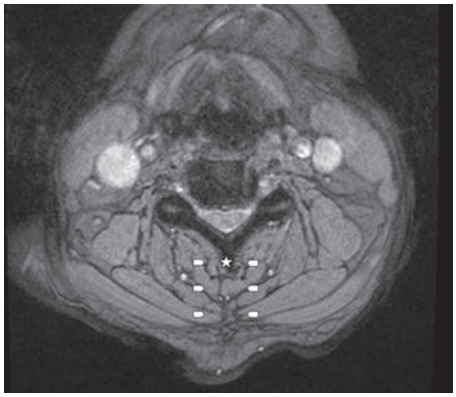

FIGURE 23-12. Axial MRI image of the cervical spine. The paraspinal muscles (*arrowheads*) are detached from the spinous processes (*star*) during the surgical approach. This dissection makes rehabilitation of these muscles challenging in the postoperative setting when an athlete is attempting to return to play.

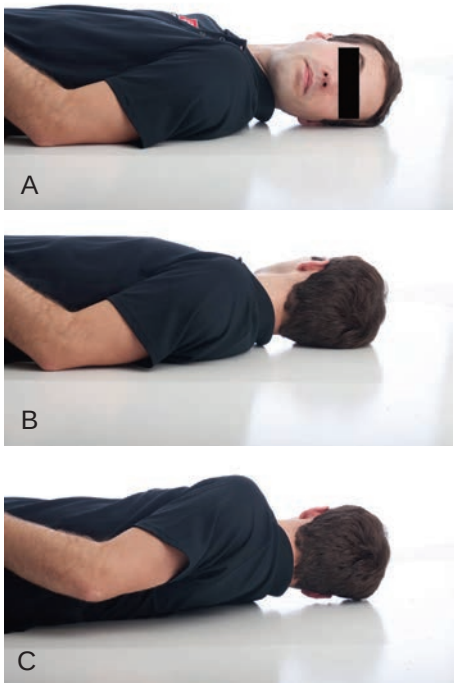

FIGURE 23-13. Side to side neck rotation is an example of a performance motion test that evaluates the athletes to perform uncompensated neck rotation which is essential in tracking sports as well as other types. The player should be able to rotate through a motion arc of 180° (**A**,**B**) without compensating for limited neck motion by rotating the entire body which results in elevation of a shoulder off the ground (**C**).

Specific Criteria for Progression to the Next Stage to Determine Readiness for Contact Sports

- Patients may progress to sport-specific training once they have achieved painless range of motion and have grossly normal neck strength. Range of motion and strength will vary from athlete to athlete and must ultimately be judged by the athletes themselves as there are no guidelines or standards for neck strength.
- Assessment of the latter requires experience on the part of the athletic trainer as the neck is an infrequent training target in most athletes not recovering from a specific injury or surgery.

Specific Criteria for Release to Unsupervised Complete Participation in Contact Sports

- Painless cervical spine control during full-speed game simulation, even after an extended period of simulation that exceeds the normal period of competition. Range of motion and strength will vary from athlete to athlete and must ultimately be judged by the athletes themselves as there are no guidelines or standards for neck strength. Functional exercises are often sport-specific and are constructed to assess the most demanding

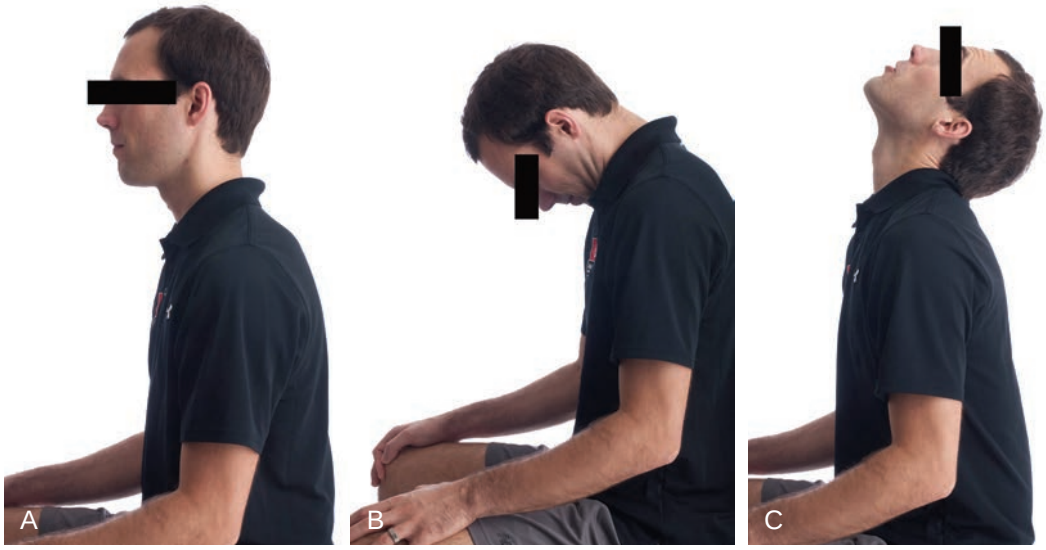

FIGURE 23-14. Starting in the neutral position (**A**), the player should be able to demonstrate the chin-on-chest position (**B**) and a vertical gaze (**C**) without any associated pain.

aspects of particular sports with respect to neck range of motion and/or strength. Examples include achievement of sufficient next extension to see the horizon in cyclists in the "tuck" position for extended periods of time, 180° of side to side head rotation in the supine position without lifting the shoulder blades from the ground (see Figure 23-13) and painless chin-on-chest and vertical gaze in Tracking athletes (see Figure 23-14).

Recommended Ongoing Exercises

Postural control should be practiced indefinitely, and patients with prior cervical injury must understand the importance of withdrawing from competition when fatigue threatens the ability to control the head as they are often susceptible to reinjury.

Evidence

There are little published data exploring the use of rehabilitation techniques after cervical injury. Other than articles describing rehabilitation theory in general, the only available literature that specifically addresses this topic of this chapter consists of review articles that communicate guidelines for return to play (see Evidence section for The Introduction and Nonoperative rehabilitation sections of this chapter) based on the experience of experts in the field.

Miranda F, Simão R, Rhea M, et al: Effects of linear vs. daily undulatory periodized resistance training on maximal and submaximal strength gains. *J Strength Cond Res* 25(7):1824–1830, 2011.

Undulatory resistance training demonstrated trends toward superior strength increases compared with linear periodization in a group of resistance trained men. (Level II evidence)

Prestes J, Frollini AB, de Lima C, et al: Comparison between linear and daily undulating periodized resistance training to increase strength. *J Strength Cond Res* 23(9):2437–2442, 2009.

This investigation compared linear and undulating periodized training programs and found that undulating regiments demonstrated a trend toward superior strength building. (Level II evidence)

Rhea MR, Ball SD, Phillips WT, et al: A comparison of linear and daily undulating periodized programs with equated volume and intensity for strength. *J Strength Cond Res* 16(2):250–255, 2002.

This prospective, randomized trial compares linear and undulating periodized programs to compare the relative ability of these programs to build endurance. (Level II evidence)

Multiple Choice Questions

QUESTION 1. What is the approximate rate of return to play for professional rugby forward or American football linemen after one or two level anterior cervical fusion procedures?

A. 70%
B. 50%
C. 95%
D. 15%

QUESTION 2. What is often used as a final step prior to release of an athlete to resume full, unsupervised training after a cervical surgery or injury?

A. Painless, full range of motion
B. Successful completion of sport-specific training exercises
C. Strength testing which demonstrates normal strength
D. Full speed game simulation with helmet if appropriate to the sport

QUESTION 3. To what does the abbreviation SAQ, used in the design of rehab regimens for return to athletics, refer?

A. Speed, Athleticism, Quickness
B. Speed, Agility, Quickness
C. Strength, Agility, Quality
D. Strength, Accuracy, Quality

QUESTION 4. How should exercises be arranged for return to sports requiring neck endurance?

A. Four sets of 15 to 20 repetitions
B. Four sets of six to eight repetitions
C. Six sets of 10 repetitions
D. Two sets of 20+ repetitions

Answer Key

QUESTION 1. Correct answer: **A** (see Introduction, Return to Play)

QUESTION 2. Correct answer: **D** (see Sports Performance Testing)

QUESTION 3. Correct answer: **B** (see Program Design/ Performance Training Program)

QUESTION 4. Correct answer: **A** (see Program Design/ Performance Training Program)

Chapter 24

Muscle Strains about the Hip and Thigh

INTRODUCTION

Timothy F. Tyler, MS, PT, ATC, and Stephen J. Nicholas, MD

Epidemiology

- Ice hockey and soccer players are particularly susceptible to adductor muscle strains.
- In professional ice hockey and soccer players throughout the world, approximately 10% to 11% of all injuries are groin strains.
- The level of experience is related to the incidence of groin strains.
- Athletes of all ages sustain groin strains.
- Older players have a higher incidence than younger ones.
- Goalkeepers have a higher incidence than position players.

Pathophysiology

- The adductor longus is the most commonly injured adductor during sporting activity (Figure 24-1).
- Groin strain injury is defined as any injury to the adductor muscle group that keeps a player out of a practice or a game, or requires the attention of the team physician.
- A groin strain is characterized by pain on palpation of the adductor tendons or the insertion on the pubic bone, or both, and groin pain during adduction against resistance.
- Groin strains are graded as a first degree strain if there is pain but minimal loss of strength and minimal restriction of motion. A second-degree strain is defined as tissue damage that compromises the strength of the muscle, but not including complete loss of strength and function. A third degree strain denotes complete disruption of the muscle tendon unit. It includes complete loss of function of the muscle.

Clinical Presentation

History

- Patient reports a feeling of a tearing in the groin region.
- Pain on push off injured lower extremity or change in direction.
- Decreased stability of the involved lower extremity on single leg stance.
- Inability to kick a ball.
- Inability to take slap shot/load body weight quickly on injured lower extremity.

Physical Examination

Abnormal Findings

- Decreased muscle force of the adductors.
- Pain on contraction of the adductor muscle group.
- Pain to passive abduction motion beyond normal range.
- Pain on palpation of the origin of the adductor longus.
- Inability to single limb stand against perturbation.
- A palpable defect of the muscle belly of the adductor longus.
- Ecchymosis in groin region.
- Swelling in groin region.
- Decreased step length.

Pertinent Normal Findings

- Symmetrical adductor force production of both lower extremities.
- Adductor strength greater than 80% abductor strength within each leg.

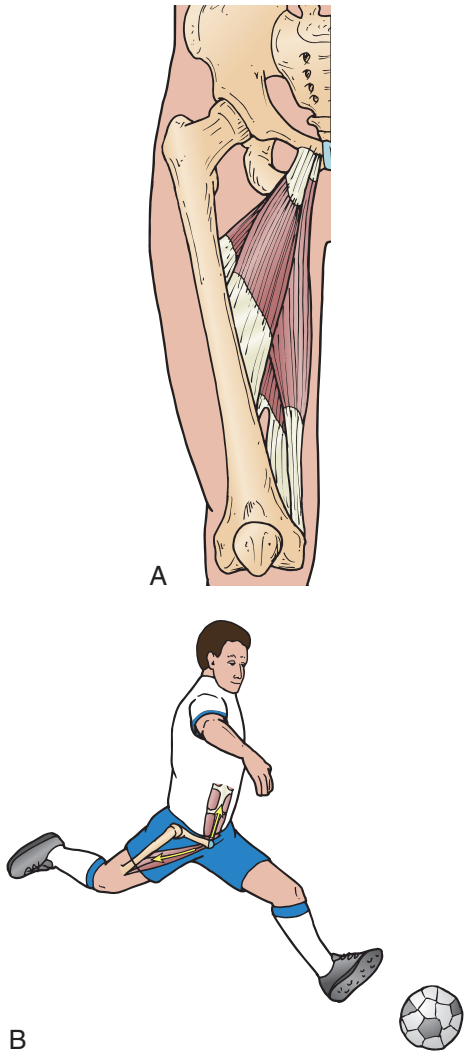

FIGURE 24-1. A, The location of the most frequently injured muscle in a groin strain, the adductor longus. **B,** An Adductor longus strain occurrence in sport.

Imaging

- X-rays
- CT scan
- MRI (Figure 24-2)

Differential Diagnosis

- Athletic pubalgia: injury to the transversalis fascia leading eventually to incompetency of the posterior inguinal wall. A diagnosis of exclusion
- Osteitis pubis: increased uptake on bone scan or CT scan at the pubic symphysis.
- Hernia: positive inguinal hernia exam.
- Hip-joint osteoarthrosis: hip X-ray revealing avascular necrosis or osteoarthritis of hip.
- Rectal or testicular referred pain: MRI of suspected region.
- A coexisting fracture of the pelvis or the hip: seen on X-ray.
- Hip flexor strain.

Treatment

Nonoperative Management

- Bracing/spica (Figure 24-3)
- Rehabilitation
- Correction of faulty biomechanics
- PRP

Guidelines for Choosing Among Nonoperative Treatments

- No bony avulsion
- No sports hernia

FIGURE 24-2. An MRI of a grade 3 adductor strain.

FIGURE 24-3. Example of a hip spica to provide support and protection to the adductors.

Surgical Indications

- Avulsion of the adductor longus
- Sports hernia

Aspects of History, Demographics, or Exam Findings that Affect Choice of Treatment

- The degree of the groin strain.
- Whether a palpable defect is present.

Aspects of Clinical Decision Making When Surgery Is Indicated

- MRI revealing bony involvement.
- Failed greater than 6 months of nonoperative treatment.

Evidence

Arnason A, Sigurdsson SB, Gudmundsson A, et al: Risk factors for injuries in football. *Am J Sports Med* 32(1 Suppl):5S–16S, 2004.

Height, weight, body composition, flexibility, leg extension power, jump height, peak O_2 uptake, joint stability, and history of previous injury were recorded for 306 male football players. Risk factors for a groin strain were a previous groin strain and decreased range of motion in hip abduction. Age and previous injury were identified as the main risk factors for injury among elite football players from Iceland. (Level III evidence).

Feeley BT, Powell JW, Muller MS, et al: Hip injuries and labral tears in the national football league. *Am J Sports Med* 36:2187–2195, 2008.

This descriptive epidemiology study defined the incidence and etiologic factors of intra- and extraarticular hip injuries in the NFL. The NFL Injury Surveillance System was used to define all hip-related injuries from 1997 to 2006. There were a total of 23,806 injuries from 1997 to 2006, of which 738 were hip injuries (3.1%) with an average of 12.3 days lost per injury. Muscle strains were the most common injury. Intraarticular injuries resulted in the most time lost. Contact injuries most likely resulted in a contusion, and noncontact injuries most often resulted in a muscle strain. (Level III evidence).

Hölmich P, Larsen K, Krogsgaard K, et al: Exercise program for prevention of groin pain in football players: a cluster-randomized trial. *Scand J Med Sci Sports* 20:814–821, 2010.

A total of 1211 soccer players were randomized to an exercise program aimed at preventing groin injuries or to a control group. The intervention program consisted of six exercises including strengthening, coordination, and core stability exercises. Twenty-two teams in each group completed the study, represented by 977 players. The risk of a groin injury was reduced by 31%, but this reduction was not significant. An analysis showed that having had a previous groin injury almost doubles the risk of developing a new groin injury and playing at a higher level almost triples the risk of developing a groin injury. (Level II evidence).

Robinson P, Barron DA, Parsons W, et al: Adductor-related groin pain in athletes: correlation of MR imaging with clinical findings. *Skeletal Radiol* 33:451–457, 2004.

The purpose of this study was to evaluate gadolinium-enhanced MR imaging in athletes with chronic groin pain and correlate with the clinical features. MR examinations performed in 52 athletes with chronic groin pain and 6 asymptomatic control athletes were independently reviewed by two radiologists masked to the clinical details. The extent and side of anterior pubis and adductor longus enthesis abnormality on MR imaging significantly and reproducibly correlated with the athletes' current symptoms in chronic adductor-related groin pain. (Level II evidence).

Tyler TF, Campbell R, Nicholas SJ, et al: The association of hip strength and flexibility on the incidence of groin strains in professional ice hockey players. *Am J Sports Med* 29:668–673, 2000.

This prospective study was conducted to determine whether hip muscle strength and flexibility play a role in the incidence of adductor and hip flexor strains in NHL ice hockey team players. Hip flexion, abduction, and adduction strength were measured in 81 players before two consecutive seasons. Preseason hip adduction strength was 18% lower in the players who subsequently sustained an adductor muscle strain compared with that of uninjured players. Adduction strength was 95% of abduction strength in the uninjured players, but only 78% of abduction strength in the injured players. A player was 17 times more likely to sustain an adductor muscle strain if his adductor strength was less than 80% of his abductor strength. (Level I evidence).

Multiple Choice Questions

QUESTION 1. When building an injury prevention program for groin strain, which muscle group should be strengthened?

A. Abductors
B. Adductors
C. Hip flexors
D. Hamstrings

QUESTION 2. What is one of the strongest intrinsic factors that predisposes an athlete to a groin injury/strain?

A. Strength ratio of the adduction to abduction muscle groups
B. Increased preseason practice sessions
C. Previous groin strain
D. A lack of mechanical advantage for the adductor longus

QUESTION 3. In a clinical examination, pertinent normal findings to look for may include:

A. Swelling in the groin region
B. Decreased muscle force of the adductors
C. Pain on contraction of the adductor muscle group
D. Symmetrical adductor force production of both lower extremities

QUESTION 4. A general guideline for choosing a nonsurgical treatment option consist of:

A. Avulsion of the adductor longus
B. Sports hernia
C. No bony avulsion
D. Hip fracture

QUESTION 5. An increased uptake on a bone scan or CT scan may differentiate which of the following from a diagnosis of groin strain?

A. Osteitis pubis
B. Athletic pubalgia
C. Hernia
D. Hip-joint osteoarthrosis

Answer Key

QUESTION 1. Correct answer: **B** (see Pathophysiology)

QUESTION 2. Correct answer: **C** (see Pathophysiology)

QUESTION 3. Correct answer: **D** (see Clinical Presentation)

QUESTION 4. Correct answer: **C** (see Treatment)

QUESTION 5. Correct answer: **A** (see Differential Diagnosis)

NONOPERATIVE REHABILITATION OF ADDUCTOR AND HIP JOINT STRAINS

Timothy F. Tyler, MS, PT, ATC, and Stephen J. Nicholas, MD

GUIDING PRINCIPLES OF NONOPERATIVE REHABILITATION

- Pain
- Range of motion
- Restore the adduction-to-abduction strength ratio of the injured leg
- Function

Phase I (weeks 0 to 3 to 6)

Protection

- Compression shorts or a wrap bandage may be helpful in decreasing swelling and provide support.
- If walking causes pain, limit weight bearing; crutches are considered for the first day or two after the injury.

Management of Pain and Swelling

- RICE (rest, ice, compression, elevation) is the standard protocol for mild to moderate muscle strains for the first 24 to 48 hours.
- Electrical stimulation, cold laser, or ultrasound can be useful in healing.

Techniques for Progressive Increase in Range of Motion

Therapy Techniques

- Gentle pain-free sub maximal contractions within 48 hours. Maintain pain-free available passive range of motion.

TIMELINE 24-1: **Nonoperative Rehabilitation of Adductor and Hip Joint Strains**

PHASE I (weeks 0 to 4)	PHASE II (weeks 4 to 8)
• RICE (rest, ice, compression and elevation) for first ~48 hours after injury • NSAIDs • Massage • TENS • Ultrasound • Submaximal isometric adduction with knees bent, with knees straight progressing to maximal isometric adduction, pain free • Hip passive range of motion (PROM) in pain-free range • Non weight-bearing hip progressive resistive exercises (PREs) without weight in antigravity position (all except abduction), pain-free, low load, high repetition exercise • Upper body and trunk strengthening • Contralateral LE strengthening • Flexibility program for noninvolved muscles • Bilateral balance board	• Bicycling/swimming • Sumo squats • Single limb stance • Concentric adduction with weight against gravity • Standing with involved foot on sliding board moving in frontal plane • Adduction in standing on cable column or Thera-Band • Seated adduction machine • Bilateral adduction on sliding board moving in frontal plane (i.e., bilateral adduction simultaneously) • Unilateral lunges (sagittal) with reciprocal arm movements • Multiplane trunk tilting • Balance board squats with throwbacks • General flexibility program • Involved lower extremity PROM equal to that of the uninvolved side and involved adductor strength at least 75% that of the ipsilateral abductors.

Soft Tissue Techniques

- Gentle massage to the area with ice to help decrease swelling.

Other Therapeutic Exercises

- Biking for maintaining fitness
- Upper body and trunk strengthening
- Core stability

Activation of Primary Muscles Involved

- Submaximal isometric adduction with knees bent (Figure 24-4), with knees straight progressing (Figure 24-5) to maximal isometric adduction.
- If pain free, progress to side-lying hip adduction against gravity (Figure 24-6).
- Hip passive range of motion (PROM) in pain-free range.

FIGURE 24-4. Submaximal adductor strengthening with short lever arm.

FIGURE 24-5. Submaximal adductor strengthening with long lever arm.

FIGURE 24-6. Side-lying hip adduction against gravity.

Sensorimotor Exercises

- Bilateral balance board
- Single leg stance on stable surface

TIMELINE 24-1: **Nonoperative Rehabilitation of Adductor and Hip Joint Strains** (Continued)

PHASE III (weeks 8 to 12)	PHASE IV (weeks 12+)
• Phase II exercises with increase in load, intensity, speed and volume • Standing resisted stride lengths on cable column to simulate skating • Slide board • On ice kneeling adductor pull togethers • Lunges (in all planes) • Correct or modify ice skating technique	• Heavy load isolated eccentrics of the adductors • On ice training forward/backwards/crossovers • Skating with without the puck • Skating with puck • Stickhandling, passing, shooting • Scrimmage NO contact • Scrimmage • Game play

Open and Closed Kinetic Chain Exercises

Nonweight-bearing hip progressive resistive exercises (PREs) without weight in antigravity position (all except abduction), pain-free, low load, high repetition exercises.

- Mini squats to full squats

Techniques to Increase Muscle Strength, Power, and Endurance

- Contralateral LE strengthening

Neuromuscular Dynamic Stability Exercises

- Flexibility program for noninvolved muscles

Sport-Specific Exercises

- Hockey: stick-handling while standing with the ball

Milestones for Progression to the Next Phase

- Pain-free passive range of motion
- Minimal swelling as measured by clinical palpation and observation.
- Concentric adduction against gravity without pain.
- Normal gait with full weightbearing

Phase II (weeks 3 to 6 and weeks 6 to 8)

Protection

- Compression shorts
- Hip spica

Management of Pain and Swelling

- Electrical stimulation
- Cold laser
- Ultrasound
- Ice

Techniques for Progressive Increase in Range of Motion

Manual Therapy Techniques

- Manual resistance to adductors. Providing minimal resistance to the leg proximal then moving more distally towards the ankle. Resistance should always be pain free.

Soft Tissue Techniques

- Graston technique and/or deep tissue massage. Gentle massage to the knee to milk the fluid away from the groin

Stretching and Flexibility Techniques for the Musculotendinous Unit

- Initiate gentle PROM of adductor and hip flexors. Gentle stretching so as not to cause plastic deformation of the muscle.

Other Therapeutic Exercises

- Elliptical
- StairMaster
- Treadmill long stride walking
- Bicycling
- Swimming

Activation of Primary Muscles Involved

- Concentric adduction with weight against gravity. Start with 2 lbs and try to achieve 3 sets of 10, then move to 3 sets of 15 followed by 1 set of 30 at the same weight. If the patient can perform 1 set of 30 with that weight, add 2 lbs and go back to doing 3 sets of 10 repetitions.
- Adduction in standing on cable column or Thera-Band. Start the athlete with yellow Thera-Band and then move to red once they achieve 30 repetitions with perfect form.
- Seated adduction machine. Use a pain free resistance level so the patient can achieve 3 sets of 10.
- General flexibility program. Perform a general flexibility assessment looking for asymmetrical tightness from anterior to posterior or restrictions from involved non-involved sides.

Sensorimotor Exercises

- Single-leg stance standing on the floor, the patient is bare foot, knee slightly bent and eyes open. Perform SLS for 30 seconds. Try and achieve this 3 times. If the patient can perform easily without pain or loss of balance, progress to 1 minute for 3 sets. If patient cannot perform for 30 seconds or 1 minute, decrease time and/or add UE support. This exercise can be progressed by adding an unstable surface (BAPS, Thera-Band, stability pad etc.)
- Quick steps: Quick alternating steps over a line on the floor. Count the number of repetitions.
- Tic tock: Feet shoulder width apart and pass the ball back and forth quickly between feet.
- Lateral band walks (Figure 24-7)
- Balance board tosses: Patient in mini squat position, perform 30 tosses in a row without touching either side of board to the floor. Perform this 3 times. Progress to overhead throw and side chops while maintaining balance.

Open and Closed Kinetic Chain Exercises

- Sumo squats (Figure 24-8): Begin with 3 sets of 10, stand on the floor with pain-free and proper form, add a kettle bell for resistance.

FIGURE 24-7. Lateral band walks.

FIGURE 24-8. Sumo squats.

- Contralateral Thera-Band: Stand on the involved leg and move the noninvolved leg into different planes of motion, for example hip abduction/extension.
- Leg Press: Perform 3 sets of 10 progressing to 3 sets of 12 and 3 sets of 15 with two legs in pain-free resistance. Progress to single leg.

Neuromuscular Dynamic Stability Exercises

- Standing with involved foot on sliding board moving in frontal plane (Figure 24-9)
- Balance board squats with throwbacks: With patient in mini squat position, perform 30 tosses in a row without touching either side of the board to the floor. Perform this 3 times. Progress to overhead throw and side chops while maintaining balance.

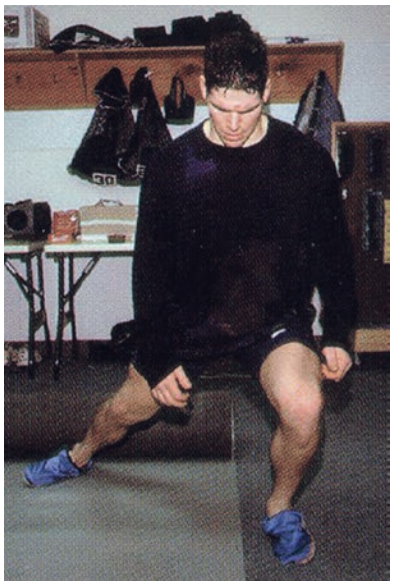

FIGURE 24-9. Standing with involved foot on sliding board moving in frontal plane.

Plyometrics

- Lateral shuffles: Maintain proper alignment in mini squat position (watch for knees diving in) shuffle side to side across the room. Begin at 50% speed pain-free and progress to 75% and then full speed.

Functional Exercises

- Lunges (forward and lateral) with reciprocal arm movements.
- Unweighted spilt jumps: Explosively jump while using the arms to assist as needed. While in mid-air switch the leg position landing softly in lunge position. Progress for maximum height and power.
- Forward/backward running drills: Begin at 50% and progress to 75% to then full speed. Therapist can add in directional changes.

Sport-Specific Exercises

- Bilateral adduction on sliding board moving in frontal plane (i.e., bilateral adduction simultaneously). Standing on sliding board slide both legs together. Perform as many as patient can pain-free.
- Skater strides (Figure 24-10): In skating position, see how many times the patient can go back and forth along the slide board. Increasing the number of reps and speed as they progress within the same timeframe.

Milestones for Progression to the Next Phase

- Involved lower extremity PROM equal to that of the uninvolved side
- Involved adductor strength at least 75% that of the ipsilateral abductors. This is determined by performing a break test using a hand held dynamometer.

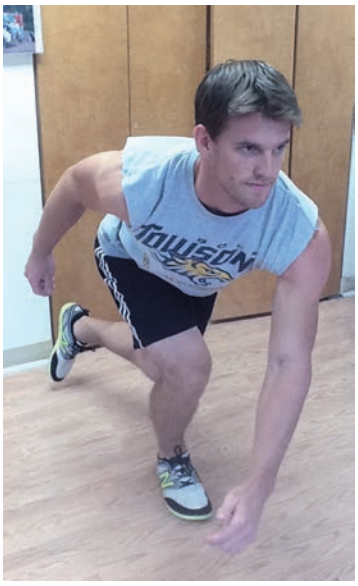

FIGURE 24-10. Skater strides.

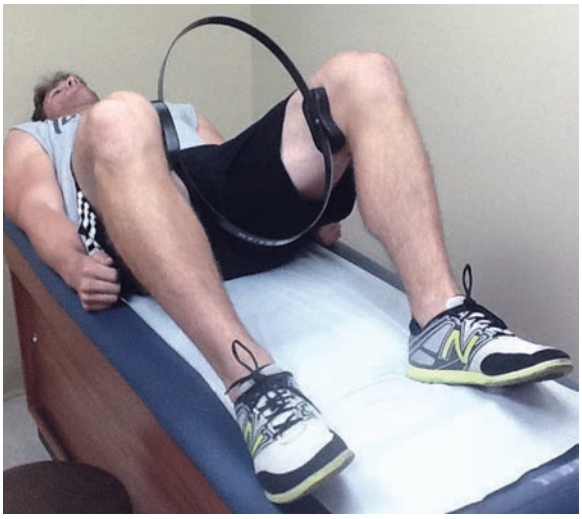

FIGURE 24-11. Ring squeezes.

FIGURE 24-12. Ring squeezes in table top.

Phase III (weeks 6 to 8 and weeks 9 to 12)

Protection

- Hip spica

Management of Pain and Swelling

- Biofreeze
- Ice
- Compression wrap

Techniques for Progressive Increase in Range of Motion

Manual Therapy Techniques

- Manual resistance to adductors

Soft Tissue Techniques

- Graston technique and/or deep tissue massage

Stretching and Flexibility Techniques for the Musculotendinous Unit

- Progressive stretching of the adductors

Other Therapeutic Exercises

- Phase II exercises with increase in load, intensity, speed, and volume
- Core stability with/without stability ball: planks, side planks, double-leg/single-leg bridges. Use a time based approach starting at 30 seconds progressing to one minute.

Activation of Primary Muscles Involved

- Eccentric lengthened state strengthening of the adductors
- Ring squeezes (Figure 24-11)
- Ring squeezes in table top position (Figure 24-12)
- Hip adductor machine

Sensorimotor Exercises

- Slide board side to side

Open and Closed Kinetic Chain Exercises

Standing resisted stride lengths on cable column to simulate skating

Techniques to Increase Muscle Strength, Power, and Endurance

- Lunges (in all planes)

Neuromuscular Dynamic Stability Exercises

- Single-leg cable column ice skating stride
- Quick kick with Thera-Band
- Perturbation training

Plyometrics

- Bounding side to side

Functional Exercises

- Correct or modify ice skating technique

Sport-Specific Exercises

- On ice kneeling adductor pull togethers

Milestones for Progression to Advanced Sport-Specific Training and Conditioning

- Adduction strength, at least 90% to 100% of the abduction strength. This is determined by performing a break test using a hand held dynamometer.
- Involved adductor muscle strength equal to that of the contralateral side. This is determined by performing a break test using a hand held dynamometer.

Phase IV (weeks 12+)

Protection

- Hip spica
- Compression shorts

Management of Pain and Swelling

- Ice

Techniques for Progressive Increase in Range of Motion

Manual Therapy Techniques

- Contract-relax

Soft Tissue Techniques

- Massage

Stretching and Flexibility Techniques for the Musculotendinous Unit

- Stretching of the adductors

Other Therapeutic Exercises

- Running
- Squats
- Dead lifts
- Cleans
- Snatches

FIGURE 24-13. Split squats.

Activation of Primary Muscles Involved

- Heavy load eccentrics of adductors and hip flexors

Sensorimotor Exercises

- Ice skating with drill

Open and Closed Kinetic Chain Exercises

- Split squats (Figure 24-13)

Techniques to Increase Muscle Strength, Power, and Endurance

- Timed slide board slides

Neuromuscular Dynamic Stability Exercises

- Ice single-limb stance

Plyometrics

- Box jumps

Milestones to Progress to Sport-Specific Training and Conditioning

- Pain-free range of motion
- Pain-free ice skating
- Symmetrical strength of adductors in shortened, mid range and lengthened state of the muscle. We determine this by performing a break test using a hand held dynamometer. Approximately 10° from the most shortened muscle length and 10° from the longest muscle length.
- No limiting symptoms with full speed functional drills

Criteria for Abandoning Nonoperative Treatment and Proceeding to Surgery or More Intensive Intervention

- No response in returning strength
- Grade 3 tear

Tips and Guidelines for Transitioning to Performance Enhancement

- All motion loaded and unloaded in the frontal sagittal and transverse plane should be pain free.
- During this period there should be no movement deviations or compensations.

Performance Enhancement and Beyond Rehabilitation: Training/Trainer and Optimization of Athletic Performance

- Perturbation training on and off the ice

Specific Criteria for Return to Sports Participation: Tests and Measurements

- Confidence in the lower extremity.
- 100 % recovery. Ask the patient what percent of 100% are they today, and then compare this to the uninjured side.

Evidence

Engebretsen AH, Myklebust G, Holme I, et al: Prevention of injuries among male soccer players: a prospective, randomized intervention study targeting players with previous injuries or reduced function. *Am J Sports Med* 36:1052–1060, 2008.

A total of 508 players were divided into high-risk (HR) (76%) and low-risk (LR) groups. The HR players were randomized individually into an HR intervention group or HR control group. A total of 505 injuries were reported, sustained by 56% of the players. Compliance with the training programs in the HR intervention group was poor, with only 27.5% in the ankle group, 29.2% in the knee group, 21.1% in the hamstring group, and 19.4% in the groin group defined as having carried out the minimum recommended training volume. The players with a significantly increased risk of injury were able to be identified through the use of a questionnaire, but player compliance with the training programs prescribed was low and any effect of the intervention on injury risk could not be detected. Randomized controlled trial. (Level II evidence).

Hölmich P, Uhrskou P, Ulnits L, et al: Effectiveness of active physical training as treatment for long-standing adductor-related groin pain in athletes: randomized trial. *Lancet* 353:439–443, 1999.

This randomized clinical trial compared an active training rehabilitation program (AT) with a passive rehabilitation program (PT) in the treatment of 68 athletes with long-standing groin pain. Twenty-three patients in the AT group returned to sports without groin pain while only four returned in the PT group. AT with a program aimed at improving strength and coordination of the muscles acting on the pelvis, in particular the adductor muscles, is very effective in the treatment of athletes with long-standing adductor-related groin pain. (Level I evidence).

Robinson P, Barron DA, Parsons W, et al: Adductor-related groin pain in athletes: correlation of MR imaging with clinical findings. *Skeletal Radiol* 33:451–457, 2004.

The purpose of this study was to evaluate gadolinium-enhanced MR imaging in athletes with chronic groin pain and correlate with the clinical features. MR examinations performed in 52 athletes with chronic groin pain and 6 asymptomatic control athletes were independently reviewed by two radiologists masked to the clinical details. The extent and side of anterior pubis and adductor longus enthesis abnormality on MR imaging significantly and reproducibly correlates with the athletes' current symptoms in chronic adductor-related groin pain. (Level II evidence).

Schlegel TF, Bushnell BD, Godfrey J, et al: Success of nonoperative management of adductor longus tendon ruptures in National Football League athletes. *Am J Sports Med* 37: 2009.

Adductor tendon ruptures documented by MRI were identified in 19 NFL players. Fourteen players were treated nonoperatively, and 5 players were treated with surgical repair using suture anchors, all players eventually returned to play. Mean time for return to play was 6.1 ± 3.1 weeks (range, 3 to 12 weeks) for the nonoperative group and 12.0 ± 2.5 weeks (range, 10 to 16 weeks) for the operative group ($p = .001$). Nonoperative treatment of proximal adductor tendon rupture results in a statistically significantly faster return to play than does operative treatment in athletes competing in the NFL. (Level III evidence).

Multiple-Choice Questions

QUESTION 1. Which is not an appropriate clinical guideline for progressing from Phase I to Phase II?

A. Pain-free PROM
B. Minimal swelling
C. Abduction strength
D. Pain-free concentric adduction against gravity

QUESTION 2. Which of the following should be avoided in Phase I?

A. Adductor strengthening
B. Submax isometrics
C. Ultrasound
D. Ice

QUESTION 3. What factors have been proven to put athletes at risk for adductor strains?

A. Gender
B. History of ITB friction syndrome
C. Ambient temperature
D. Poor hip adductor to abductor ratio

QUESTION 4. Which of the following is NOT a guiding principle of rehab for an adductor strain?

A. Thigh girth
B. ROM
C. Function
D. Restoring abduction to adduction strength ratio

QUESTION 5. What added protection may a sports clinician give to a player to return to play?

A. Tape
B. Thera-Band
C. Hip spica
D. Underwear

Answer Key

QUESTION 1. Correct answer: **B** (see Phase I)

QUESTION 2. Correct answer: **A** (see Phase I)

QUESTION 3. Correct answer: **D** (see Introduction, Evidence)

QUESTION 4. Correct answer: **A** (see Guiding Principles)

QUESTION 5. Correct answer: **C** (see Phase IV)

BEYOND BASIC REHABILITATION: RETURN TO HOCKEY AFTER ADDUCTOR STRAIN

Timothy F. Tyler, MS, PT, ATC, and Stephen J. Nicholas, MD

Introduction

- Groin strains are a prevalent pathology associated with ice hockey and have a high recurrence rate.
- It is particularly challenging to return to the sport because the player needs stability on a single leg on a skate blade, which requires adductor strength.
- The three mechanisms of ice hockey hip and adductor strains are (Figure 24-14*A, B, and C*):
  - Excessive ROM
  - Contact with an opposing player
  - Contact with ice

ASPECTS OF HOCKEY THAT REQUIRE SPECIAL ATTENTION IN REHABILITATION

- Balance
- Agility
- Strength
- Power
- Kinetics
- Anaerobic power
- Speed endurance and training

Phase I: Advanced Strength and Conditioning Programs

Periodization

- Linear
- Microcycles

Program Design/Performance Training Program

Sport-Specific Concepts of Integrated Training

- Training continuum
- Flexibility/joint mobility for joint stability
- Training with hockey posture
- Sensorimotor and balance training
- Core training
- Cardiorespiratory training
- Multiplanar training activities
- Training for optimum muscle balance
- Training for optimum muscle functional strength
- Training for optimum muscle functional power
- Neuromuscular dynamic stability exercises
- Training for speed, agility, quickness (SAQ)
- Plyometric training
- Functional training
- Sport-specific training

Olympic Lifts Used in the Training Program

- Snatch
- Clean and jerk
- Power clean

Training Principles Used in the Design of the Program

- Principle of progression
- Principle of overload
- Principle of variation
- Principle of individualization
- Principles of specificity–specific adaptation to imposed demands (SAID)

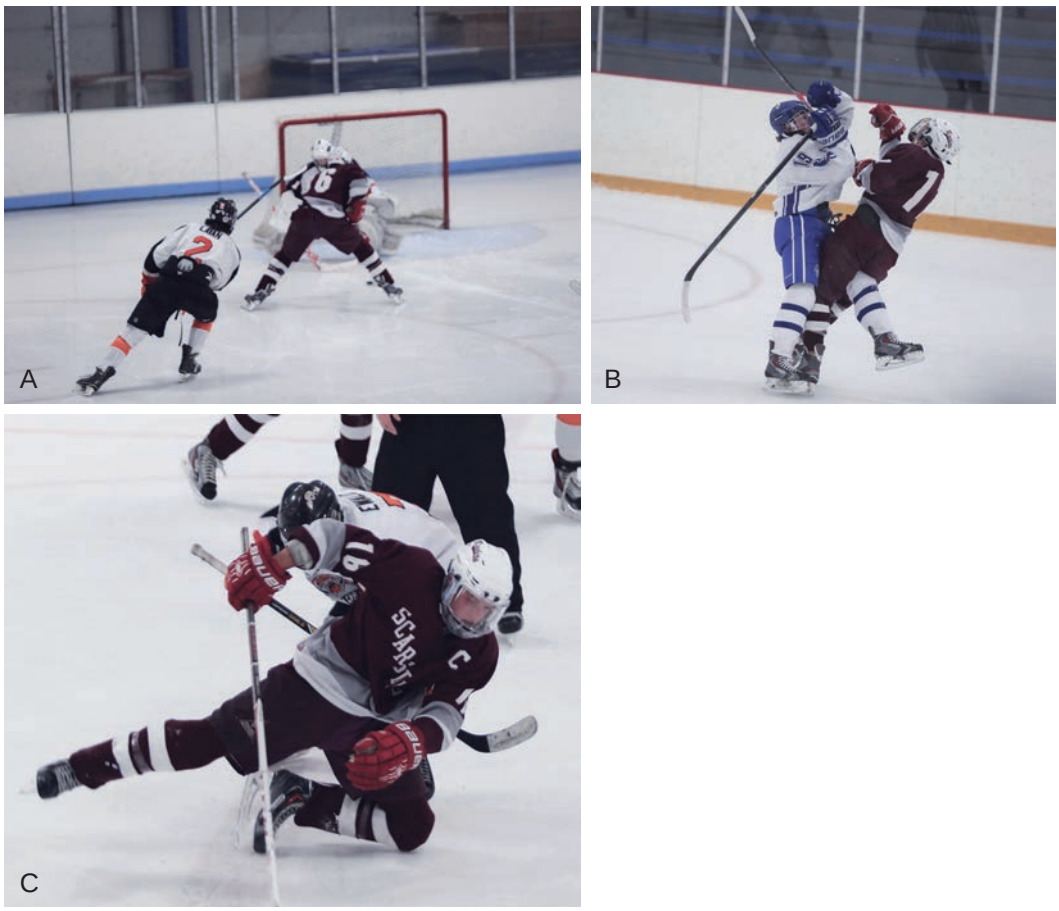

FIGURE 24-14. The three mechanisms of ice hockey hip and adductor strains. **A**, Excessive ROM. **B**, Contact with an opposing player. **C**, Contact with ice.

Application of Acute Training Variables

- High repetitions
- 5 to 14 sets
- 30 to 60 second rest interval
- Moderate intensity
- Training frequency of TIW
- Training duration of 10 to 20 minutes
- Training volume of 8 to 14 sets
- Specific exercises used in the training are sumo squats, on-ice squeezes, isometric ball squeezes.

TIMELINE 24-2: **Beyond Basic Rehabilitation: Return to Hockey after Adductor Strain**

PHASE I	PHASE II	PHASE III
Warmup	**Advanced Strengthening Program**	**Sport-Specific Training**
• Bike • Adductor stretching • Sumo squats • Side lunges • Kneeling pelvic tilts	• Bilateral adduction on sliding board moving in frontal plane (i.e. bilateral adduction simultaneously) • Unilateral lunges with reciprocal arm movements	• On-ice kneeling adductor pull togethers • Standing resisted stride lengths on cable column to simulate skating • Slide skating • Cable column crossover pulls
Strengthening Program		
• Ball squeezes (legs bent to legs straight) • Different ball sizes • Concentric adduction with weight against gravity • Adduction in standing on cable column or elastic resistance • Seated adduction machine • Standing with involved foot on sliding board moving in sagittal plane		

Phase II: Performance Enhancement Training Techniques

Periodization

- Linear
- Undulating
- Macrocycles
- Mesocycles
- Microcycles

Program Design/Performance Training Program

Sport-Specific Concepts of Integrated Training

- Core training
- Cardiorespiratory training
- Multiplanar training activities
- Training for optimum muscle balance
- Training for optimum muscle functional strength
- Training for optimum muscle functional power
- Neuromuscular dynamic stability exercises
- Training for speed, agility, quickness (SAQ)
- Plyometric training
- Functional training on the ice
- Sport-specific training on the slide board

Olympic Lifts used in the Training Program

- Snatch
- Clean and jerk
- Power clean

Training Principles Used in the Design of the Program

- Principle of progression
- Principle of overload
- Principle of variation
- Principle of individualization
- Principles of specificity–specific adaptation to imposed demands (SAID)

Application of Acute Training Variables

- 6 to 12 repetitions
- 8 to 10 sets per body part
- Rest interval of 60 seconds
- High intensity
- Slow repetition tempo
- Training frequency of 48 hours rest for each body part
- Training duration of 6 to 10 weeks
- Training volume of no more than 30 repetitions
- Specific exercises used in the training
  - Split squats (See above: gives some guidelines to the readers regarding volume of training for the different exercises)
  - Squats
  - Lunges
  - Slide board
  - Diagonal PNF
  - Light agility program with on-ice directional changes

Application of Chronic Training Variables

- Repetition to create muscle memory.

Phase III: Sport-Specific Training

Periodization

- Linear
- Macrocycles: full year and will rest after the season is over
- Mesocycles: resistance training to balance adductor to abductor strength ratio.
- Microcycles: individual sport specific eccentric training

Program Design/Performance Training Program

Sport-Specific Concepts of Integrated Training

- Training continuum
- Flexibility/joint mobility for joint stability
- Sport-specific on-ice training

Training Principles Used in the Design of the Program

- Principle of progression: The Delorme principle is recommended to progress resistance training.
- Principle of overload: The Oxford training principles are recommended.
- Principle of variation: Perform dry land training 2 times per week during the hockey season.
- Principle of individualization: An example of this is to emphasize the end range strength in goaltenders who are functioning often in their end ROM.

Application of Acute Training Variables

- 2 to 5 repetitions on-ice
- 2 minute rest interval
- Maximum intensity
- Repetition tempo as fast as the athlete can
- Daily training frequency
- 10 to 20 minute training duration
- High training volume
- Specific exercises used in the training
  - Forward skating
  - Backwards skating
  - Clockwise cross overs
  - Counter clockwise cross overs
  - One on ones
  - Two on ones
  - Three on twos
  - Scrimmage no contact
  - Scrimmage with checking
  - Game

Application of Chronic Training Variables

- Applied to the athlete's tolerance.

Sports Performance Testing

General Information

- General history
- Subjective questionnaires
- Medical history
- Sports injury history
- Surgical history
- Chronic conditions/medication
- Impact testing
- Eye exam

Specific Criteria for Progression to the Next Stage to Determine their Readiness for Hockey

Objective Tests

- Physiological assessments. Girth measurements to asses for atrophy.
- Body composition tests BMI, skin-fold testing.
- Movement performance testing to look for ROM and strength deficits forward and backward shuttle runs looking for asymmetrical body movement.
- Sport-specific testing: Timed slide board slides.
- Impact testing for concussion management.
- On-ice testing: Timed circles in both directions to assess single limb stance ability on skates.

Criteria for Determining Readiness for Sport

- Rate of perceived exertion

Specific Criteria for Releasing an Athlete to Unsupervised Complete Participation in Hockey

- Pain-free full ROM and strength throughout the range.
- Symmetrical adduction strength, symmetrical single-leg hop for distance. Hand held dynamometer testing in which the involved hip adductors are 80% of the hip abductors of the involved leg.
- Subjective 100% confidence of patient that they are ready to return.

Recommended Ongoing Exercises

- Standing unilateral elastic resistance, slide board, balance board.

Evidence

Tyler TF, Campbell R, Nicholas SJ, et al: The effectiveness of a preseason exercise program on the prevention of groin strains in professional ice hockey players. *Am J Sports Med* 30:680–683, 2002.

A total of 33 of 58 players from the same NHL team were identified as at risk on the basis of preseason hip adductor strength and participated in an intervention program. The program consisted of 6 weeks of exercises aimed at functional strengthening of the adductor muscles. Adductor strains were reduced by 78% compared to the previous seasons. A therapeutic intervention of strengthening the adductor muscle group appears to be an effective method for preventing adductor strains in professional ice hockey players. (Level I evidence).

Multiple-Choice Questions

QUESTION 1. Where should most sport specific training be done?

A. On ice
B. Gym
C. Training room
D. At night at home

QUESTION 2. What is a good acute training exercise for warming up?

A. Box jumps
B. Isokinetics
C. Sumo squats
D. Ultrasound

QUESTION 3. Repeated sprints should take how long to complete?

A. Each 5 to 6 minutes to complete
B. All day
C. Each takes 4 to 6 seconds
D. Each takes 45 to 60 seconds

QUESTION 4. Why is it particularly challenging to return to hockey after a groin strain?

A. Hockey players have less stability than other athletes
B. Younger people play hockey
C. Most are multisport athletes
D. The player needs stability on a single leg on a skate blade, which requires adductor strength

QUESTION 5. During speed training the training should include how many turns?

A. 4
B. 3
C. 9
D. 1

Answer Key

QUESTION 1. Correct answer: **A** (see Box 24-1)

QUESTION 2. Correct answer: **C** (see Warm-up phase of guidelines)

QUESTION 3. Correct answer: **D** (see Box 24-1)

QUESTION 4. Correct answer: **D** (see Introduction)

QUESTION 5. Correct answer: **D** (see Box 24-1)

BOX 24-1 Advanced Rehabilitation Program: On- and Off-Ice Workouts

On-Ice Workouts

ANAEROBIC POWER TRAINING

- Repeated sprints that each take 45 to 60 seconds to complete. Move goals forward to approximately in line with the end zone face-off spots and have athletes skate 3 laps as fast as they can. Rest period should be 4 to 6 times the sprint time. Players should complete 6 to 8 sets. The rest time can be dictated by how many players are in a group.
- For example, if you want a 5:1 recovery to sprint ratio and you have 18 players, divide the players into 3 groups of 6 with each group stationed at different points around the ice. The first players in each group complete their first set, then the 2nd players go and so on until all 6 players have completed their first set of 3 laps. Then the first 3 players start their 2nd set.
- Direction should be reversed between each set and the goals should be moved to spread the wear on the ice.
- The distance can be fixed by tying a rope between both goals. When the goals are moved, to spread the wear on the ice, make sure the rope remains taught.
- Regardless of how the workout is executed the goal is to have players go all out for 45 to 60 seconds and give them 4 to 6 minutes recovery and repeat 6 to 8 times.
- The distance will depend on the time after injury of the athlete. The shorter the recovery time the slower the subsequent sets.
- The traditional mentality is to have short recovery times so everyone is exhausted for the last couple of sets and crawl over the finish line (no pain no gain mentality). Training adaptations will be better if there is only a small decline in speed from first to last sets.

SPEED ENDURANCE TRAINING

- Repeated sprints that each take 20 to 30 seconds to complete. Figure of 8 sprints performed across the width of the ice, where players start in the middle and have to complete 3 laps (i.e. cross their starting point 6 times).
- The recovery to sprint ratio should be the same or similar to the anaerobic power training i.e. 4:1, 5:1, or 6:1.
- This test is more technically demanding than anaerobic power training because skating ability during turns is critical. Thus this tests a combination of skating ability and fitness.
- The practical issue in doing this test is wear on the ice. Actual distance can be manipulated to match the fitness of the players to stay within the 20 to 30 second time requirements.

SPEED TRAINING

- All out sprint with only 1 turn. The goal is to test instantaneous power.
- For example, start on goal line, sprint to opposite goal line and back to blue line at end where you started (292 foot sprint).
- This should take approximately the same time as the figure of 8 test, but should only be repeated a max of 6 times, with the same 4 to 6:1 recovery:sprint ratio.

Off-Ice Workouts

AEROBIC POWER

- On track 200 meters in 45 second, 200 meters in 90 seconds, repeat 10 to 12 times. This workout is designed for athletes with a VO_2 max of 50 ml/kg/min.
- If you want an accurate measure of their VO_2 max have them run 8 laps (2 miles) and get an accurate time for their max effort. A VO_2 max of 50 ml/kg/min equates to 2 miles in 14 min.

ANAEROBIC POWER

- 30 meter sprint every 30 seconds repeated 6 times, 2 minute recovery, repeat 6 times.
- Players can do alternating 20 sit-ups or pushups during 2 minute recovery.
- In any of these sprint workouts (on-ice or off-ice) it is essential to provide sufficient recovery so that the later sprints are not performed at walking speed.
- Some decrement is expected, but if it is no longer a sprint, that is, they are too fatigued to go fast, then the exercise is not going to be beneficial.
- The key to training the targeted energy systems is quality of the sprint.

Strength workouts

SQUATS*

1. Single-leg split squats with rear leg held back and parallel to ground (2 × 15 or 20)
2. Single-leg split squats with rear leg back and up on bench (approx. 3 feet high) (2 × 15 or 20)
3. Walking split squats; also called lunge walking (20 repetitions)
4. Split squat plyometric jumps; also called lunge jumping (2 × 15 or 20)

JUMPS

1. Lateral jumps: single leg lateral jumps across markings 2 feet apart. Jump for 10 seconds (count repetitions). Do 4 sets each leg, alternating between legs.
2. Skater jumps: lateral jumps across a 5 foot distance (6 feet for adults). Take off on 1 leg and land on the other leg. Do 10 repetitions, rest 1 minute, do 3 sets.

OTHER

Sit-ups and pushups as needed.

*Do numbers 1 and 2 on one day and numbers 3 and 4 on another day

NONOPERATIVE REHABILITATION OF HAMSTRING STRAINS AND CONTUSIONS

Marc Sherry, PT, DPT, LAT, CSCS, PES, Bryan C. Heiderscheit, PT, PhD, and William Clancy, MD, PhD

GUIDING PRINCIPLES OF NONOPERATIVE REHABILITATION

- Excessive or aggressive stretching of the injured hamstrings should be avoided, as this can result in a dense scar formation in the area of injury prohibiting muscle regeneration. However, early mobilization and movement, with pain defining the range of motion limit, is safe and effective for return to sport with minimal chance for injury recurrence.
- Rehabilitation interventions should focus on progressive agility, trunk stabilization, eccentric strengthening and eliminating muscle imbalances.
- Specific evaluation of strength, mobility and apprehension are key indicators for return to sport readiness.

Phase I: Acute (weeks 0 to 4)

Phase I starts as soon as possible after the injury and continues for 5 to 25 days depending on the severity of injury.

Protection

- Crutches may be used in moderate to severe injuries.
- In mild to moderate injuries athletes should be able to shorten their normal stride length to ambulate pain free.

Management of Pain and Swelling

- Modification of activity, particularly avoiding tension on the hamstring during the acute phase
- Compression thigh wraps for moderate to severe injuries to help decrease swelling
- Slight elevation above the heart for moderate to severe injuries to help decrease swelling
  Note: the elevation should not be so great as to stretch the injured hamstrings during this time.
- Cryotherapy
- Use of NSAIDs for this type of injury remains controversial

Therapeutic Exercises

- Stationary biking
- Progressive agility and trunk stabilization (PATS), Phase I
  - Low- to moderate-intensity side stepping, 3 times 1 minute
  - Low- to moderate-intensity grapevine stepping (lateral stepping with the trail leg going over the lead leg and then under the lead leg), both directions, 3 times 1 minute (Figure 24-15)
  - Low- to moderate-intensity steps forward and backward over a tape line while moving sideways, 2 times 1 minute (Figure 24-16)
  - Single-leg stand, progressing from eyes open to eyes closed, 4 times 20 seconds (Figure 24-17)

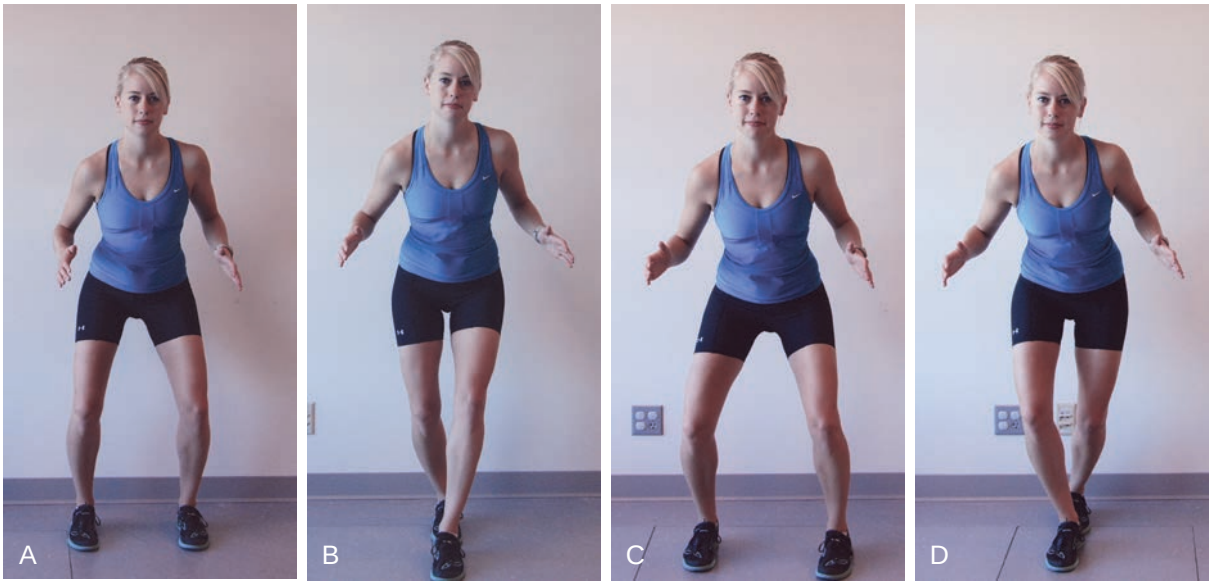

FIGURE 24-15. Grapevine stepping.

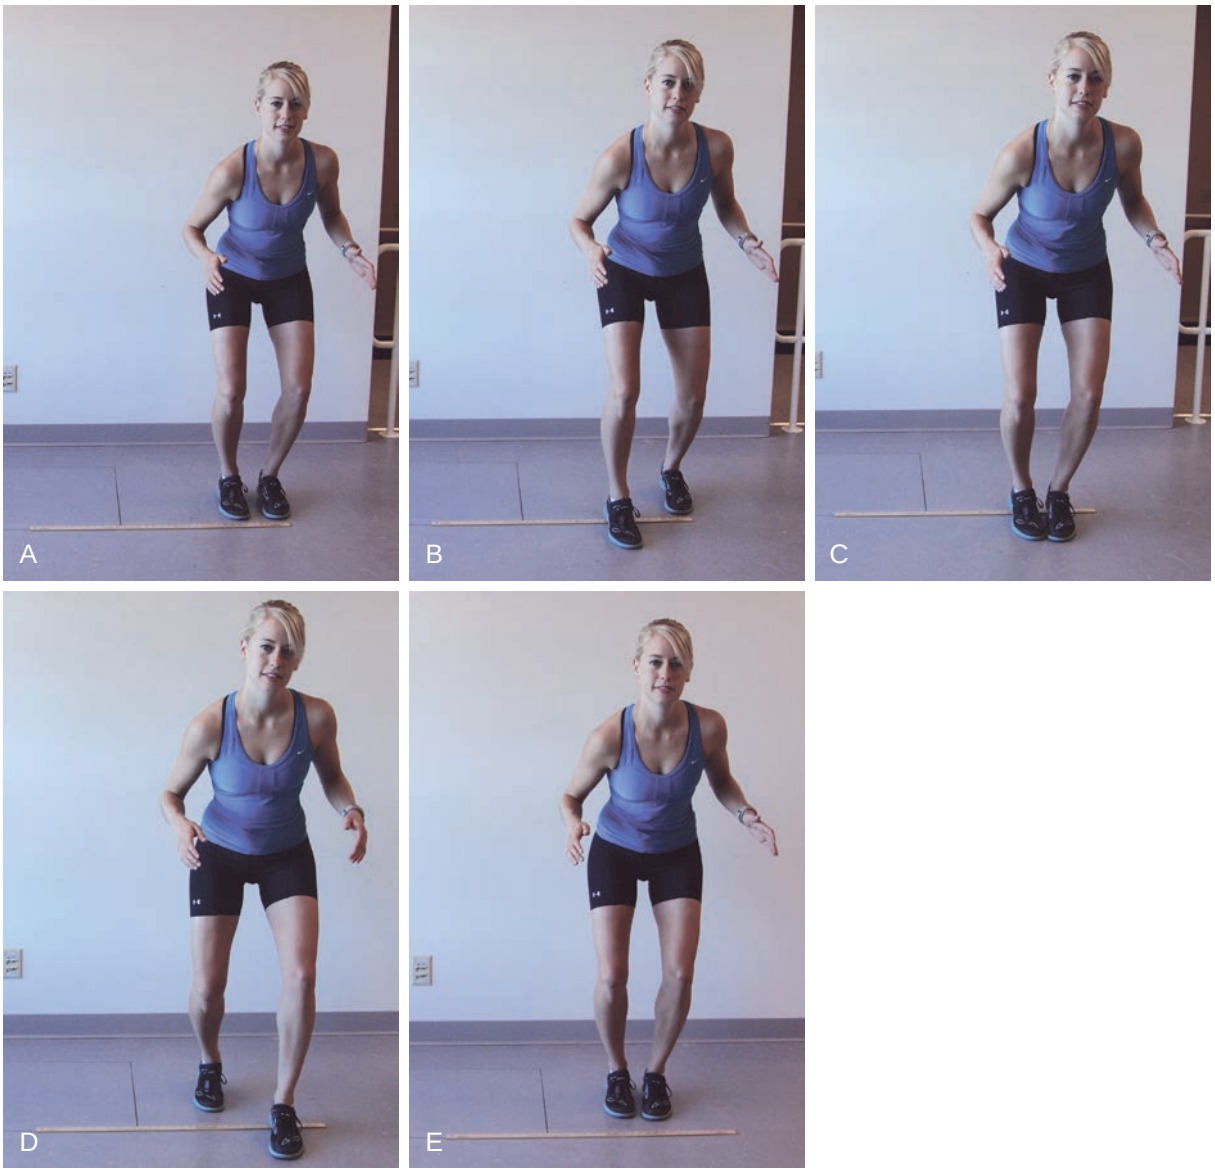

FIGURE 24-16. Forward-backward stepping over a line while moving sideways.

- Prone abdominal body bridge (performed by using abdominal and hip muscles to hold the body in a face down straight plank position with the elbows and feet being the only point of contact), 4 times 20 seconds (Figure 24-18)
- Supine extension bridge (performed by using abdominal and hip muscles to hold the body in a supine hook lying position with the head, upper back, arms and feet being the points of contact), 4 times 20 second (Figure 24-19)
- Side bridge (performed by using abdominal and hip muscles to hold the body in a side-lying plank position with the lower elbow and feet being the only point of contact), four times 20 seconds on each side (Figure 24-20)

Activation of Primary Muscles Involved

- Core muscles of the hip and pelvis, hip abductors and adductors, medial and lateral hamstrings

Sensorimotor Exercises

- Single leg stand, progressing from eyes open to eyes closed

Open and Closed Kinetic Chain Exercises

- Progress agility and trunk stabilization; see above

Techniques to Increase Muscle Strength, Power, and Endurance

- Progress agility and trunk stabilization; see above

Neuromuscular Dynamic Stability Exercises

- Progress agility and trunk stabilization; see above

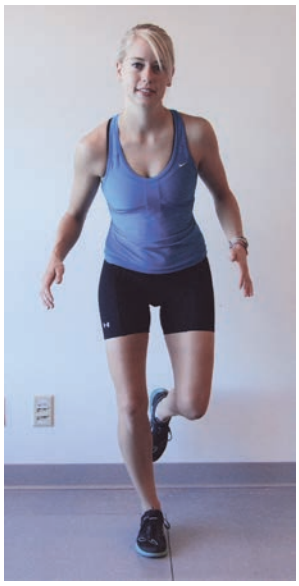

FIGURE 24-17. Single leg standing, progress from eyes open to eyes closed.

FIGURE 24-18. Prone body bridge.

FIGURE 24-19. Supine extension bridge.

Functional Exercises

- Progress agility and trunk stabilization; see above

Milestones for Progression to the Next Phase

- Walk with a normal gait pattern without pain.
- Do a knee to waist height march in place without pain.

TIMELINE 24-3: **Nonoperative Rehabilitation of Hamstring Strains and Contusions**

PHASE I (weeks 0 to 4)	PHASE II (weeks 2 to 8)	PHASE III (starting weeks 4 to 8 postinjury and continuing until return to sport)
Week 1 • Crutches as needed to normalize gait • Begin PATS Phase I • Avoid stretching • Ice and compression wrap to control pain and swelling	• PATS Phase III • Allow gentle hamstring stretching if needed • Neuromobilization techniques • Eccentric strengthening • End-range strengthening • Soft tissue and manual therapy techniques for indirect mobility impairments • Medium-to-high velocity sport-specific and functional drills and skills • Cardiovascular conditioning • Ice as needed	• PATS Phase III (cont) • Lower extremity dynamic mobility drills, including A and B skips • Neuromobilization techniques • End-range eccentric strengthening • Soft tissue and manual therapy techniques for indirect mobility impairments • High-velocity sport-specific and functional drills and skills • Single-leg balance exercises and perturbation type exercises • Sport-specific conditioning
Week 2 • Crutches as needed to normalize gait; DC crutches • PATS Phases I–II • Avoid stretching • Ice and compression wrap to control pain and swelling		
Week 3 • DC crutches • PATS Phases II–III • Avoid stretching • Neuromobilization techniques • Eccentric strengthening • End-range strengthening • Soft tissue and manual therapy techniques for indirect mobility impairments • Low-velocity sport-specific and functional drills and skills • Ice to control pain and swelling		

FIGURE 24-20. Side bridge.

- Have at least 4+/5 strength with one repetition for prone knee flexion at 90° of flexion without pain.

Phase II: Subacute (weeks 2 to 6)

Phase II starts after Phase I milestones are met and continues for 7 to 28 days depending on the severity of injury.

Management of Pain and Swelling

- Ice as needed for postrehabilitation soreness

Manual Therapy Techniques

- During this time if the individual has indirect joint mobility or flexibility limitations, which may have contributed to their injury or the recovery of it, the appropriate manual therapy interventions should be employed. Examples:
  - Restricted ankle dorsiflexion secondary to decreased posterior talar glide (Figure 24-21)
  - Restricted spinal mobility, such as thoracic spine hypomobility limiting upper body rotation and causing increased lumbar lordosis and anterior pelvic tilt
  - Sacroiliac joint restrictions affecting pelvic mobility (Figure 24-22)

FIGURE 24-21. Talar glide to facilitate ankle dorsiflexion.

FIGURE 24-22. Sacroiliac manipulation.

Soft Tissue Techniques

- Manual or self-directed (the Stick, foam roller, etc.) soft tissue mobilization may be gently initiated in this phase for moderate to severe injuries when there is a concern for excessive scar tissue formation (Figure 24-23).

Stretching and Flexibility Techniques for the Musculotendinous Unit

- During this time, isolated and/or aggressive hamstring stretching should be avoided.
- If the individual has indirect mobility or flexibility limitations, which may have contributed to the injury or the recovery of it, corrective therapeutic interventions should be prescribed.
  - Examples include restricted ankle dorsiflexion, restricted spinal mobility or hip flexor tightness.

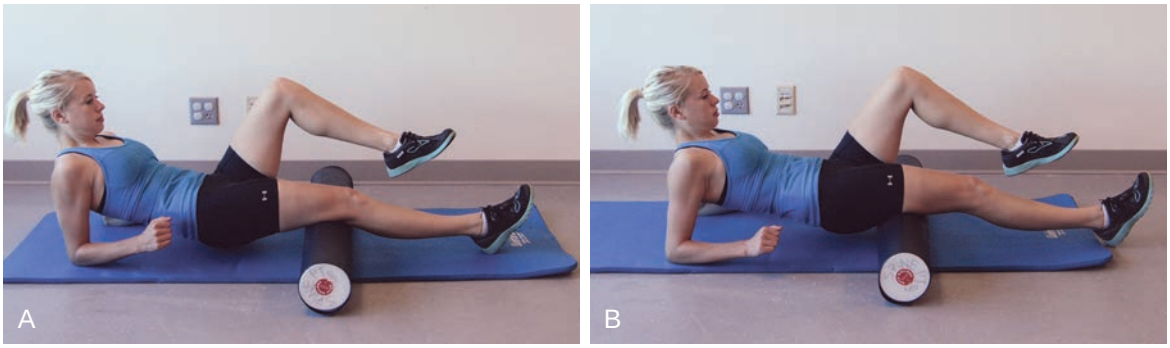

FIGURE 24-23. Foam rolling to hamstrings.

Other Therapeutic Exercises

- Progressive agility and trunk stabilization (PATS), Phase II
  - Moderate to high-intensity side stepping, 3 times 1 minute
  - Moderate– to high-intensity grapevine stepping, 3 times 1 minute
  - Moderate- to high-intensity steps forward and backward while moving sideways, 2 times 1 minute
  - Single leg stand windmill touches (performed by standing on one leg, then rotating the trunk and flexing the hips to bring the hand down in front of the lower leg), 4 times 20 seconds of repetitive alternate hand touches (Figure 24-24)
  - Pushup stabilization with trunk rotation (performed by starting at the top of a full pushup, then maintain this position with one hand while rotating the chest toward the side of the hand that is being lifted to point toward the ceiling, pause and return to the starting position), 2 times 15 reps on each side. (Figure 24-25)
  - Fast feet in place (performed by jogging in place with increasing velocity, picking the foot only a few inches off the ground), 4 times 20 seconds
  - High-to-low and low-to-high wood chops with Thera-Band, 2 × 15 to the right and left of each (Figures 2-26 and 24-27)
- Neuromobilization techniques may be used if the injured athlete demonstrates any sign of adverse lower limb tension as a result of the injury or recovery process. Care should be taken to tension the nerve without overtensioning the injured hamstring, thus limiting the hip flexion component of the neural mobilization techniques (Figure 24-28).

Activation of Primary Muscles Involved

- Core muscles of the hip and pelvis, hip abductors and adductors, medial and lateral hamstrings

Sensorimotor Exercises

- In addition to the balance exercises listed in the PATS program, balance board and unstable surface balance training are appropriate for this phase.

Open and Closed Kinetic Chain Exercises

- See Phase II PATS above.

FIGURE 24-24. Single-leg stand windmill touches.

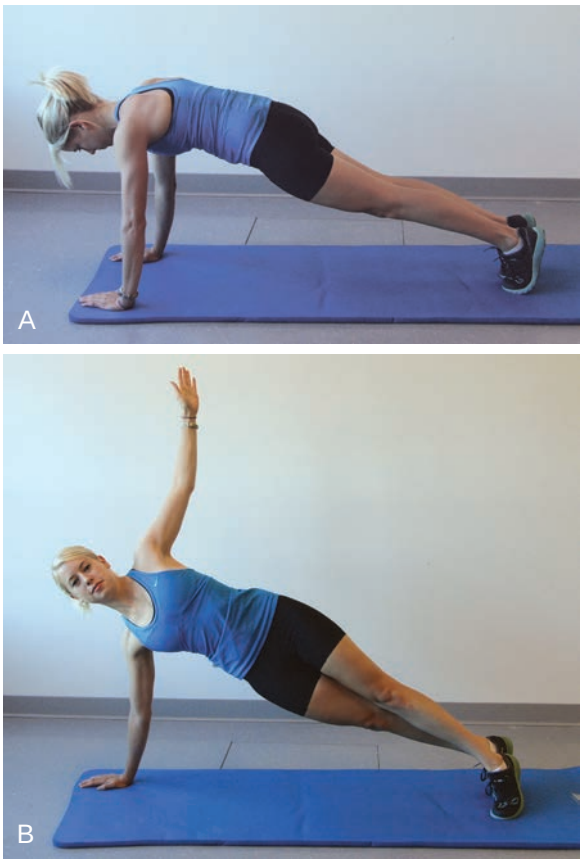

FIGURE 24-25. Pushup stabilization with trunk rotation.

Techniques to Increase Muscle Strength, Power, and Endurance

- Sub-maximal eccentric strengthening exercises near mid-length of the muscle are initiated as part of functional movement patterns rather than through exercises isolating the hamstring.

Neuromuscular Dynamic Stability Exercises

- See Phase II PATS above.

Plyometrics

- Begin initiating plyometric exercises near mid-length of the muscle. These exercises are initiated as part of functional movement patterns rather than through exercises isolating the hamstring.

Functional Exercises

- See Phase II PATS above.

Sport-Specific Exercises

- Symptom-free practice and skill-related drills without high-speed maneuvers.

Milestones for Progression to the Next Phase

- Ability to jog without pain
- Have 5/5 strength for prone knee flexion at 30° of flexion without pain.

Phase III: Early Functional (weeks 4 to 8 and beyond)

Management of Pain and Swelling

- Ice as needed for postrehabilitation or practice soreness

FIGURE 24-26. High to low wood chops.

FIGURE 24-27. Low to high wood chops.

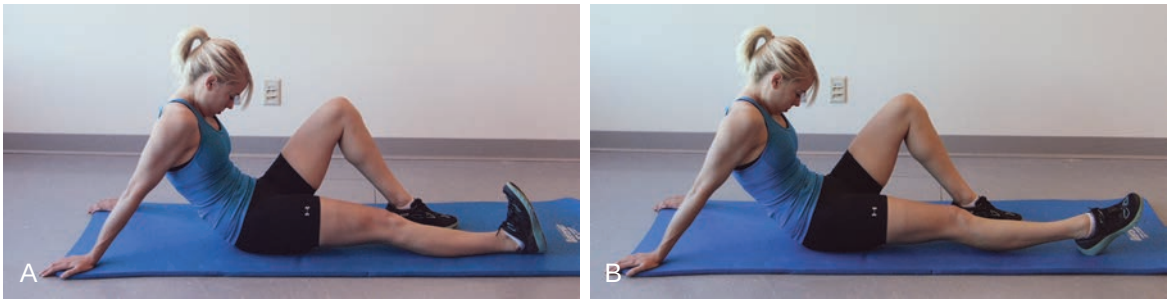

FIGURE 24-28. Neural mobilization.

Manual Therapy Techniques

- Continue during this time working on indirect joint mobility or flexibility limitations, which may have contributed to their injury or the recovery of it, the appropriate manual therapy interventions should be employed. Examples:
  - Restricted ankle dorsiflexion secondary to decreased posterior talar glide
  - Restricted spinal mobility, such as thoracic spine hypomobility limiting upper body rotation and causing increased lumbar lordosis and anterior pelvic tilt.
  - Sacroiliac joint restrictions affecting pelvic mobility

Soft Tissue Techniques

- Manual, augmented (Graston, ASTYM) or self directed (the Stick, foam roller, etc.) soft tissue mobilization may be more aggressively used in this phase for moderate to severe injuries when there is a concern for excessive scar tissue formation.

Stretching and Flexibility Techniques for the Musculotendinous Unit

- During this phase if the athlete has nearly recovered hamstring strength, yet still has limitations in flexibility, then it would be appropriate to include dynamic hamstring stretches.
- The individual should continue to work on indirect flexibility limitations, which may have contributed to the injury or the recovery of it, and they should be given corrective therapeutic interventions.
- Examples would include restricted ankle dorsiflexion, restricted spinal mobility or hip flexor tightness.

Other Therapeutic Exercises

- Dynamic agility drills: Side shuffle, cariocas, boxer shuffles (Figure 24-29), A skips (Figure 24-30) and B skips (Figure 24-31), forward and backward running
- Dynamic core stabilization: Rotating body bridge with dumbbells (Figure 24-32), physioball pushup rotations (Figure 24-33), physio ball bridges with single-leg hold (Figure 24-34)

Activation of Primary Muscles Involved

- Working toward maximal eccentric strengthening exercises near end-length of the muscle are included as part of functional movement patterns. Functional exercises begin to focus on power by being more explosive and reactive.

Sensorimotor Exercises

- This phase should include single-leg balance exercises, especially those involving core control and hamstring activation in a lengthened position. Examples include

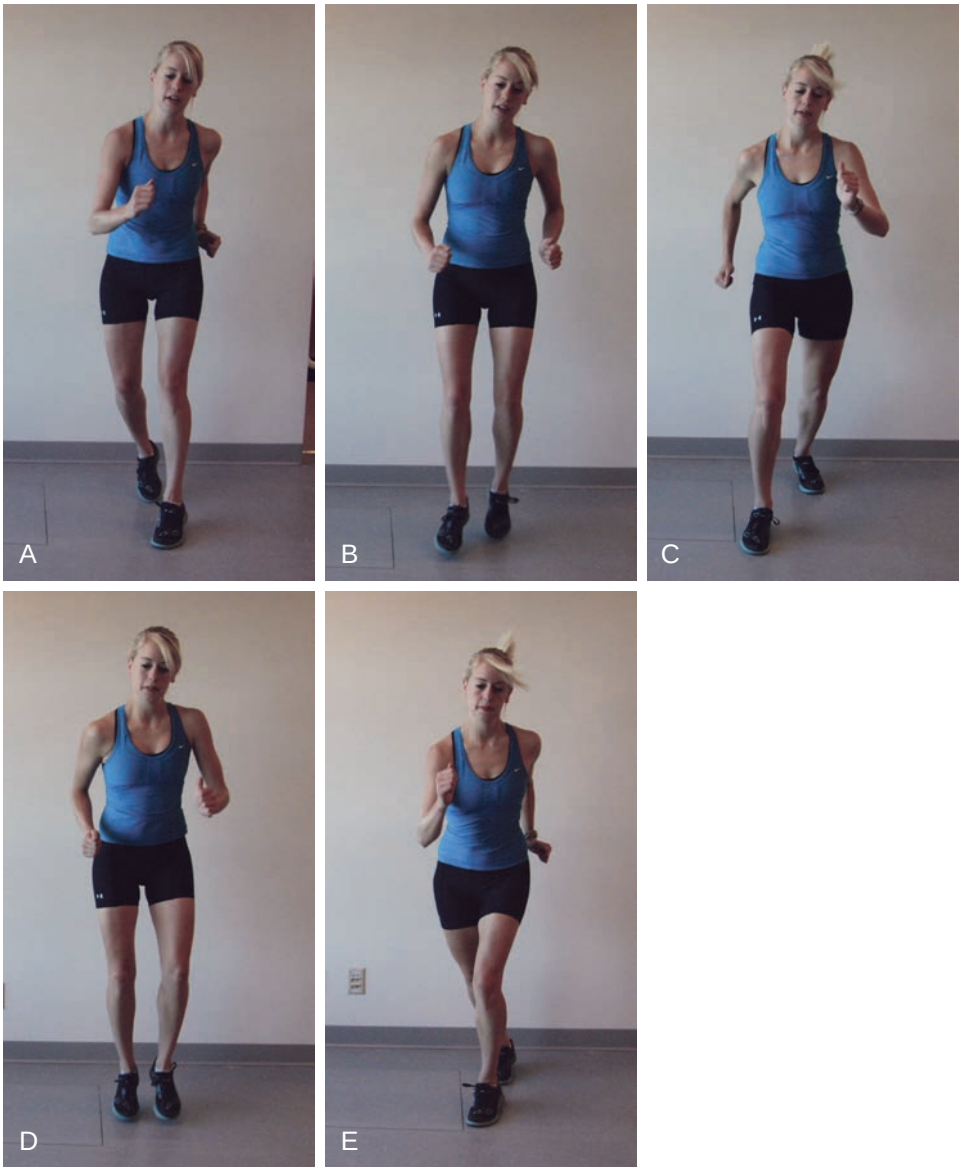

FIGURE 24-29. Boxer shuffles.

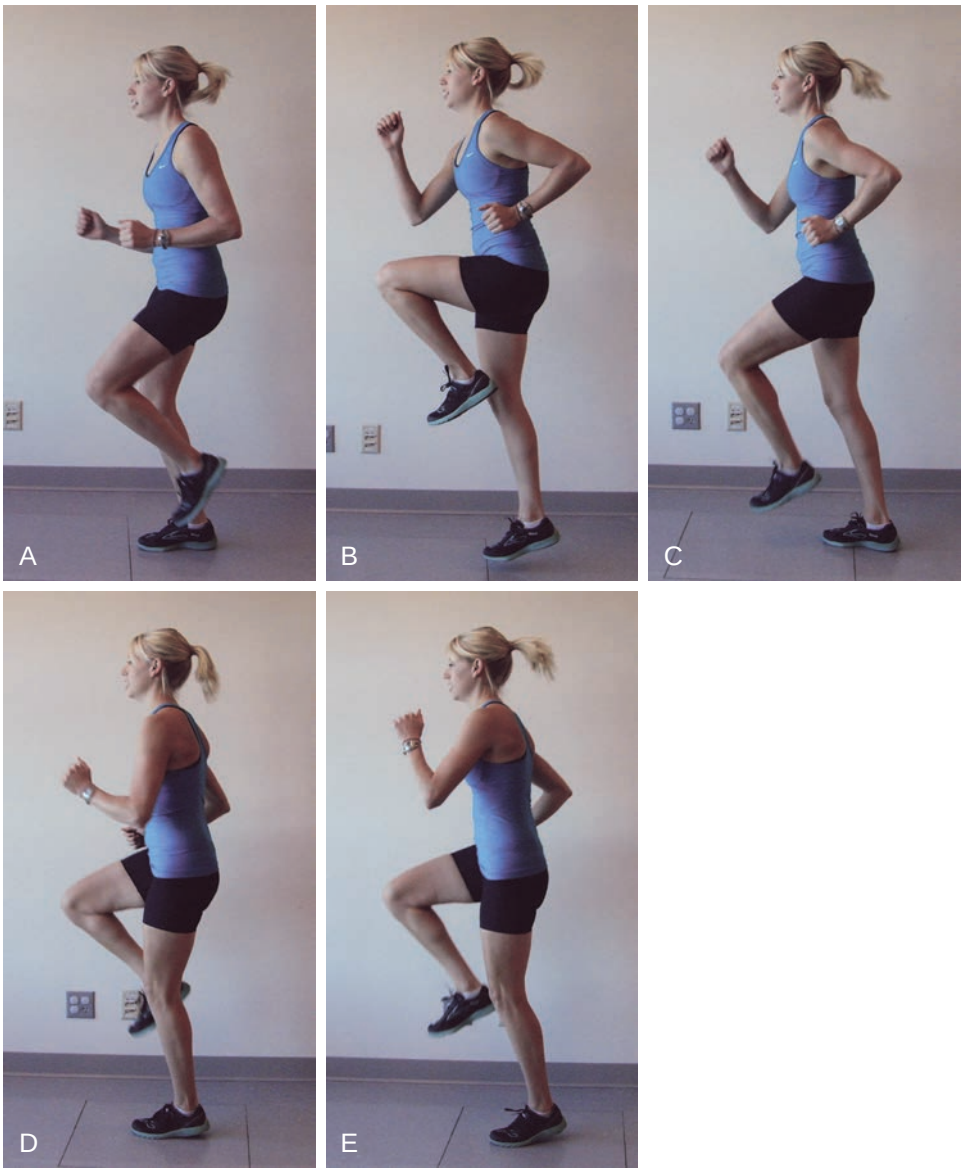

FIGURE 24-30. A skips.

single-leg deadlifts, single-leg dumbbell hang cleans, single-leg windmill touches with dumbbells, and repetitive hop for distance.

Open and Closed Kinetic Chain Exercises

- The transition from open to closed chain movement is important in this phase. Specific exercises that can work on this include B skips, repetitive hopping, alternating leg windmill touches with dumbbell reach and alternating short arc bridge curl on a physio ball.

Techniques to Increase Muscle Strength, Power, and Endurance

- Olympic Lifts
- Snatches
  - Clean and jerk
  - Power clean

Neuromuscular Dynamic Stability Exercises

- Single-leg balance exercises, especially those involving core control and hamstring activation in a lengthened position.
- Examples include the following:
  - Single-leg deadlifts
  - Single-leg dumbbell hang cleans
  - Single-leg windmill touches with dumbbells
  - Repetitive hop for distance

Plyometrics

- Plyometrics are used in this phase to help increase power; focus should be in single-leg activities to prevent overcompensating with the uninvolved leg.

Functional Exercises

- See exercises above.

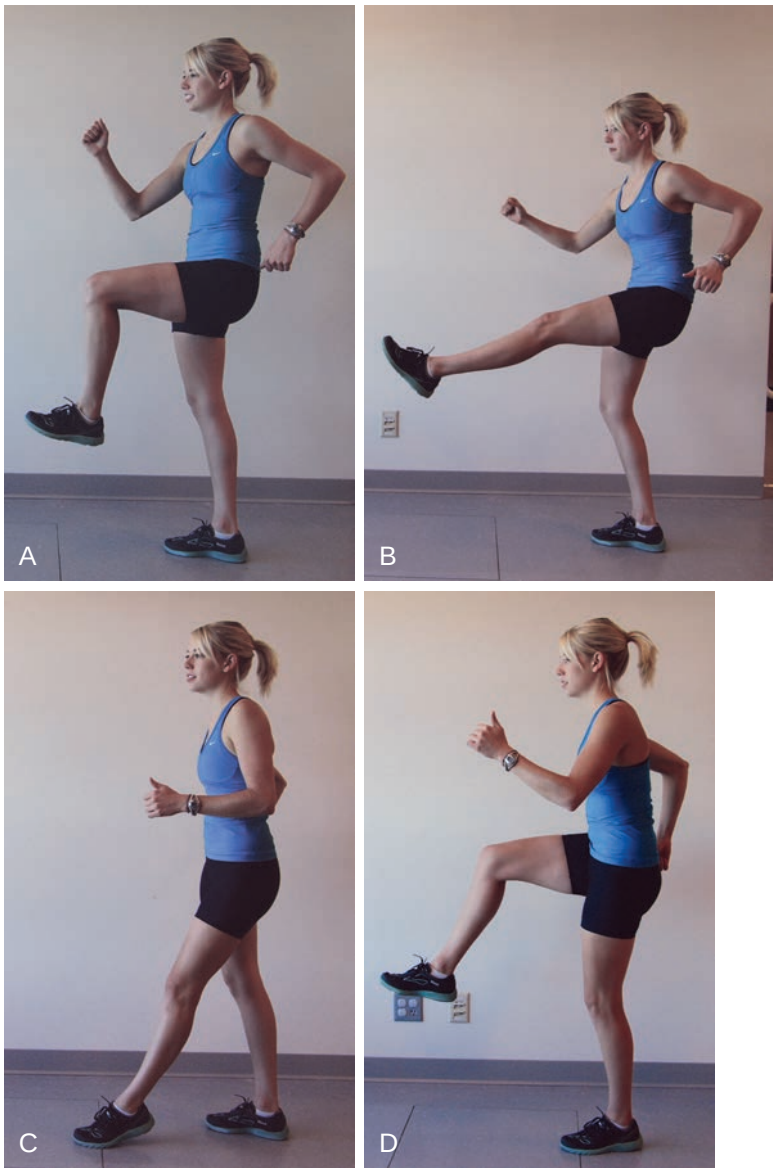

FIGURE 24-31. B skips.

Sport-Specific Exercises

- Symptom-free practice and skill-related drills building up to high-speed maneuvers.
- Running drills that incorporate change of direction as well as change of head and body position are potentially very important during this phase.
- These drills will challenge core control and also train the hamstring activation patterns in various positions and lengths.

Milestones for Progression to Return to Sport

- No apprehension or fear by the athlete. This can be measured and compared to the other side with Asking's active hamstring test.
- Full strength:
  - 5/5 strength on manual muscle testing of the hamstrings in prone at 15° of knee flexion. This should be done with 4 consecutive repetitions with the tibia in external rotation, neutral and internal rotation and then compared with the other side.
  - Less than 5% bilateral deficit in eccentric hamstrings (30°/second): concentric quadriceps (240°/second) ratio during isokinetic testing.
  - Bilateral symmetry in knee flexion angle of peak isokinetic concentric knee flexion torque at 60°/second
- Good control of dynamic single-leg balance and support movements.
- Replication of sport-specific movements near maximal speed without pain or apprehension (e.g., incremental sprint test for running athletes)
- If patient is not making consistent improvement in strength or progression toward the milestones listed above by 12 to 14 weeks, they should be reevaluated by the physician. There are not standard surgical options or time-frames for this injury but adjuncts to rehabilitation, such as PRP or dry needling, may be considered.

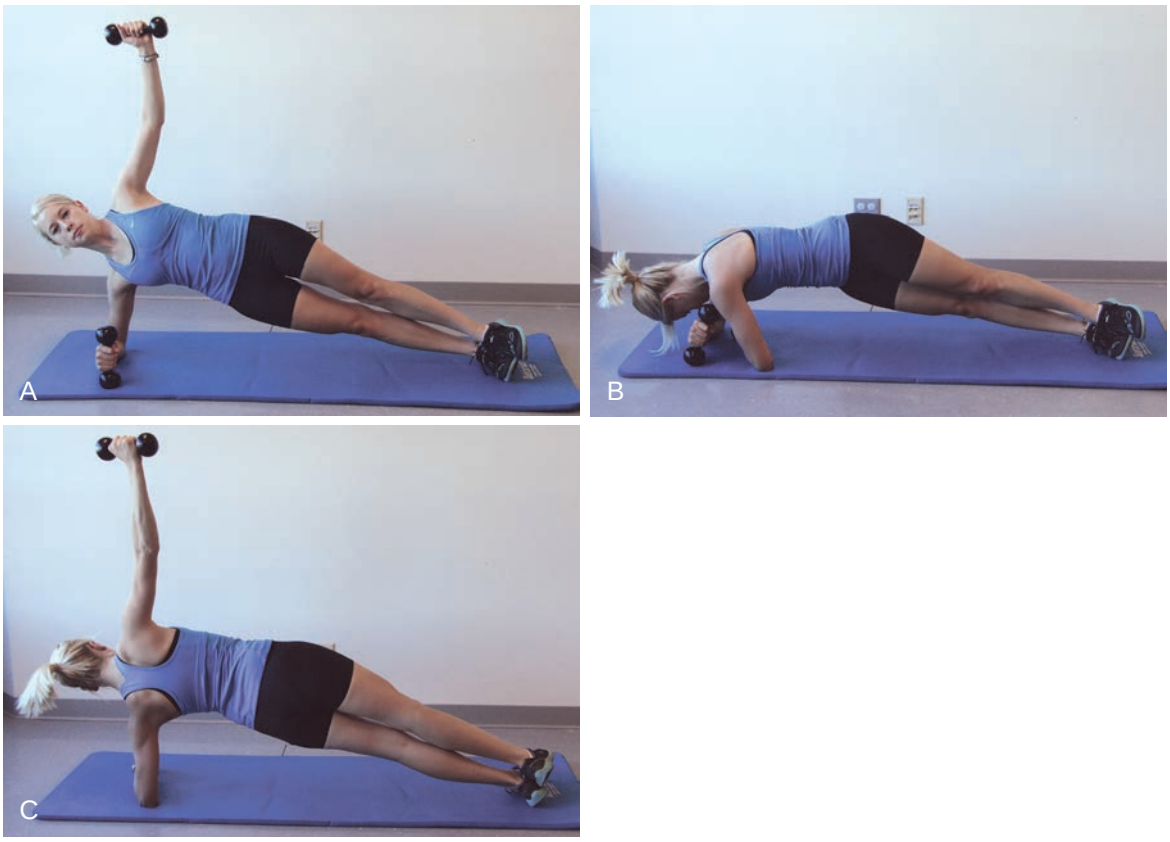

FIGURE 24-32. Rotating body bridge with dumbbells.

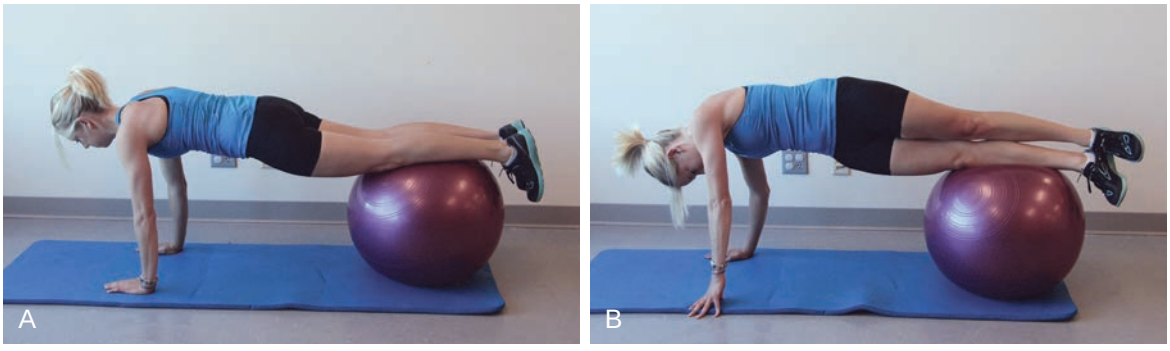

FIGURE 24-33. Physio ball pushup rotations.

FIGURE 24-34. Physio ball bridges with single-leg hold.

Performance Enhancement and Prevention of Reinjury

- Once the athlete has met milestones for return to sport, it is suggested they continue a program for performance enhancement and prevention of reinjury for the rest of that season and following off-season. The physician or physical therapist should reevaluate after the season and prior to the next season to screen for potential muscle imbalances, compensations, or weaknesses that have developed and subsequently make that athlete at higher risk for reinjury.

- Program components should include:
  - Single-leg balance exercises and perturbation type exercises
  - Dynamic agility drills
  - Eccentric hamstring strengthening, especially in a lengthened position
  - Core and trunk stabilization exercises

Specific Criteria for Return to Sports Participation: Tests and Measurements

- Pain free to palpation over the site of muscle strain
- Full concentric and eccentric strength of the hamstrings (as compared to the uninjured side) tested in a lengthened position. This can be done with an isokinetic dynometer, a mobile force sensor, or estimated with manual muscle testing.
- Full concentric and eccentric muscular endurance of the hamstrings (as compared to the uninjured side) tested in a lengthened position. This can be done with an isokinetic dynometer, a mobile force sensor, or estimated with repetition manual muscle testing.
- No fear or kiniesophobia, as measured by the hamstring active test (H Test) or modified hamstring active test.
- No pain or fear with a progressive sprint test of at least 30 yards (70% to 80% to 90% to 95% speed intervals).

Evidence

Askling CM, Nilsson J, Thorstensson A: A new hamstring test to complement the common clinical examination before return to sport after injury. *Knee Surg Sports Traumatol Arthrosc* 18:1798–1803, 2010.

Eleven healthy subjects (average age, 28 years) were tested on repeated occasions, and 11 athletes (average age, 21 years) with MRI-verified acute hamstring strain were tested when common clinical examination revealed no signs of remaining injury. Flexibility (highest range of motion of three consecutive trials) was calculated during active ballistic hip flexions and conventional passive slow hip-flexions in a supine position. A VAS-scale (0-100) was used to estimate experience of insecurity during active tests. No significant test-retest differences were observed. Active flexibility was greater (23%) than passive flexibility. In the athletes, the injured leg showed smaller (8%) active, but not passive, flexibility than the uninjured leg. Average insecurity estimation was 52 (range 28-98) for the injured and 0 for the uninjured leg, respectively. The authors report that in their own clinical experience they have used the feeling of insecurity as a guide for return to play, and in doing so they have not experienced reinjuries during the first 4 weeks. Therefore, they recommend that if an athlete has insecurity, the test should be repeated in 2 weeks, and return to sport should not be allowed until no insecurity is present. (Level III and Level V evidence).

Cameron ML, Adams RD, Maher CG, et al: Effect of the Ham-Sprint Drills training programme on lower limb neuromuscular control in Australian football players. *J Sci Med Sport* 12:24–30, 2007.

This randomized controlled trial of 29 footballers from one professional Australian Football League club compared drills specific to the improvement of running technique, coordination, and hamstring function to normal training. The training group showed significant improvement in lower limb neuromuscular control with movements similar to the late-swing, early stance phase of running. (Level I evidence).

Chumanov ES, Heiderscheit BC, Thelen DG: The effect of speed and influence of individual muscles on hamstring mechanics during the swing phase of sprinting. *J Biomech* 40:3555–3562, 2007.

The purpose of this study was to characterize the effect of speed and influence of individual muscles on hamstring stretch, loading, and work during the swing phase of sprinting at speeds ranging from 80% to 100% of maximum speed. Swing phase simulations were used to characterize the effects of speed on the peak stretch, maximum force, and negative work of the biceps femoris long head (BF), the most often injured hamstring muscle. Perturbations of the double float simulations were used to assess the influence of individual muscles on BF stretch. Peak hamstring musculotendon stretch occurred at approximately 90% of the gait cycle (late swing) and was independent of speed. Peak hamstring force and negative musculotendon work increased significantly with speed ($p<0.05$). Muscles in the lumbo-pelvic region had greater influence on hamstring stretch than muscles acting about the knee and ankle, with the hip flexors were found to induce the most hamstring stretch in the opposite limb. They concluded that hamstring strain injury during sprinting may be related to the performance of large amounts of negative work over repeated strides and/or resulting from a perturbation in pelvic muscle coordination that induces excessive hamstring stretch in a single stride. (Level II evidence).

Croisier JL, Ganteaume S, Binet J, et al: Strength imbalances and prevention of hamstring injury in professional soccer players: a prospective study. *Am J Sports Med* 36:1469–1475, 2008.

This prospective cohort study of professional soccer players determined whether strength variables could be predictors of subsequent hamstring strain and if normalization of strength imbalances could reduce the incidence of hamstring injury. The rate of muscle injury was significantly increased in subjects with untreated strength imbalances; normalizing the isokinetic parameters reduced the risk factor for injury to that observed in players without imbalances. (Level II evidence).

Kraemer R, Knobloch K: A soccer-specific balance training program for hamstring muscle and patellar and achilles tendon injuries: an intervention study in premier league female soccer. *Am J Sports Med* 37:1384–1393, 2009.

This prospective cohort study of 24 elite female soccer players determined whether proprioceptive training can reduce the incidence of hamstring muscle injuries. Soccer-specific balance training reduced noncontact hamstring injuries with a dose-effect relationship between duration of balance training and injury incidence present. (Level III evidence).

Sherry MA, Best TM: A comparison of two rehabilitation programs in the treatment of acute hamstring strains. *J Phys Ther Orthop Sports* 34:116–125, 2004.

This randomized controlled trial of 24 athletes with an acute hamstring strain compared rehabilitation programs

comprised of static stretching and isolated progressive hamstring resistance exercises or progressive agility and trunk stabilization exercises. Seventy percent (70%) of the athletes who completed the hamstring stretching and strengthening program, as compared to only 7.7% of the athletes who completed the progressive agility and trunk stabilization program, suffered a recurrent hamstring strain during a 1-year period. (Level I evidence).

Sole G, Milosavljevic S, Nicholson HD, et al: Selective strength loss and decreased muscle activity in hamstring injury. *J Orthop Sports Phys Ther* 41:354–363, 2011.

This cross-sectional laboratory study compared muscle isokinetic torque patterns and EMG activity in 15 individuals without hamstring injury and 15 individuals who had sustained a hamstring injury within the past year but had returned to at least partial sports training. Eccentric flexor torque was significantly less in the lengthened range of in the hamstring injured limb in comparison to the uninjured limb, despite no significant differences in absolute peak torque throughout the range. Differences were also found between groups in EMG amplitudes during eccentric flexor contractions, indicating neurophysiological factors may contribute to the changes in torque. (Level II evidence).

Sole G, Milosavljevic S, Nicholson H, et al: Altered muscle activation following hamstring injuries. *Br J Sports Med* 46:118–123, 2012.

In this study, 16 participants with a hamstring injury and 18 control participants participated. The EMG activity of gluteal, quadriceps, and hamstring muscles was recorded during a movement from double- to single-leg movement using surface electrodes. The EMG onsets of biceps femoris and medial hamstrings were significantly earlier for the HG injured and the uninjured sides in preparation for single-leg standing when compared with the CG average. There were no differences in onsets for the gluteal and quadriceps muscles when comparing the injured or uninjured legs of the HG to the bilateral average of the CG. This earlier onset of the injured and the uninjured hamstrings in preparation for single-leg stance of the HG in comparison with the CG suggests an alteration in the motor control of these muscles and thus neuromuscular control following a hamstring injury may be an important consideration in the rehabilitation of hamstring injuries. (Level II evidence).

Gabbe BJ, Bennell KL, Finch CF, et al: Predictors of hamstring injury at the elite level of Australian football. *Scand J Med Sci Sports* 16:7–13, 2006.

A prospective cohort of 222 players underwent baseline measurement in the form of a self-report questionnaire and a musculo-skeletal screen during the preseason period of the 2002 Australian football season. Injury surveillance and exposure data were collected for the full season. Logistic regression analyses were used to identify independent predictors of hamstring injury in this group of players. A total of 31 players sustained a hamstring injury. A past history (previous 12 months) of hamstring injury and increasing age were found to be independent predictors of hamstring injury. Restricted ankle dorsiflexion range of movement showed trends toward predicting injury and thus also warrants consideration in the development of prevention programs for hamstring injury. (Level I evidence).

Warren P, Gabbe BJ, Schneider-Kolsky M, et al: Clinical predictors of time to return to competition and of recurrence following hamstring strain in elite Australian footballers. *Br J Sports Med* 44:415–419, 2010.

A total of 59 Aussie football players who suffered a hamstring strain underwent a clinical assessment by a physiotherapist and questionnaire. This study found players taking more than 1 day to walk pain free were significantly more likely (p=0.018) to take longer than 3 weeks to return to competition (adjusted odds ratio 4.0; 95% CI 1.3 to 12.6). Nine players (15.2%) experienced an injury recurrence, all involving the biceps femoris. Recurrence was more likely in players who reported a hamstring injury in the past 12 months (adjusted odds ratio 19.6; 95% CI 1.5 to 261.0; p=0.025). Time to walk pain free and previous hamstring injury are predictors of time to return to competition and recurrence, respectively. (Level III evidence).

Multiple-Choice Questions

QUESTION 1. Which of the following should be avoided in Phase I of the hamstring injury rehabilitation program?

A. Core stabilization
B. Agility drills
C. Aggressive stretching
D. Icing

QUESTION 2. Which statement most accurately describes the hamstring active test?

A. It is more sensitive when done in standing instead of supine
B. The injured leg shows smaller passive, but not active, flexibility than the uninjured leg
C. This test should only be used after the athlete has returned to sport.
D. Apprehension or insecurity is the most important clinical measure from the test in regards to return to sport.

QUESTION 3. Which factor is important to incorporate in to hamstring rehabilitation?

A. Eccentric strengthening
B. Neuromuscular control
C. End-range hamstring strengthening
D. Core strengthening
E. All of the above

QUESTION 4. Which best describes the progression of agility exercises in the PATS program

A. Start with slow, small movements in the frontal plane progressing to faster, then bigger, then transverse and sagittal plane movements.
B. Start with slow, large movements in the frontal plane progressing to faster, then smaller, then transverse and sagittal plane movements.
C. Start with slow, small movements in the sagittal plane progressing to faster, then bigger, then transverse and frontal plane movements.
D. Start with fast, small movements in the frontal plane progressing to slower heavier resistance in the transverse and sagittal plane movements.

QUESTION 5. The most appropriate criteria for return to sport includes:

A. More passive than active motion in the injured leg on the hamstring active test, 5/5 end range strength on repeated hamstring manual muscle testing, confidence with sport-specific movements
B. No insecurity on the hamstring active test, 5/5 end range strength on repeated hamstring manual muscle testing, confidence with sport-specific movements
C. More active than passive motion in the injured leg on the hamstring active test, 5/5 end range strength on repeated hamstring manual muscle testing, confidence with sport-specific movements
D. No insecurity on the hamstring active test, 5/5 strength on hamstring manual muscle testing at 90° knee flexion, confidence with sport-specific movements

Answer Key

QUESTION 1. Correct answer: **C** (see Phase I).

QUESTION 2. Correct answer: **D** (see Askling, 2010).

QUESTION 3. Correct answer: **E** (see Annotated Evidence).

QUESTION 4. Correct answer: **A** (see Sherry, 2004).

QUESTION 5. Correct answer: **B** (see Phase III).

BEYOND BASIC REHABILITATION: RETURN TO SPRINTING ACTIVITIES AFTER HAMSTRING STRAIN

Bryan Heiderscheit, PT, PhD, Marc Sherry, PT, DPT, LAT, CSCS, and William Clancy, MD

Introduction

ASPECTS OF SPRINTING THAT REQUIRE SPECIAL ATTENTION IN REHABILITATION

- During the terminal swing phase of running, the hamstring muscles are active while elongating, resulting in substantial eccentric loading.
- The mechanical energy absorbed by the hamstrings during this eccentric loading exponentially increases with running speed.
- Hamstring injury during running is most likely to occur during the terminal swing phase.

Hamstring injuries are very common during high-speed running, particularly sprinting. This injury remains challenging as up to 30% of individuals will experience an injury recurrence upon returning to sport despite completing a formalized rehabilitation program.

The return to running program is given in Box 24-2.

Literature

- Persistent strength deficits, in particular eccentric hamstring strength, have been found to increase the risk of running-related reinjury to the hamstring muscles.[1]
- In addition, inaccuracies in perceiving running-like leg movements have been associated with an increased risk for hamstring strain injury.[2]
- Finally, individuals with a prior hamstring strain often show altered recruitment of the hamstring muscles, potentially affecting the neuromuscular coordination needed to sprint safely.[3]

Advanced Strength and Conditioning Programs

Periodization

- The program is progressed in a linear manner over time.

Program Design/Performance Training Program

Sport-Specific Concepts of Integrated Training

- Training continuum
- Flexibility/joint mobility for joint stability
- Training with optimum posture
- Sensorimotor and balance training
- Core training
- Cardiorespiratory training
- Multiplanar training activities
- Training for optimum muscle balance
- Training for optimum muscle functional strength
- Training for optimum muscle functional power
- Neuromuscular dynamic stability exercises
- Training for speed, agility, quickness (SAQ)
- Plyometric training
- Functional training
- Sport-specific training

BOX 24-2 Return to Sprinting Program

This program is designed for individuals who have recently completed rehabilitation for a hamstring strain injury and are now returning to a sport that involves sprinting. Because the greatest risk for reinjury is present during the initial 2 weeks of returning to sport, it is important that this transition be made gradually and progressively. As such, the program is divided into 3 phases, each lasting 2 weeks:

- The initial 2 weeks are focused on the persistent neuromuscular deficits that may remain such as reduced hamstring recruitment, endurance, and ease of movement. The exercises are a continuation of those performed during rehabilitation but with greater speed and intensity.
- During weeks 3 and 4, sport-specific movements with challenging body posture are initiated as are aggressive eccentric training of the hamstrings.
- Finally, weeks 5 and 6 are designed to simulate competition but in a slightly more controlled manner. These exercises are designed to be performed as a stand-alone program. If the individual is also participating in an organized practice or training program, the volume involved with this program should be reduced to avoid overtraining.
- In addition, the strength training aspects should be performed after practice as the gains from eccentric training are better when the muscle is fatigued.

Weeks 1 to 2

GOALS:

1. Promote residual healing
2. Promote full range ease of movement
3. Facilitate hamstring muscle recruitment
4. Promote neuromuscular endurance

EXERCISES/DRILLS:

Dynamic warmup

1. Leg cycling drill, 3 × 10 each leg
2. High knee marching, 3 × 30 meters, jog back to start between repetitions
3. Heel kicks, 3 × 30 meters, jog back to start between repetitions
4. Quick carioca, 2 × 30 meters each direction
5. Cross-over skip, 2 × 30 meters each direction
6. A and B skips, 3 × 30 meters, jog back to start between repetitions A and B skips are a hurdle drill to work on the drive of the lead leg up to the hurdle. The A consists of the initial drive up and the B consists of the extension when the height of the hurdle trajectory is reached.
7. Forward-backward accelerations (20 meters), 3 × 1 minute

Running

8. Falling starts, 3 × 40 meters, walk back to start between repetitions
9. 3-point start, 3 × 40 meters, walk back to start between repetitions
10. Sprinting (70% to 90% intensity), 4 × 60 meters, walk back to start between repetitions

Strength and endurance

11. Rotating body bridge with dumbbells, 5 second hold each side, 2 × 15
12. Supine single-limb chair-bridge, 3 × 15, fast speed
13. Single-limb balance windmill touches with dumbbells, 4 × 10 per arm each leg
14. Prone hip extension off the edge of bed or table for full ROM with ankle weight, start at the top then drop and catch the leg, 2 × 20
15. Lunge walk with trunk rotation, opposite hand dumbbell toe touch and T-lift, 2 × 15 steps per limb (Figure 24-35)

Weeks 3 to 4

GOALS:

1. Promote residual healing
2. Facilitate hamstring muscle hypertrophy with eccentric focus
3. Facilitate symmetrical sprinting mechanics

EXERCISES/DRILLS:

Dynamic warmup

1. Leg cycling drill, 3 × 10 each leg, jog back to start between repetitions
2. High knee marching, 3 × 30 meters, jog back to start between repetitions
3. Heel kicks, 3 × 30 meters, jog back to start between repetitions
4. Quick carioca, 2 × 30 meters each direction
5. Cross-over skip, 2 × 30 meters each direction
6. A and B skips, 3 × 30 meters, jog back to start between repetitions
7. Forward-backward accelerations (20 meters), 3 × 1 minute

BOX 24-2 Return to Sprinting Program *(Continued)*

FIGURE 24-35. Lunge walk with trunk rotation, opposite hand dumbbell toe touch, and T-lift.

Running

8. 3-point start, 3 × 40 meters, walk back to start between repetitions
9. Squat jump and go, 3 × 40 meters, walk back to start between repetitions
10. Sprinting (80% to 95% intensity), 4 × 80 meters, walk back to start between repetitions
11. Sports-specific movements with changing body posture and head positions

Strength

12. Nordic hamstring drop-curl progression (Figures 24-36 and 24-37)
    a. 3 × 8–12, drop and return
    b. Can initially use physio ball to reduce range of motion and bands/cables to reduce load
13. Rotating body bridge with dumbbells, 5 second hold each side, 2 × 15
14. Backward weight throw standing on 2 legs, 2 × 15 (Figure 24-38)

Weeks 5 to 6

GOALS:

1. Facilitate hamstring muscle hypertrophy with eccentric focus and end-range strength
2. Facilitate symmetrical sprinting mechanics

EXERCISES/DRILLS:

Dynamic warmup

1. Leg cycling drill, 3 × 10 meters each leg, jog back to start between repetitions
2. High knee marching, 3 × 30 meters, jog back to start between repetitions
3. Heel kicks, 3 × 30 meters, jog back to start between repetitions
4. Quick carioca, 2 × 30 meters each direction
5. Cross-over skip, 2 × 30 meters each direction
6. A and B skips, 3 × 30 meters, jog back to start between repetitions
7. Forward-backward accelerations (20 meters), 3 × 1 minute

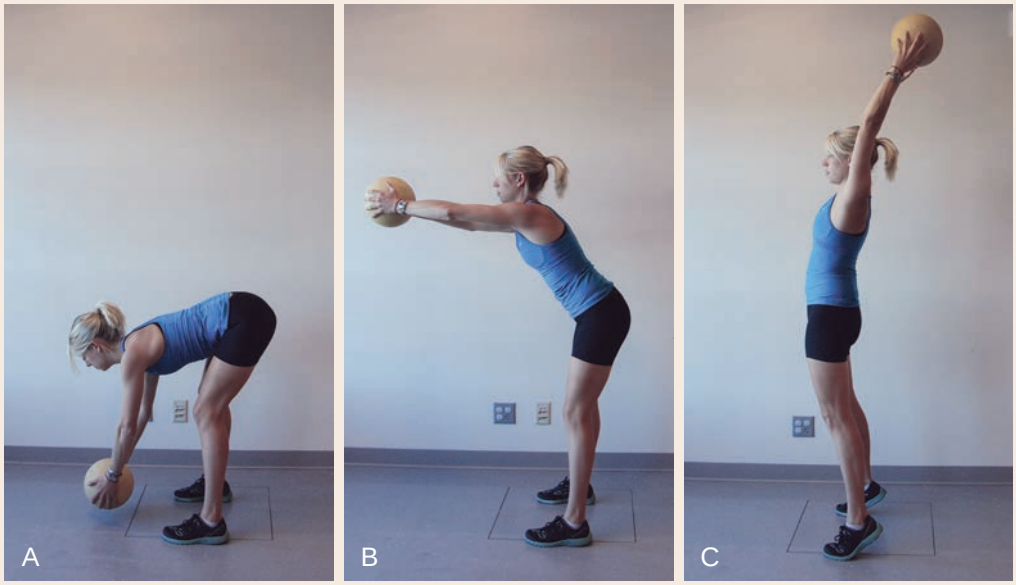
Continued on following page

BOX 24-2 Return to Sprinting Program *(Continued)*

FIGURE 24-36. Nordic hamstring curls.

FIGURE 24-37. Nordic hamstring curls with elastic band assistance.

BOX 24-2 Return to Sprinting Program *(Continued)*



Running

8. Squat jump and go, 3 × 40 meters, walk back to start between repetitions
9. Straight leg running, 3 × 20 meters, walk back to start between repetitions
10. Sprinting (85% to 100% intensity), 4 × 100 meters, walk back to start between repetitions
11. Sports-specific movements with changing body posture

Strength

12. Nordic hamstring drop-curl progression
    a. 3 × 12 reps drop and return with increased drop speed
13. Rotating body bridge with dumbbells, 5 second hold each side, 2 × 15
14. Backward weight throw standing on 1 leg, 2 × 15

TIMELINE 24-4: **Beyond Basic Rehabilitation: Return to Sprinting Activities After Hamstring Strain**

PHASE I (weeks 1 to 2)	PHASE II (weeks 3 to 4)	PHASE III (weeks 5 to 6)
• Leg cycling drill • High knee marching • Heel kicks • Quick carioca • Cross-over skip • A and B skips • Forward-backward accelerations • Falling starts • Three-point start • Sprinting (70%–90%) • Rotating body bridge with dumbbells • Supine single-limb chair-bridge • Single-limb balance windmill touches with dumbbells • Prone hip extension off the edge of bed or table for full ROM with ankle weight • Lunge walk with trunk rotation, opposite hand dumbbell toe touch and T-lift	• Leg cycling drill • High knee marching • Heel kicks • Quick carioca • Cross-over skip • A and B skips • Forward-backward accelerations • Three-point start • Squat jump and go • Sprinting (80%–95%) • Sports-specific movements with changing body posture • Nordic hamstring drop-curl progression • Rotating body bridge with dumbbells • Backward weight throw standing on two legs	• Leg cycling drill • High knee marching • Heel kicks • Quick carioca • Cross-over skip • A and B skips • Forward-backward accelerations • Squat jump and go • Straight leg running • Sprinting (85%–100%) • Sports-specific movements with changing body posture • Nordic hamstring drop-curl progression • Rotating body bridge with dumbbells • Backward weight throw standing on one leg

Training Principles Used in the Design of the Program

- Principle of progression
- Principle of overload
- Principle of variation
- Principle of individualization
- Principles of specificity; specific adaptation to imposed demands (SAID)

Sports Performance Testing

General Information

- General history
- Medical history
- Sports injury history
- Surgical history
- Chronic conditions/medication

Subjective Questions

- Perceived ease of movement throughout full hip/knee range of motion
- Minimal self-reported insecurity of movement with active straight leg raise

Objective Tests

- Dynamic muscle performance testing
  - Isokinetic testing performed at time of return to sport and 6 weeks later
    - Concentric strength of the quadriceps and hamstrings at 60°/second and 240°/second
    - Eccentric strength of the hamstrings at 0°/second
    - Less than 5% bilateral asymmetry in hamstring to quadriceps peak torque ratio (H_{ECC30}: Q_{CON240})
- Movement performance testing
  - Nordic drops (assessing during each training session)
    - assessing depth of drop and ability to return
- Sport-specific testing
  - Straight line sprinting (assessing during each training session)
    - Bilateral symmetry in heel height during swing phase
    - Bilateral symmetry in foot-ground contact pattern
  - Sprinting with changing body posture specific to sport
    - Appropriate pelvic motion but not excessive
    - Able to bend forward at hips without excessive lumbar motion

Specific Criteria for Progression to the Next Stage to Determine Readiness for Sprinting

- Time criteria only, as the player is no longer injured and is back to sport

Recommended Ongoing Exercises

- The program should be repeated as part of each year's preseason training.
- The core stabilization exercises should be completed indefinitely.

Evidence

Askling C, Karlsson J, Thorstensson A: Hamstring injury occurrence in elite soccer players after preseason strength training with eccentric overload. *Scand J Med Sci Sport* 13:244–250, 2003.

This randomized controlled trial of 30 premier-league soccer players compared preseason strength training with emphasis on eccentric overload to a normal preseason training. The training group showed a decreased incidence of hamstring strain injuries over the subsequent 10 months with an increase in strength and speed. (Level I evidence).

Brooks JH, Fuller CW, Kemp SP, et al: Incidence, risk, and prevention of hamstring muscle injuries in professional rugby union. *Am J Sports Med* 34:1297–1306, 2006.

This prospective cohort study defined the incidence, severity, and risk factors associated with hamstring strain injuries in professional rugby, as well as whether hamstring strengthening and stretching exercises reduce the incidence and severity of these injuries. Running accounted for the majority of hamstring injuries but kicking resulted in the most severe. Nordic hamstring exercises reduced the incidence and severity of injury during practice and competition. (Level III evidence).

Cameron ML, Adams RD, Maher CG, et al: Effect of the Ham-Sprint Drills training programme on lower limb neuromuscular control in Australian football players. *J Sci Med Sport* 12:24–30, 2007.

This randomized controlled trial of 29 footballers from one professional Australian Football League club compared drills specific to the improvement of running technique, coordination and hamstring function to normal training. The training group showed significant improvement in lower limb neuromuscular control with movements similar to the late-swing, early stance phase of running. (Level 1 evidence).

Croisier JL, Ganteaume S, Binet J, et al: Strength imbalances and prevention of hamstring injury in professional soccer players: a prospective study. *Am J Sports Med* 36:1469–1475, 2008.

This prospective cohort study of professional soccer players determined whether strength variables could be predictors of subsequent hamstring strain and if normalization of strength imbalances could reduce the incidence of hamstring injury. The rate of muscle injury was significantly increased in subjects with untreated strength imbalances; normalizing the isokinetic parameters reduced the risk factor for injury to that observed in players without imbalances. (Level I evidence).

Engebretsen AH, Myklebust G, Holme I, et al: Intrinsic risk factors for hamstring injuries among male soccer players: a prospective cohort study. *Am J Sports Med* 38:1147–1153, 2010.

This cohort study of 508 players from 31 amateur teams determined whether previous hamstring injuries, reduced function scores, abnormalities on a clinical examination, high maximum sprint speed, poor hamstring strength, or low hamstring/quadriceps ratio can predict increased risk of new hamstring injuries. Previous acute hamstring injury was found to be the most important risk factor for new injury, with previously injured players having more than twice as high a risk of sustaining a new hamstring injury. (Level II evidence).

Kraemer R, Knobloch K: A soccer-specific balance training program for hamstring muscle and patellar and achilles tendon

injuries: an intervention study in premier league female soccer. *Am J Sports Med* 37:1384–1393, 2009.

This prospective cohort study of 24 elite female soccer players determined whether proprioceptive training can reduce the incidence of hamstring muscle injuries. Soccer-specific balance training reduced noncontact hamstring injuries with a dose-effect relationship between duration of balance training and injury incidence present. (Level III evidence).

Sherry MA, Best TM: A comparison of 2 rehabilitation programs in the treatment of acute hamstring strains. *J Orthop Sports Phys Ther* 34:116–125, 2004.

This randomized controlled trial of 24 athletes with an acute hamstring strain compared rehabilitation programs comprised of static stretching and isolated progressive hamstring resistance exercises or progressive agility and trunk stabilization exercises. Seventy percent (70%) of the athletes who completed the hamstring stretching and strengthening program, as compared to only 7.7% of the athletes who completed the progressive agility and trunk stabilization program, suffered a recurrent hamstring strain during a 1-year period. (Level I evidence).

Verrall GM, Slavotinek JP, Barnes PG: The effect of sports-specific training on reducing the incidence of hamstring injuries in professional Australian Rules football players. *Br J Sports Med* 39:363–368, 2005.

This prospective cohort study of one team of Australian Rule football players assessed the effect of a sport-specific intervention program on the incidence and consequence of hamstring strain injuries. During the 2 years with the intervention, a decreased incidence of hamstring injuries was observed, as well as fewer games missed caused by this injury. (Level III evidence).

Multiple-Choice Questions

Question 1. During sprinting, the hamstring muscles are at the great risk for reinjury at:

A. Midstance
B. Push-off
C. Initial swing
D. Terminal swing

Question 2. After returning to sport following a hamstring strain injury, what neuromuscular deficit has not been identified?

A. Muscle weakness
B. Altered proprioception
C. Increased stiffness
D. Altered recruitment

Question 3. Because of the residual evidence of muscle injury that is common at the time of return to sport, what type of exercise is delayed until week 3?

A. High-speed running/sprinting
B. Eccentric strength training
C. Progressive agility
D. Trunk stabilization

Question 4. Which of the following is not part of the sports performance testing for return to sprinting activities following a hamstring strain injury?

A. Isokinetic strength testing
B. Sprinting mechanics
C. Nordic drops
D. Passive straight leg raise

Question 5. Based on the Engebretsen et al. (2010) study, what is the single biggest risk factor for incurring another hamstring strain injury?

A. A previous hamstring injury
B. Straight leg raise less than 60°
C. Hamstring strength bilateral difference of 15%
D. Athlete perception of reduced performance

Answer Key

QUESTION 1. Correct answer: **D** (see Introduction)

QUESTION 2. Correct answer: **C** (see Introduction)

QUESTION 3. Correct answer: **B** (see Box 24-2).

QUESTION 4. Correct answer: **D** (see Sports Performance Testing).

QUESTION 5. Correct answer: **A** (see Evidence).

POSTOPERATIVE REHABILITATION AFTER REPAIR OF PROXIMAL HAMSTRING AVULSION

Matthew Joseph Salzler, MD, Steve Brian Behrens, MD, and James P. Bradley, MD

Indications for Surgical Treatment

- All three hamstring origins avulsed
- Sciatic nerve symptoms secondary to hamstring avulsion
- Two hamstring origins avulsed with >2 cm of retraction
- One or two hamstring origin chronic avulsion with <2 cm of retraction with persistent pain, despite adequate nonoperative management

Brief Summary of Surgical Treatment

Major Surgical Steps

- General anesthesia with patient in prone position and table flexed ~30° at the waist (Figure 24-39)
- Transverse infragluteal incision, retract gluteus maximus proximally (Figure 24-40)
- Protect sciatic nerve
- Longitudinally incise hamstring fascia, mobilize hamstring origins
- Prepare ischial tuberosity and proximal hamstrings (Figure 24-41)
- Place five 2.8 to 3.0 mm PLDLA/calcium phosphate suture anchors loaded with high-strength nonabsorbable sutures in an X configuration (Figure 24-42)
- Pass sutures through tendons in horizontal mattress fashion and tie down securely (Figure 24-43); we prefer horizontal mattress sutures through the tendon over a whipstitch to prevent tendon bunching
- Careful multilayered wound closure covered with a waterproof dressing
- Postop precautions: Touchdown weight bearing with knee immobilizer locked at 40°
- Complications: Wound dehiscence, sitting discomfort, posterior thigh/foot numbness

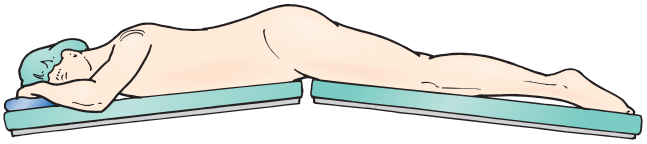

FIGURE 24-39. Illustration of flexed operative table (approximately 20°) for hamstring repair. *(Reproduced with permission from Pombo M, Bradley JP. Proximal hamstring avulsion injuries: A technique note on surgical repairs. Sports Health 1:261–264, 2009.)*

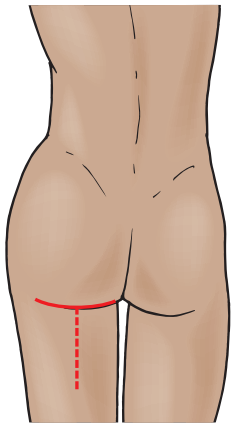

FIGURE 24-40. Illustration of transverse infragluteal incision. *(Reproduced with permission from Pombo M, Bradley JP. Proximal hamstring avulsion injuries: A technique note on surgical repairs. Sports Health 1:261–264, 2009.)*

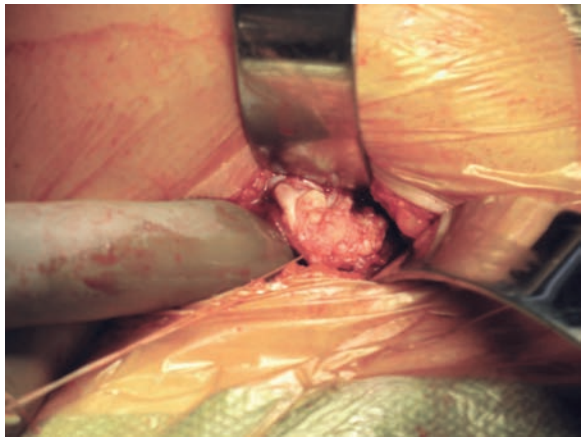

FIGURE 24-41. Intraoperative photograph of mobilized and debrided proximal hamstring tendon. *(Reproduced with permission from Pombo M, Bradley JP. Proximal hamstring avulsion injuries: A technique note on surgical repairs. Sports Health 1:261–264, 2009.)*

Factors that may Affect Rehabilitation

Anesthetic

- Avoid regional and spinal anesthesia; impairs assessment of sciatic nerve postoperatively

Surgical

- Number of hamstring tendons repaired, chronicity, and amount of retraction
  - Greater number of tendons avulsed, more retraction, and longer time of retraction all potentially increase tension on the repair. If concerned for strength of repair or tension on repair, consider a slower and more conservative protocol.

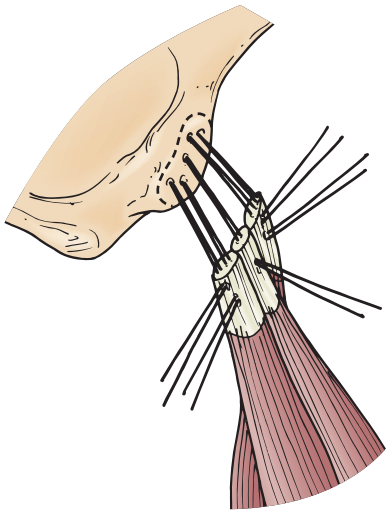

FIGURE 24-42. Illustration of suture anchors in an X configuration with sutures through the proximal tendon in a horizontal mattress fashion. *(Reproduced with permission from Pombo M, Bradley JP. Proximal hamstring avulsion injuries: A technique note on surgical repairs. Sports Health 1:261–264, 2009.)*

Before Surgery: Overview of Goals, Milestones, and Guidelines

GUIDING PRINCIPLES OF POSTOPERATIVE REHABILITATION

- Understand the anatomic structures involved and their rate of healing
- Understand position and activities that stress the repair
- Proper selection of therapy and ROM at the appropriate phase of healing

Phase I: Immediate Postoperative Period (days 0 to 14)

Clinical Pearls

If there are concerns about the strength of the repair, tension on the repair, or the patient's compliance, consider a more conservative rehabilitation protocol. This would involve utilizing a hip abduction brace instead of a hinged knee brace and potentially delaying the phases of rehab by 1 to 2 weeks.

Goals

- Allow for wound healing; dehiscence is a disastrous complication
- Protect the repaired structures
- Minimize the effects of immobilization
- Decrease pain and inflammation

Protection

- Toe-touch weight bearing on crutches at all times
- Avoid the "7" position (hips flexed and knees extended straight (Figure 24-44)
- Hinged knee brace locked at 40° to be removed briefly only for bathing/dressing and minimize hip flexion when out of brace (Figure 24-45.)
- Hip flexion brace locked in full extension if concerned about the strength of the repair or about patient compliance (Figure 24-46)

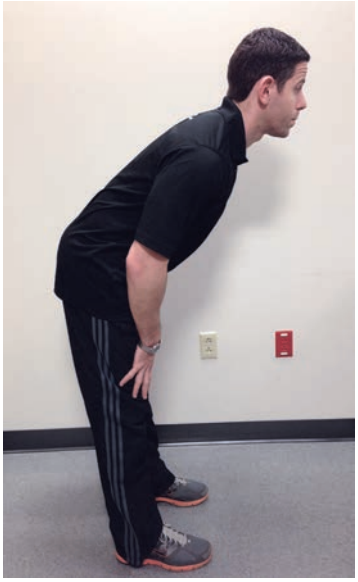

FIGURE 24-44. Photograph of the "7" position (hips flexed and knees extended straight) to be avoided.

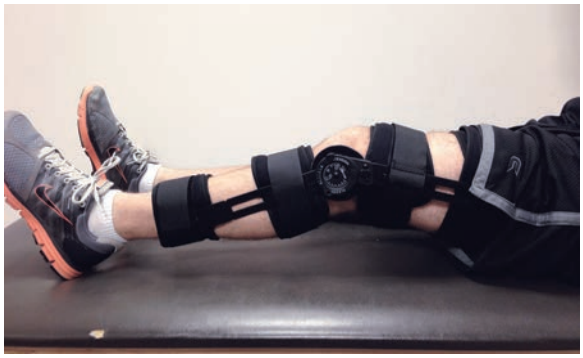

FIGURE 24-45. Photograph of a hinged knee brace locked at 40°.

FIGURE 24-46. Photograph of a hip flexion brace locked in full extension.

Management of Pain and Swelling

- Oral pain medications
- Therapeutic modalities for pain and inflammation to include TENS, E-Stim, and ice/continuous cryotherapy
- Patient education: Find a "position of comfort" that relaxes the repair with the hips extended and knee flexed
- Light desensitization massage of the incision may reduce the occurrence of hypersensitivity

Techniques for Progressive Increase in Range of Motion

- Ankle ROM only

Other Therapeutic Exercises

- Ankle pumps should be performed 20 to 30 times per hour
- Quad sets should be performed for 10 to 15 minutes, 3 times a day
- Any additional therapeutic exercises should be avoided to prevent stressing the repair

Milestones for Progression to the Next Phase

- Adequate wound healing
- No evidence of failure of repair (palpable gap at repair site)

Phase II (weeks 3 to 6)

Goals

- Protect the repaired structures
- Minimize the effects of immobilization
- No marked pain at area of repair
- Progress towards normal gait pattern

Protection

- Continue with crutches for 6 weeks postop
- Continue with knee brace locked at 40 degrees for full 4 weeks; okay to remove for PT

TIMELINE 24-5: **Postoperative Rehabilitation After Repair of Proximal Hamstring Avulsion**

PHASE I (weeks 0 to 2)	PHASE II (weeks 3 to 6)	PHASE III (weeks 6 to 10)
• Hinged knee brace locked at 40° (or hip flexion brace locked in full extension) • PT modalities • TDWB on crutches • Ankle ROM only • Ankle pumps and quad sets	• Hinged knee brace locked at 40° (or hip flexion brace locked in full extension) • PT modalities • TDWB on crutches: increase WB by 25% body weight every week • PROM – knee flexion in prone position • Wk 4 – PROM of hip extension • Wk 4 – gentle AROM/AAROM avoiding hip flexion & terminal knee extension • Ankle pumps and quad sets	• DC hinged knee brace • Wean off crutches when normal gait pattern established • PT modalities as needed • PROM – avoid combined hip flexion/knee extension • TBS/TAS activities as recommended & tolerated • TLS – gluteus medius/maximus PREs • OKC standing hamstring curls • CKC quarter depth squats and heel raises

- At 4 weeks, brace can be unlocked as tolerated
- Begin partial weight bearing at 25% of body weight increasing by 25% every week over next 4 weeks

Management of Pain and Swelling

- Continue with oral pain medications
- Continue therapeutic modalities including TENS, E-Stim, and cryotherapy
- Continue with cryotherapy as needed

Techniques for Progressive Increase in Range of Motion

Manual Therapy Techniques

- Avoid hip flexion and 40° of terminal knee extension up to 4 weeks
- At 2 weeks, PROM flexion of the knee in the prone position should be initiated to prevent knee stiffness
- Ankle and lumbar spine ROM is encouraged

Soft Tissue Techniques

- Scar mobilization to surgical incision once closed.

Stretching and Flexibility Techniques for the Musculotendinous Unit

- At 4 weeks, PROM of hip extension and knee flexion is initiated with cessation of ROM with any discomfort

Other Therapeutic Exercises

- Continue with ankle pumps and quad sets
- Persistent limitation of activity beyond ADLs to protect repair for 4 to 6 weeks

Activation of Primary Muscles Involved in Injury Area or Surgical Structures

- Initiate gentle isotonic AAROM/AROM at week 4 with avoidance of hip flexion and terminal knee extension

Milestones for Progression to the Next Phase

- No evidence of failure of repair
- Pain tolerable with limited PROM

Phase III (weeks 6 to 10)

Clinical Pearl

Flexibility exercises remain contraindicated at this point to protect the repair. Tightness and/or cramping is not uncommon, and, if experienced, gentle stretching with hip and knee flexion as tolerated can be initiated (Figure 24-47)

FIGURE 24-47. Photograph of "knee-to-chest" stretch with hip and knee flexion.

Goals

- Protect repaired structures
- Normal gait pattern
- Return of pain-free ADLs at home
- Limited pain with gentle strengthening

TIMELINE 24-5: **Postoperative Rehabilitation After Repair of Proximal Hamstring Avulsion** (Continued)

PHASE IV (weeks 10 to 14)	PHASE V (weeks 14 to 24)	PHASE VI (weeks 24 to 52)
• PT modalities as needed • PROM – avoid combined hip flexion/knee extension • TBS/TAS activities as recommended & tolerated • TLS – gluteus medius/maximus PREs • OKC standing hamstring curls • CKC half-depth squats and heel raises • CKC leg press PREs • NMS half-depth multidirectional step lunges • Double leg Swiss ball curls	• PT modalities as needed • PROM – full as tolerated (limited goals relative to contralateral side) • TBS/TAS/TLS activities as recommended and tolerated • OKC standing hamstring curls • CKC full depth squats and heel raises • CKC leg press, Romanian dead lifts—PREs • NMS full depth multidirectional step lunges • Plyometrics jumping rope • Single leg Swiss ball curls	• PROM – full as tolerated (limited goals relative to contralateral side) • TBS/TAS/TLS activities as recommended & tolerated • OKC standing hamstring curls • CKC full-depth squats and heel raises • CKC leg press, Romanian dead lifts – PREs • NMS single-leg stance, movement on unstable surfaces • Plyometrics sport-specific high intensity exercises • Plyometrics agility drills, side to side and box jumps • Single-leg Swiss ball curls • Sport-specific exercises initiated and progressed

Protection

- Crutches can be weaned off once a normal gait pattern is reestablished
- Knee brace discontinued

Management of Pain and Swelling

- Oral analgesic use is continued as needed
- NSAID therapy may be prescribed for persistent pain
- TENS and E-Stim for pain control PRN
- Cryotherapy is used posttherapy to mitigate postexercise inflammation and soreness

Techniques for Progressive Increase in Range of Motion

Manual Therapy Techniques

- ROM Precautions: Avoid combined hip flexion/knee extension
- Knee PROM: techniques used to improve knee flexion and extension within limits of comfort

Soft Tissue Techniques

- Light desensitization massage to surgical incision and posterior hip.

Stretching and Flexibility Techniques for the Musculotendinous Unit

- Gentle isolated knee stretches within limits of comfort
- Avoid combined hip flexion/knee extension stretches

Other Therapeutic Exercises

- Cardiovascular: aquatic walking and an upper body ergometer with gel seat cushioning may be initiated with resistance as tolerated.
- Upper body strengthening is initiated with closed and open chain exercises.
- Initiate core pelvic strength training with avoidance of hip flexion.
- Gluteus maximus strength exercises begin and progress from the prone to supine position
- Gluteus medius strengthening is initiated in the side lying position and progresses to the upright position

Activation of Primary Muscles Involved in Injury Area or Surgical Structures

- Increasing resistance in isotonics in limited range-of-motion; continued avoidance of terminal range of knee extension

Sensorimotor Exercises

- Gait training without crutches is continued
- Step-down exercises are initiated using progressively higher steps

Open and Closed Kinetic Chain Exercises

- Emphasis of CKC isotonics with initiation of OKC exercises

FIGURE 24-48. Photograph of standing hamstring curl.

- CKC: Quarter-depth squats and heel raises progress from bilateral to unilateral status
- OKC: Standing hamstring curls are initiated with hip joint held in neutral and lower leg moving against gravity in pain free arc. Resistance is increased a pound at a time as tolerated with emphasis on high reps and frequency (Figure 24-48)
- Initiate unilateral leg press activities with light resistance and increase as the operative leg tolerates. (Starting hip position should be below 90° and pain free)

Techniques to Increase Muscle Strength, Power, and Endurance

- Machine hamstring curls initiated with 8 to 10 lb at high reps once a full and pain-free knee flexion arc is obtained.

Milestones for Progression to the Next Phase

- Restoration of normal gait pattern
- Return to complete home ADLs without pain

Phase IV (weeks 10 to 14)

Clinical Pearl

Patients may have discomfort while sitting during ADLs and seated exercises. Upright exercises may avoid the sensitive area and a gel seat pad with/without an incision protecting cutout can mitigate the discomfort.

Goals

- Return to unrestricted pain free ADLs at home and at work (excluding heavy labor)
- Performance of nonimpact cardiovascular exercise
- Transition hamstring strengthening from machines to exercises combining strength and balance

Management of Pain and Swelling

- Oral NSAIDs may be continued. If pain continues to be a limiting factor to progression, the patient should return to the surgeon for reassessment.
- TENS, E-Stim, and cryotherapy for pain control PRN
- Cryotherapy is used posttherapy to mitigate postexercise inflammation and soreness

Techniques for Progressive Increase in Range of Motion

Manual Therapy Techniques

- ROM precautions: Avoid combined hip flexion/knee extension
- Knee PROM: Techniques used to improve knee flexion and extension within limits of comfort
- Hip PROM: Techniques used to improve hip flexion and extension within limits of comfort

Soft Tissue Techniques

- Light desensitization massage to surgical incision and posterior hip

Stretching and Flexibility Techniques for the Musculotendinous Unit

- Gentle hip and knee stretches within limits of comfort
- Avoid combined hip flexion/knee extension stretches

Other Therapeutic Exercises

- Cardiovascular: Progression to three to five nonimpact aerobic sessions weekly lasting 30 minutes including upper body ergometer, aquatic walking, elliptical, or stationary cycling.
- Continuation of core pelvic and upper body strengthening
- Continued focus on strengthening the hip stabilizers including the gluteus medius and maximus

Activation of Primary Muscles Involved in Injury Area or Surgical Structures

- Increasing resistance in isotonics with progression to full range of motion

Sensorimotor Exercises

- Continuation of step-down exercises

Open and Closed Kinetic Chain Exercises

- Continuation of CKC and OKC exercises
- CKC: Unilateral half-depth squats and heel raises progress
- CKC: Leg press activities with increasing resistance, reps, and frequency
- OKC: Continued standing hamstring curls with increasing resistance, reps, and frequency

Techniques to Increase Muscle Strength, Power, and Endurance

- Machine hamstring curls with increasing resistance

Neuromuscular Dynamic Stability Exercises

- Half-depth squats with progression to half depth walking lunges is initiated
- Progression to half-depth multidirectional step lunges

Functional Exercises

- Initiation of double leg Swiss ball curl (Figure 24-49 *A*,*B*)

Milestones for Progression to the Next Phase

- Pain free participation in ADLs at home and at work (excluding heavy labor)
- Performance of nonimpact cardiovascular exercise
- Tolerance of strength and balance exercises

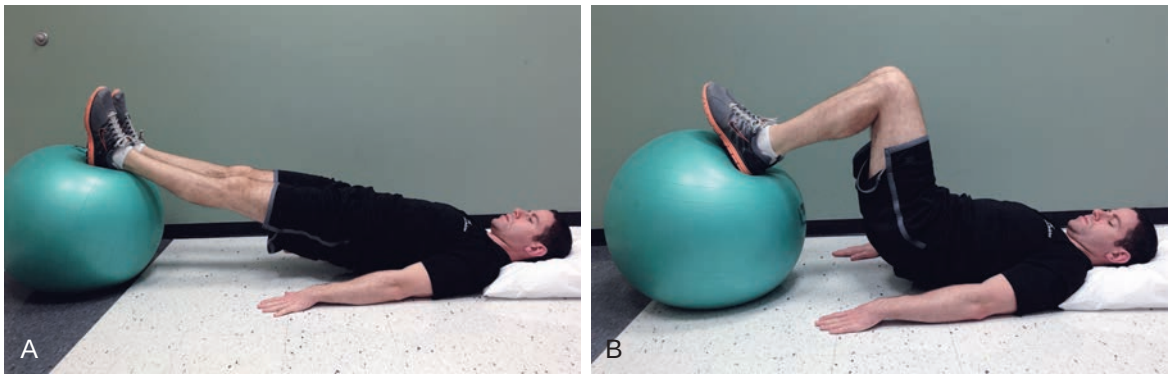

FIGURE 24-49. Photographs of a double-leg Swiss ball curl.

Phase V (weeks 14 to 24)

Clinical Pearl

Hamstring flexibility exercises are initiated in this Phase. The goal of hamstring flexibility is **not** to match the contralateral side; the goal is to alleviate cramping and allow enough flexibility for return to sport.

Goals

- Complete return to work, including heavy labor
- Hamstring strength 75% of contralateral side
- Successful initiation of light jogging

Management of Pain and Swelling

- Oral NSAIDs may be continued. If pain continues to be a limiting factor to progression, the patient should return to the surgeon for reassessment.
- TENS, E-Stim, and cryotherapy for pain control PRN
- Cryotherapy is used posttherapy to mitigate postexercise inflammation and soreness

Techniques for Progressive Increase in Range of Motion

Manual Therapy Techniques

- ROM precautions: Within limits of comfort
- PROM: Gentle initiation of hip flexion/knee extension stretching may be initiated; flexibility should remain limited relative to the contralateral side.

Soft Tissue Techniques

- Desensitization massage to surgical incision and posterior hip

Stretching and Flexibility Techniques for the Musculotendinous Unit

- Initiation of gentle combined hip flexion/knee extension stretches within limits of comfort

Other Therapeutic Exercises

- Cardiovascular: Continuation of prior aerobic exercise with the slow introduction of jogging on soft surfaces with avoidance of a treadmill.
- Continuation of core pelvic and upper body strengthening
- Continued focus on strengthening the hip stabilizers including the gluteus medius and maximus

Activation of Primary Muscles Involved in Injury Area or Surgical Structures

- Increasing resistance in isotonics with progression to full range of motion

Sensorimotor Exercises

- Continuation of step-down exercises

Open and Closed Kinetic Chain Exercises

- CKC: Unilateral full depth squats and heel raises progress
- CKC: Leg press activities with increasing resistance, reps, and frequency
- CKC: Initiation of Romanian dead lifts
- OKC: Continued standing hamstring curls with increasing resistance, reps, and frequency
- OKC: Initiation of resisted inclined hip extensions

Techniques to Increase Muscle Strength, Power, and Endurance

- Machine hamstring curls with increasing resistance

Neuromuscular Dynamic Stability Exercises

- Progression from half- to full-depth squats
- Progression from half- to full-depth multidirectional step lunges

Plyometrics

- Jumping rope
- Multidirectional step lunges at increasing speeds
- Walking lunges at full depth

Functional Exercises

- Progression from double to single leg Swiss ball curls
- Knee pushups with hip extensions (Figure 24-50)

Milestones for Progression to the Next Phase

- Complete return to all home and work activities
- Successful initiation of jogging and light plyometrics
- Hamstring strength 75% of the contralateral side

FIGURE 24-50. Photograph of knee pushup with hip extension.

Phase VI (weeks 24 to 52)

Clinical Pearl

> Cramping and activity-related discomfort are common as the intensity of the workouts increase.

Goals

- Ability to tolerate exercise with higher impact, resistance, agility, and speed
- Hamstring strength 90% of contralateral side
- Complete return to sport

Management of Pain and Swelling

- Cryotherapy is used posttherapy to mitigate postexercise inflammation and soreness

Techniques for Progressive Increase in Range of Motion

Manual Therapy Techniques

- ROM precautions: Within limits of comfort
- PROM: Gentle hip flexion/knee extension stretching may be continued; flexibility should remain limited relative to the contralateral side.

Soft Tissue Techniques

- Desensitization massage to surgical incision and posterior hip PRN

Stretching and Flexibility Techniques for the Musculotendinous Unit

- Continuation of gentle combined hip flexion/knee extension stretches within limits of comfort. The goal is to maintain and not increase ROM.

Other Therapeutic Exercises

- Integrated training activities at this stage should include multijoint movements (i.e., Romanian dead lifts, front squats, power or hang cleans, clean and press, etc.)

Activation of Primary Muscles Involved in Injury Area or Surgical Structures

- Focus in the late stage of recovery is on establishing preinjury levels of function

Sensorimotor Exercises

- Ball toss exercises while standing
- Medicine balls
- Progression to slosh balls
- Rapid repositioning drills and reaction movement drills

Open and Closed Kinetic Chain Exercises

- Advancing the previous exercises in accordance with sport-specific demands
- Examples of progression may include kettlebell swings

Techniques to Increase Muscle Strength, Power, and Endurance

- Machine hamstring curls with increasing resistance
- Utilizing isolation and combination exercises as appropriate for the athlete's desired sport

Neuromuscular Dynamic Stability Exercises

- Single leg stance and movement on unstable surfaces as necessary to replicate anticipated performance demands

Plyometrics

- Focus on high intensity activities that simulate the athlete's desired sport
- Examples include side to side jumps, box jumps, and agility drills (tires, ropes, etc.)

Functional Exercises

- Progression from double- to single-leg Swiss ball curls
- Knee pushups with hip extensions

Sport-Specific Exercises

- Return to light sport-specific training can begin as early as 24 weeks
- Light jogging can progress to running with slow build-up of speed
- After tolerating full speed running, then explosive activity, speedwork, and agility drills can be added as tolerated

Milestones for Progression to the Next Phase

- Hamstring strength 90% of the contralateral side on isokinetic testing
- Patient has subjective sense of return to baseline

Criteria for Return to Sport

- Hamstring strength 90% of contralateral side on isokinetic testing
- Single leg lop distance 90% of contralateral side
- Ability to complete activities associated with the sport without pain
- For sports requiring rapid deceleration, acceleration, and direction change (football, basketball, track, rugby, soccer, etc.) there should be symmetric lower extremity motion during sprinting and agility drills that persists despite fatigue.

After Return to Sport

Continuing Fitness or Rehabilitation Exercises

- Continued lower body and whole body strengthening exercises

Exercises and Other Techniques for Prevention of Recurrent Injury

- Limitation of bilateral hamstring stretching beyond what is required for the athlete's desired sport
- Ensure appropriate dynamic neuromuscular control (strength, mobility, kinesthetic awareness, and proprioception of the hamstrings, core muscles, and ipsilateral hip and lower extremity musculature).
- Avoidance or limitation of activities (as appropriate) that cause eccentric loading of the hamstring with concomitant hip flexion and knee extension (e.g., water skiing)

Evidence

Cohen S, Bradley J: Acute proximal hamstring rupture. *J Am Acad Orthop Surg* 15:350–355, 2007.

A review article focusing on indications, surgical technique, and treatment outcomes in proximal hamstring injuries with a review of available evidence. (Level V evidence).

Cohen SB, Rangavajjula A, Vyas D, et al: Functional results and outcomes after repair of proximal hamstring avulsions. *Am J Sports Med* 40:2092–2098, 2012.

Fifty two patients undergoing chronic or acute proximal hamstring repairs had successful outcomes as determined by LEFS, Marx, and custom proximal hamstring questionnaires. (Level IV evidence).

Hamersly S, Schrader M: Postoperative rehabilitation of proximal hamstring tears. *Oper Tech Sports Med* 17:219–224, 2009.

Overview of the authors' rehabilitation protocol with comparison to other protocols. (Level V evidence).

Lefevre N, Bohu Y, Naouri JF, et al: Returning to sports after surgical repair of acute proximal hamstring ruptures. *Knee Surg Sports Traumatol Arthrosc* 21:534–539, 2013.

Prospective observational study of thirty four patients that underwent proximal hamstring repair with good results determined by activity level on UCLA and Tegner scores. (Level III evidence).

Pombo M, Bradley JP: Proximal hamstring avulsion injuries: a technique note on surgical repairs. *Sports Health* 1:261–264, 2009.

A technical guide for surgical repair of proximal hamstring injuries. (Level V evidence).

Multiple Choice Questions

QUESTION 1. Which of the statements below is true regarding ROM goals for the repaired hamstring?

A. Preventing postoperative stiffness is a key guiding principle in postoperative rehabilitation of proximal hamstring repairs
B. ROM exercises emphasizing combined hip flexion and knee extension should be started when the patient notes postoperative tightness and cramping.
C. The final goal for ROM is to have functional ROM, but not to match the contralateral side.
D. The final goal for ROM is to have an equal ROM of the operative and contralateral sides.

QUESTION 2. When is it safe to initiate gentle combined hip flexion and knee extension exercises?

A. 0 to 6 weeks
B. 6 to 10 weeks
C. 10 to 14 weeks
D. 14 to 24 weeks

QUESTION 3. When is it safe to begin gentle isotonic AAROM/AROM with avoidance of terminal knee extension?

A. 0 weeks
B. 2 weeks
C. 4 weeks
D. 6 weeks

Answer Key

QUESTION 1. Correct answer: **C** (see Clinical Pearl week 14–24)

QUESTION 2. Correct answer: **D** (see Phase V)

QUESTION 3. Correct answer: **C** (see Phase II)

BEYOND BASIC REHABILITATION: RETURN TO RUGBY AFTER REPAIR OF HAMSTRING AVULSION

James R. Ross, MD, Michael J. Keating, MS, ATC, CSCS, and Bruce S. Miller, MD

Introduction

ASPECTS OF RUGBY THAT REQUIRE SPECIAL ATTENTION IN REHABILITATION

- Improved agility and quickness to allow quick changes in direction, starting and stopping, and sprinting.
- Good joint mobility and muscle flexibility, especially with muscular balance between the quadriceps and hamstrings to be able to better handle explosives, isometric contractions during contact such as tackling, rucking, lineouts and scrimmaging (Figure 24-51).
- Optimal core and back strength to control the body's movements, especially in highly variable conditions such as scrums and lineouts.
- Ability to control the lower extremity during kicking

Literature

- Lefevre et al.[1] demonstrated return to sport at a mean of 5.7 months after surgical repair of proximal hamstring ruptures. Approximately 80% of patients were able to participate at the same level as before the injury. Although the level of activity according the UCLA scale was good (8.7), it was slightly lower than the preoperative score (9.1).
- Cohen and Bradley[2] similarly demonstrated return to sport at a mean of 6.6 months after surgical repair. Besides waterskiing, approximately 94% were able to return to the sport in which they injured their hamstrings.

Phase I: Advanced Strength and Conditioning Programs

A perioperative rehabilitation program is given in Box 24-3. Specific exercises are shown in Figures 24-52 to 24-57).

Periodization

- Linear
- Undulating
- Macrocycles
- Mesocycles
- Microcycles

Program Design/Performance Training Program

Sport-Specific Concepts of Integrated Training

- After the initial phases of traditional rehabilitation have been completed and the athlete has restored basic mobility and strength, it is imperative the athlete is integrated back into physical training to bridge the gap from patient to athlete. This will encompass total body training including cardiovascular, strength, power and agility.

FIGURE 24-51. Good joint mobility and muscle flexibility, especially with muscular balance between the quadriceps and hamstrings, is necessary to better handle explosive movements and isometric contractions during contact such as tackling, rucking, lineouts, and scrimmaging.

BOX 24-3 Perioperative Rehabilitation: Preparation for Return to Sport

Preoperative Period

GOALS:

- Decrease pain
- Diminish effusion
- Maintain quad strength
- Patient education

GENERAL OUTLINE:

- Adequate patient education including explaining the surgical procedure, early postoperative care, and the anticipated rehabilitation program
- Crutches for weight-bearing as needed
- Avoidance of any strengthening and stretching exercises of the injured hamstring muscle to minimize muscular and tendinous retraction
- Isometric contractions of the quadriceps and gluteal muscles to minimize muscular atrophy
- Ankle pumps to minimize the risk of deep vein thrombosis

Week 1: "Protection Phase"

- Goal: maintain the hamstring muscle in a shortened and relaxed position, thus avoiding traction on the tendon repair. A brace is typically not needed with acute (< 2 weeks) repairs so long as the leg can be maintained in a neutral position.
- Avoid sitting and direct pressure on the affected ischial tuberosity, except when using an elevated toilet seat
- Toe-touch weight bearing is permitted with crutch-assistance
- Exercises: four times daily with 3 sets of 10 repetitions
  - Isometric quadriceps and gluteal muscle contractions
  - Ankle pumps
  - Supine heel slides up to 30° to 45° of knee flexion

Week 2: Initiation of formal physical therapy (1 to 2 supervised sessions per week)

- Full weight bearing (with crutches) is allowed when patient is able to perform a straight leg raise to 30° of hip flexion
  - Short strides, 10 times daily for 20 minute intervals
- Patient allowed single leg stance to perform minor knee flexion/extension exercises from 0° to 20° of knee flexion.
  - Four times daily, 3 sets of 10 repetitions
- "Safe" isometric hamstring contractions for 6 seconds
  - Supine with 30° of knee flexion
  - Two times daily, 3 sets of 10 repetitions
- Prone, passive knee flexion/extension exercises
  - Three times daily, 3 sets of 10 repetitions

Week 3

- Continue exercises from week 2
- Standing anti-gravity knee flexion curls with ankle in plantar flexion
  - Once daily, 3 sets of 3 repetitions
- Stationary slow walking on a thick pad
  - Twice daily, 3 sets, 30 seconds per set
- Calf strengthening in standing position with straight leg

Week 4

- Continue exercises from week 2 and 3
- If good posture and balance control, discontinue crutch use indoors, continue when outdoors
- Initiate pool therapy if wound is healed
  - Forward/backward and side-to-side walking
  - Two times weekly, 20 minutes per session
- Stationary bicycle with seat in high position when patient is able to perform 70° of hip flexion with the knee flexed 90°

Week 5: Hamstring strengthening initiated

- Discontinue exercises from weeks 1 to 3; continue with week 4 exercises
- Static or isometric leg curls in the seated position on the edge of chair
  - Press the heel of the operative leg against the toe of the non-operated leg (6 second holds)
  - Two times daily, 2 sets of 10 repetitions
- Standing single-leg catches with a cable or a Thera-Band
  - Three times weekly, 3 sets of 10 repetitions on each leg

BOX 24-3 Perioperative Rehabilitation: Preparation for Return to Sport *(Continued)*

- Single leg balance training
  - Start on floor and progress with eyes open and progress to eyes closed
  - Two times daily
- Core stability exercises
  - Supine pelvic thrusts or bridges (Figure 24-57), initially with the majority of body weight on the nonoperative limb. Progressively increase body weight onto the operative leg in a pain-free manner
  - Three times weekly, 3 sets of 10 repetitions

Week 6

- Gait should be normal; discontinue all crutch weight bearing
- Continue exercises from weeks 4 and 5
- Muscle flexibility training: supine, active knee extension exercises with the hip joint held at 90° of flexion with grasped hands under thigh
  - Two times daily, 3 sets of 10 repetitions
- Lunge walking: start with minimal stride length and gradually increase stride
  - Three times weekly, 3 sets of 10 strides
- Step ups on stair or stool
  - Two times daily, 3 sets of 10
- Gluteus medius strengthening—lateral resisted walking with Thera-Band
  - Two times daily, 20 yards, 4 times
- Single leg balance
  - Progress to mini-trampoline and other devices as able
  - Two times daily
- Leg curls in prone position with resistance: 6 seconds for contraction and 6 seconds for relaxation
  - Three times weekly, 3 sets of 10 repetitions

Week 7 and beyond: initiation of eccentric hamstrings training

- Ensure 2 days of rest per week for recovery
- 2 to 4 hamstring exercises at each training session
- Cautious forward and backward jogging with short strides, including acceleration and decelerations
- Stationary jogging with high knee lifts at increasing intensity over time
  - Four times weekly, 3 sets, 20 seconds per set
- Single-leg supine pelvic thrust
  - Progress by moving the heel away from the hip
  - Three times weekly, 3 sets of 8 repetitions
- Combine complex exercises such as lunges, squats, and jumping
- Dynamic leg curls in both the prone and sitting positions
  - Three times weekly, 3 sets of 10 to 15 repetitions

Return to Sport

- Aggressive, sport-specific activities allowing full unrestricted range of motion
- Outdoor training, slope training
- Can return to preinjury level when functional abilities such as jumping, running, and cutting can be performed without pain, stiffness or a feeling of insecurity
- Active hamstring flexibility test without any pain or feeling of insecurity
- 5 consecutive pain-free repetitions of maximal effort in both prone and supine positions
- May take up to 1 year to regain equal strength

Modified from Askling CM, Koulouris G, Saartok T, Werner S, Best TM: Total proximal hamstrings ruptures: clinical and MRI aspects including guidelines for postoperative rehabilitation. Knee Surg Sports Traumatol Arthrosc 21: 515–533, 2013.

- The rugby athlete requires both aerobic and anaerobic conditioning and both should be addressed during this phase—beginning with attaining an aerobic base.
- In regards to strength training, the athlete is now able to begin traditional strength training including all upper body, core and reintroducing lower extremity exercises such as squats and dead lifts. As muscular strength improves and normalizes compared to the uninvolved side, we look to convert this strength to power.

Olympic Lifts Used in the Training Program

- None at this phase, it typically can begin 16 weeks postoperatively

Training Principles Used in the Design of the Program

- Principle of progression
- Principle of overload
- Principle of variation

FIGURE 24-52. Lunge with medicine ball and truck rotation.

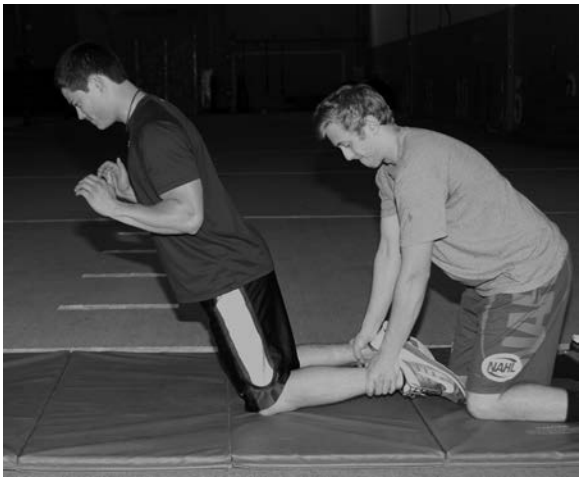

FIGURE 24-54. Russian hamstring curl with partner.

FIGURE 24-53. Single-leg Romanian dead lift on balance disk.

FIGURE 24-55. Single-leg hamstring curl with Swiss ball.

- Principle of individualization
- Principles of specificity—specific adaptation to imposed demands (SAID)

Application of Acute Training Variables

- The basic concept of this phase is to build strength and mass that has likely decreased during the injury and subsequent surgery and recovery.
- Moderate resistance combined with higher reps and sets are preferred. As a strength base is developed, the overload principle should be applied which uses heavier resistance in conjunction with fewer sets and reps. Here are some examples of specific exercises:
  - Back squat
  - Single leg lunge
  - Dead lifts

TIMELINE 24-6: **Beyond Basic Rehabilitation: Return to Rugby after Repair of Hamstring Avulsion**

Weeks 0 to 2	Weeks 3 to 4	Weeks 5
• Crutches with toe touch only • PT modalities • Soft tissue massage (STM) • Gentle PROM of knee/ankle • Isometrics of quads and glutes	• Crutches with progressive weight bearing—discharge at wk 4 indoors, but use outdoors • PT modalities • STM • Gait training • Pool therapy—walking forward, backward and lateral • Begin stationary bike at wk 4 with a high seat	• Crutches only as needed outdoors • PT modalities as needed • Progress hamstring flexibility • Single leg balance • Core strength progression • Hamstring isometrics

FIGURE 24-56. High bench step-up with medicine ball.

- RDL (Romanian dead lift)
- Eccentric hamstring curl
- Step-ups
- Split squats

Phase II: Performance Enhancement Training Techniques

Periodization

- Linear
- Undulating
- Macrocycles
- Mesocycles
- Microcycles

Program Design/Performance Training Program

Sport-Specific Concepts of Integrated Training

- During the Return to Sport phase, we begin to transfer the strength that has been established into power and speed.

FIGURE 24-57. Double-leg bridge with Swiss ball.

- This will include review of proper running mechanics (sprint), deceleration and agility with change of direction.
- Addition of a plyometric program is critical during this phase.
- It is important that drills are selected that best represent the demands of the athlete based on the position they play. As an example, a back in rugby will require more agility and a forward will require more explosive power.

Olympic Lifts Used in the Training Program

- Snatch
- Clean and jerk
- Power clean

Training Principles Used in the Design of the Program

- Principle of progression
- Principle of overload
- Principle of variation
- Principle of individualization
- Principles of specificity—specific adaptation to imposed demands (SAID)

Application of Acute Training Variables

- This phase will focus on technique—especially with proper running mechanics. Proper forward lean, knee drive, foot position and arm mechanics are critical to maximize performance and avoid future injury.

TIMELINE 24-6: **Beyond Basic Rehabilitation: Return to Rugby after Repair of Hamstring Avulsion** (Continued)

Weeks 6 to 10	Weeks 11 to 16	Weeks 17+
• Crutches DC • Normal gait • PT modalities as needed • PROM and flexibility progressing • Closed kinetic chain exercises • Step-ups • Lunges • Single-leg balance • Core strengthening • Glut strengthening • Add dynamic warm-up	• ROM and flexibility without limits • STM as needed • Continue strengthening per above • Single-leg hamstring strengthening • Hamstring eccentric strengthening • Begin return to run progression • Double-leg jumping	• Full motion • Begin strength training program with team • Begin agility training with change of direction • Add deceleration drills • Single leg jumping/plyometric drills • Sport-specific training

- Over-striding and heel strike during sprint mechanics are common causes of recurrent hamstring injury.
- Additionally, as most hamstring injuries occur during the eccentric phase, it is important to select training drills that challenge the hamstring eccentrically. This will include change of direction drills and jump and land drills.
- Specific exercises used in the training
  - Running mechanic instruction—plus drills
  - Sprint progression
  - Sprint with deceleration
  - Agility ladder drills
  - Depth drops
  - Single-leg exploding Harvards

Phase III: Sport-Specific Training

Periodization

- Linear
- Undulating
- Macrocycles
- Mesocycles
- Microcycles

Program Design/Performance Training Program

Sport-Specific Concepts of Integrated Training

- During this phase it is critical to identify the specific needs of the rugby athlete—specific to their position. For example, a back in rugby will need to have amazing agility and also kicking skills. A forward needs to have explosive and sustained power for scrimmaging and lineouts.
- Analyzing the needs and selecting sport specific exercises is vital for successful return to play.

Olympic Lifts Used in the Training Program

- Snatch
- Clean and jerk
- Power clean

Training Principles Used in the Design of the Program

- Principle of progression
- Principle of overload
- Principle of variation
- Principle of individualization
- Principles of specificity—specific adaptation to imposed demands (SAID)

Application of Acute Training Variables

- During this phase, replication of match play intervals is critical.
- Specific exercises used in the training
  - Kicking drills—conversion/penalty kicks and punting (backs)
  - Lineout and lifting drills (forwards)
  - Scrimmaging drills (forwards)
  - Tackling and rucking drills (all)
  - Passing drills (all)

Sports Performance Testing

General Information

- General history
- Subjective questionnaires
- Medical history
- Sports injury history
- Surgical history
- Chronic conditions/medication

Specific Objective Tests

- Physiological assessments—VO_2 max,
- Body composition tests—Body fat/lean mass assessment, height, weight
- Static/dynamic postural assessments—Functional movement screen, biomechanical movement analysis
- Dynamic muscle performance testing
- Movement performance testing—Functional movement screen
- Sport-specific testing
- Others
  - Yo-Yo Interval Recovery Test (YIRT)
  - Vertical jump
  - Standing broad jump
  - 5–10–5 proagility shuttle
  - 40 m sprint
  - 10 m sprint—with and without ball

Specific Criteria for Progression to the Next Stage to Determine Readiness for Rugby

- Athlete should be demonstrating increases in strength and power and meeting goals of each stage without disability.

Specific Criteria for Release to Unsupervised Complete Participation in Rugby

- Functional testing that demonstrates 90% or better as compared to the uninvolved extremity.
- Functional testing might include: single leg lateral hop in 20 to 30 seconds for max repetitions, single leg triple hop, single leg excursion tests

Recommended Ongoing Exercises

- The athlete should continue to incorporate both hamstring flexibility/mobility exercises along with a regular hamstring eccentric strengthening program.

Evidence

Birmingham P, Muller M, Wickiewicz T, et al: Functional outcome after repair of proximal hamstrings avulsions. *J Bone Joint Surg* 93:1819–1826, 2011.

This retrospective review of 30 patients who were noted to have a complete rupture of the proximal origin of the hamstrings underwent surgical repair and were evaluated. At a mean follow-up of 43.3 months, 91% of patients returned to activity at an average of 95% of their preinjury level. (Level IV evidence).

Chahal J, Bush-Joseph CA, Chow A, et al: Clinical and magnetic resonance imaging outcomes after surgical repair of complete proximal hamstrings ruptures: Does the tendon heal? *Am J Sports Med* 40:2325–2330, 2012.

This retrospective review of 15 consecutive patients that underwent surgical repair of complete proximal hamstrings tears were evaluated with postoperative MRI. The MRI was performed at a mean of 36 months after repair. 100% of the patients had healed the hamstrings repair, with signs of tendinopathy and mild atrophy in 25% of patients. (Level IV evidence).

Cohen SB, Rangavajjula A, Vyas D, et al: Functional results and outcomes after repair of proximal hamstrings avulsions. *Am J Sports Medicine* 40:2092–2098, 2012.

This retrospective review of 52 patients that underwent proximal hamstrings repair with a mean follow-up of 33 months demonstrated improved clinical outcomes (LEFS, Marx, and proximal hamstrings scores). Acute repairs, however, had higher functional and hamstrings scores, as well as estimated hamstring strength. (Level IV evidence).

Lefevre N, Bohu Y, Naouri JF, et al: Returning to sports after surgical repair of acute proximal hamstrings ruptures. *Knee Surg Sports Traumatol Arthrosc* 21:534–539, 2013.

This prospective observational study of 34 patients with a mean follow-up of 27.2 months demonstrated a return to sport at a mean of 5.7 months, with 79.4% of patients reaching the same level of activity. (Level IV evidence).

Multiple Choice Questions

QUESTION 1. The most common lower extremity injury in rugby players is:

A. Anterior cruciate ligament tear
B. Patellar tendon rupture
C. Proximal hamstring rupture
D. Achilles tendon rupture

QUESTION 2. The expected return to play after surgical repair of a proximal hamstrings tear is approximately:

A. 6 weeks
B. 3 months
C. 6 months
D. 9 months

Answer Key

QUESTION 1. Correct answer: **C** (see Introduction)

QUESTION 2. Correct answer: **C** (see Literature)

Chapter 25

Groin Injuries

INTRODUCTION

Bruce Charles Twaddle BHB, MBChB, FRACS, and Kristian Thorborg, PT, MSportsphty, PhD

Introduction

The anatomy of the pubic symphysis region makes it a diagnostic challenge because of the confluence of numerous musculoskeletal attachments, a variety of potential weaknesses in the abdominal wall and its close proximity to both the symphysis pubis and the hip joint.

Groin pain and injury are terms used to describe problems that present with pain in this general region. The complex nature of the anatomy of this region and the close proximity of many anatomical structures that could be the source of pain in this area, make isolating the exact source of pain felt in the lower abdominal or groin region very difficult. The often insidious nature of the onset of pain with a minor initiating injury and the referral or associated pain into the symphysis, the groin or adductor region and towards the hip makes pain and symptoms in this region a diagnostic dilemma. Consequently such terms as abdominal strain, Athletic pubalgia, sportsman's hernia, Gilmore's groin, hockey goalie syndrome, and osteitis pubis can all be attributed to the same or different injuries in this region. As a result "groin pain" has been a curse for athletic trainers, physiotherapists, sports physicians, orthopedic surgeons and musculoskeletal radiologists alike with individual biases and experiences. This has led to varying schools of thought as to the true origin of pain of the same presenting characteristics and inevitably varying beliefs in "successful" treatment. As is often the case where such a diagnostic dilemma and variation in treatment exists, this suggests that either all treatments have some success reflective in part of the self-limiting nature of the condition or none of the treatments are particularly successful. Groin pain in itself can be a very frustrating condition to treat supporting the difficulties with diagnosis and as a consequence the difficulties in tailoring treatment.

Epidemiology

- The incidence of groin injuries appears to be growing in frequency and is now recognized as a significant contributor to time off the field in several professional sports, in particular in various football codes and ice hockey.
- Athletes, particularly those involved in high level competition, can often play through minor symptoms and so the prevalence is likely to be much higher than previous reports of injuries causing time off the field.

Age

- Groin injury occurs more common in athletes who have been competing at an elite level for a number of seasons.
- They were uncommonly seen in rookies in a study of NFL footballers with 95% of players with this injury having played in the NFL for 5 years or longer.
- Average age in the majority studies for patients presenting with this injury is in the late twenties.

Sex

- Groin injury is almost exclusively reportedly as an injury of the male athletic population, most likely because of the sports it has been studied in such as NFL football, soccer, and ice hockey.
- The statistics and reasons for the different incidence between males and females have not been specifically studied.

Sport

- Certain sports, namely ice hockey and soccer, report the highest amount of groin injuries, with an incidence

of 0.8 to 1.3 injuries per 1000 hours of athletic activity, and strains, accounting for up to 43% of all muscle strains in elite Finnish ice hockey players and 10% of all injuries in a study of elite Swedish Ice hockey players.
- The incidence of groin strains in a single National Hockey League (NHL) team was 3.2 strains per 1000 player-game exposures.
- Only limited information exists on acute groin injuries. The only study looking exclusively at acute groin injuries in soccer reports a groin injury incidence of 0.8 injuries per 1000 hours play. In male soccer a prospective study of the elite teams hip/groin injuries accounted for 12% to 16% of all injuries per season. The total injury incidence was 1.1/1000 hours with 3.5/1000 match hours and 0.6/1000 training hours. Adductor-related and iliopsoas-related groin injuries were the most common injuries and 15% of the injuries were re-injuries.
- In the National Football League (NFL) (American football) the most common muscle-tendonous injuries related to the groin were rectus femoris strain and adductor strains.

Position

- The effect of position seems to be far less important than the type of sport. In a review of NFL data, the problem appears to predominantly affect linesmen whereas most playing positions in soccer and ice hockey (the two most common sports for this injury) position has not been highlighted as playing such an important role. Recently, however, it has been shown that hip and groin injuries account for one third of the injuries in goalkeepers in soccer.
- The incidence of hip and groin injuries is higher in goalkeepers than in field players. This highlights that sporting actions such as kicking, stretching out in an abnormal position or rapid change of direction may be of particular importance, and responsible for the development of these injuries.

Pathophysiology

The Pathophysiology of injuries to the groin region is complex and complicated. Anatomically it is a confluence of a number of structures, and a number of structures have been implicated as the "primary" source of groin pain with little supporting robust scientific evidence. The latest example of this is the finding of reduced range of motion and radiological signs of femoro-acetabular-impingement (FAI) in hips of athletes who also get adductor localized groin pain. There have however been no studies that show treating the hip problem makes a difference to the risk or recovery from groin problems in these athletes whereas the response to a well-structured rehabilitation regime has shown significant improvement in well-constructed studies.

Intrinsic Factors

The tendons of the rectus abdominis and the adductor longus effectively form a continuous structure, termed by some authors as the "common adductor-rectus abdominis origin" (Figure 25-1). Biomechanically this acts as a dynamic stabilizer of the pubic symphysis such that any dysfunction of either tendon unit predisposes the other to failure as a result of increased load. Secondary loss or dysfunction of the stabilizers of the symphysis can lead to increased load on this joint as well and as a result symptoms and signs in the region can be distributed over a wide area. Injury to the attachment of the posterior wall of the inguinal canal as part of the anterior rectus sheath

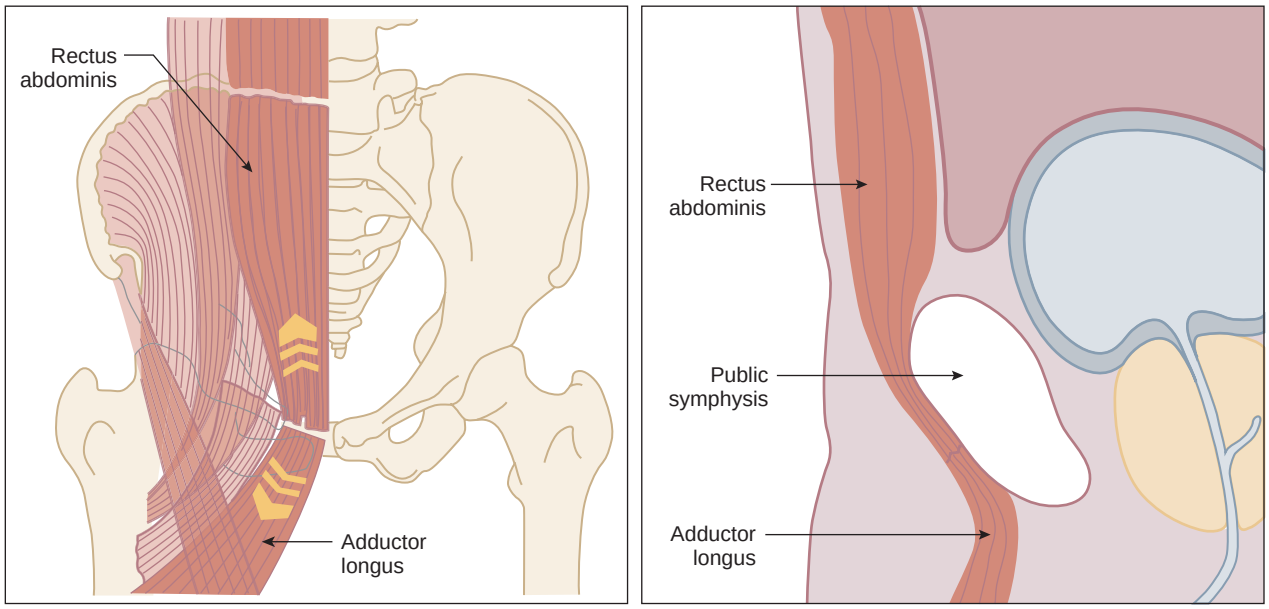

FIGURE 25-1. Schematic representation of the confluent but apposing muculotendinous units of the rectus abdominis and adductor longus muscles. *(Courtesy of Prof. Adam C. Zoga, Department of Radiology, Thomas Jefferson University, Philadelphia, PA.)*

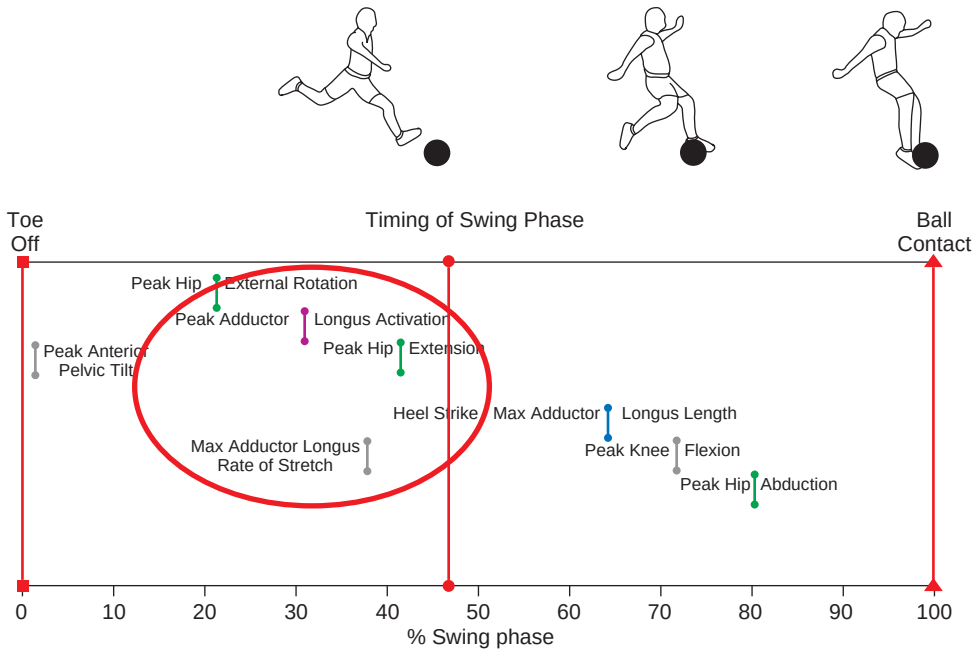

FIGURE 25-2. Timing of the swing phase. *(From Charnock BL, Lewis CL, Garrett WE Jr, Queen RM. Adductor longus mechanics during the maximal effort soccer kick. Sports Biomech 8(3):223-224, 2009.)*

can result in hernia-like formation and symptoms as part of the spectrum of injuries in this region.

Injury to the structures around the groin is intrinsically related to repeated loading of this complex of muscles and the joints they support. It can be seen that specific muscles are activated during the different phases of kicking a football and the maximal activation of the adductors as the leg is reversed from a fully extended position approaching impact with the ball. This places this musculotendinous structure of the adductors at risk of injury. Musculotendinous structures of the adductors are at greatest risk when at their maximal length, which is also the part of the kicking phase (the initial swing phase) where there is peak adductor longus activation, predisposing this region to injury. Also, the specific action of skating on the ice and the necessity for rapid and often unplanned changes of direction, again especially stressing the adductors and the abdominals places repeated maximal loads on the groin region. It is possible that the nature of the walking gait as man has become bipedal also changes the muscle dynamic of the adductor region. Rather than going through phases of rapid stretch and forceful muscle activation, this muscle is seldom stressed in this way in regular walking so activities that require sports-specific movements such as kicking and skating could be seen as atypical for this muscle group (Figure 25-2).

Extrinsic Factors

The unique nature of skating on ice including the rapid acceleration/deceleration and changing direction on skates clearly demonstrates how increasing forces can play a role in this injury. Similarly, injuries to the rectus abdominis insertion have been described in tennis players because of the unique repeated loading of this muscle in this sport. The role of the introduction of artificial turf into the frequency of groin-related injuries has been discussed with American Football injuries, but no good study has been able to correlate an increasing reported incidence of this injury with changes to the playing surface as a significant dependent variable.

Traumatic Factors

Acute muscle tear or strain: Injuries that are the result of a direct blow or rapid stretching/twisting movement can potentially injure a number of structures in the groin region. Characteristically, the patients describe planting and twisting or getting twisted or rapidly bringing the leg from a neutral to an abducted position. Once this region has been injured, it is often the case that repeated minor trauma can continue to aggravate the symptoms and cause ongoing recalcitrant pain, restriction and avoidance of provocative maneuvers whenever possible.

Classic Pathological Findings

Adductor/Abdominal Muscle-Tendinous Injury

Pain arising from adductor tendon damage can be very difficult to localize. The tendon of insertion of the rectus and origin of the adductor have been shown to be very close anatomically and their function is antagonistic in stabilizing the pelvis and the symphysis in a variety of activities. Pain in this region can therefore be classically referred into both areas as well as towards the symphysis and almost impossible to separate out. Such diagnoses

BOX 25-1 Blazina Grading of Tendinopathy

Grade 1	Pain after activity with no functional impairment
Grade 2	Pain at the beginning of activity, disappearing after warm up, reappearing after activity
Grade 3	Pain during and after activity with functional impairment
Grade 4	Complete tendon rupture

fall under the classification of most tendon strains or chronic injuries and can be grouped as the treating physician prefers and finds useful. This can include clinical grading such as that described by Blazina (Box 25-1) in association with the degree of damage defined by imaging studies. Less severe injuries may just have an awareness of pain aggravated by intense loading of the muscles concerned, more symptomatic examples may have pain or discomfort at rest that is initially eased by activity only to return and with increased intensity once the activity has ceased.

Muscular or tendinous injury in this region is far more common in males than females and so making the diagnosis in the female should always make the examiner check for other "pelvic"-related problems as a potential source. Relationship of the pain to the frequency or intensity of activity should allow the examiner to lean towards a tendon or muscle strain or tendinopathy. Aggravation of symptoms by palpation and resisted isometric testing of the affected muscle, either during adductor contraction or abdominal "crunch" type activity, brought on by repeated use or testing can help attribute the symptoms to either one or the other but often testing of both muscles can bring on the symptoms. Use of local anesthetic injection may help localize the pathology but in more severe examples, which have been going on for some time and chronicity, where the pain can be over a wide area and reference zone, makes localizing of the cause of the pain more difficult.

Iliopsoas Muscle-Tendinous Injury

The iliopsoas muscle can also be acutely strained or injured through repetitive overuse. This usually happens as a consequence of specific of repetitive forceful hip flexion during running, skating, jumping, or kicking. It can also be injured during an eccentric contraction, as when the thigh is suddenly forced into extension and the iliopsoas will try to decelerate the movement by an instantaneous eccentric muscle action. The overused iliopsoas tendon will sometimes appear with a spindle shape, near the insertion point on the trochanter minor, which can be visualized by ultrasound examination. Again the use of use of local anesthetic injection may also help localize the pathology from other structures, as iliopsoas symptoms can often coexist with other pathologies, such as adductor related injuries and intraarticular hip problems.

Clinical Presentation

History

These patients will often give a history of one precipitating event or action but may on more detailed questioning admit to having had some aching discomfort in the groin region before this. These minor symptoms are so common in the sports such as soccer and ice hockey that players almost accept it as the "norm." It is only with sudden worsening of intensity to the point where performance begins to be affected do they bring it to the treating clinicians attention. Characteristically these patients have a central aching discomfort in the groin region on one side or the other, aggravated by activity and localizing tenderness to clinical examination made worse by bracing maneuvers or single leg stance loading. The pain will often linger long after exercise has finished and may create sleep disturbance and early morning symptoms. This pain is characteristically brought on by resisted adduction of the leg, typically worsened when performed in an abducted position.

Muscular or tendinous injury in this region is far more common in males than females and so making the diagnosis in the female should always make the examiner check for other "pelvic"-related problems as a potential source. Relationship of the pain to the frequency or intensity of activity should allow the examiner to lean towards a tendon or muscle strain or tendinopathy. Relationship of the pain to bracing or "crunching" activities but not so obvious with resisted adduction should make the clinician consider a hernia or "sports hernia" as part of the differential diagnosis.

A number of risk factors (Table 25-1) have been identified and should be looked for in the history and examination of these patients to alert the examiner to possible cause(s) of the pain. Previous injury, increasing age, weak adductors, and low levels of off-season sports-specific activities have been shown to be significant risk factors for sustaining a groin injury. In Australian Rules Football (AFL) young players reporting a previous hip or groin injury at the draft medical assessment demonstrated a rate of hip/groin injury in the AFL more than six times higher than players without a pre-AFL hip or groin injury history.

Table 25-2 highlights the range of clinical entities that can contribute alone or in combination when taking a history and examining these types of patients.

Physical Examination

Examination of these patients must be comprehensive and cover a large number of potential entities that can contribute to the problem and as can be seen from the previous table, more than one entity can appear to be contributing to the symptoms.

Assessment of gait and leg length is mandatory, as well as signs of bruising for evidence of acute muscle/tendon injury which is usually an obvious sign (see Figure 25-3). In less obvious cases, local tenderness at the origin of the adductor tendons is helpful but localizing tenderness for other of the differential diagnoses is difficult to elicit and the pain can often be in a broad region making localizing

Table 25-1 Multivariate Analysis of Potential Risk Factors for Adductor Injury

Risk Factors	Adjusted OR	95% CI	*p* Value
Player-Dependent Factors			
Age	1.10	0.74–1.63	.65
Counter-movement jump test	1.01	0.89–1.14	.92
Leg-Dependent Factors			
Previous acute groin injury (yes/no)	2.60	1.10–6.11	.03
GrOS total score	1.04	0.78–1.41	.77
Clinical Examination			
External rotation in the hip joint (painful or not)	2.90	0.55–15.2	.21
Functional testing of rectal abdominal muscles (painful or not)	0.89	0.28–2.79	.84
Strength of adductor muscles (weak or not weak)	4.28	1.31–14.0	.02
Strength of iliopsoas muscles (weak or not weak)	2.23	0.39–12.7	.36

From Engebretsen AE, Myklebust G, Holme E, et al: Intrinsic risk factors for groin injuries among male soccer players: A prospective cohort study. Am J Sports Med 38:2051–2057, 2010.

the source difficult. Any swellings or signs of true hernias should be checked for and recurrence of symptoms more proximally in the region, with abdominal "crunching" testing may be more indicative of a "sports hernia" as a potential source of the pain. This, however, is usually a diagnosis of exclusion, often after surgical treatment of other conditions has failed (Figure 25-3).

Hip range of motion is often reduced and has led to the theory, unsupported by scientific evidence so far, that hip impingement may be a contributing factor.

Pain on palpation and aggravation of symptoms by resisted isometric testing of the affected muscle, either during adductor contraction or abdominal "crunch" type activity, brought on by repeated use or resistance testing can help attribute the symptoms to either one or the other but often testing of both the adductors and the abdominal rectus can bring on the symptoms. Use of local anesthetic injection may help localize the pathology but in more severe examples, which have been going on for some time and chronicity, the pain can be over a wide area and reference zone, making localizing of the cause of the pain more difficult.

FIGURE 25-3. Bruising associated with acute adductor longus rupture injury.

Table 25-2 Primary, Secondary, and Tertiary Clinical Entities in Soccer Players with Groin Pain

Clinical Entity	Primary, *n* (%)	Secondary, *n* (%)	Tertiary, *n* (%)
Adductor-related pain	94 (686.)	4 (2.9)	
Iliopsoas-related pain	35 (25.5)	31 (22.6)	6 (4.4)
Sports hernia	2 (1.5)		1 (0.7)
Snapping Iliopsoas	1 (0.7)

Rectus abdominus-related pain	1 (0.7)	11 (8)	3 (2.2)
Sacrotuberal ligament pain	1 (0.7)	4 (2.9)	1 (0.7)
Sacroiliac joint dysfunction	1 (0.7)		
Hip arthrosis	1 (0.7)	1 (0.7)	
Pain of thorocolumbar origin	1 (0.7)		
Hernia	1 (0.7)		
Piriformis-related pain	1 (0.7)	1 (0.7)	
Stress fracture	1 (0.7)		
Total	137 (100)	52 (38)	11 (8)

From Hölmich P. Long-standing groin pain in sportspeople falls into three primary patterns, a "clinical entity" approach: a prospective study of 207 patients. Br J Sports Med 2007 Apr;41(4):247-52; discussion 252, 2007.

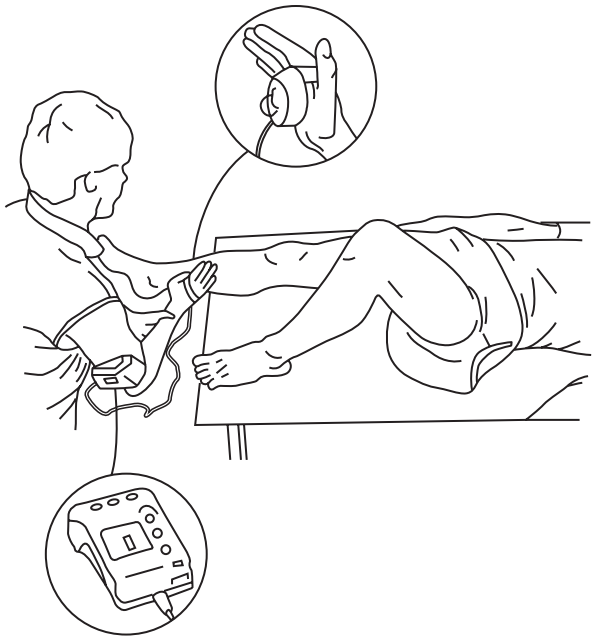

FIGURE 25-4. Use of a hand-held dynamometer to measure adductor strength. *(From Thorborg et al. Clinical assessment of hip muscle strength is reliable. SJMSS 20:493-501, 2010, with permission.)*

Quantifying adductor strength will often make obvious more subtle differences in adductor related problems and highlight the need for a strengthening program as an essential part of overall treatment. Use of a hand-held dynamometer to do this has been shown to be accurate and reproducible and is most sensitive when performed at the ankle with the leg in 0° of hip flexion (Figure 25-4).

One of the challenges with these patients is that the examination findings may be almost entirely normal or very difficult to isolate a single cause for the patient's symptoms. Use of imaging to support the clinical suspicions and exclude such pathologies as stress fractures can be diagnostic. At times "abnormal findings" on imaging will not correlate with your clinical findings and imaging studies should not replace clinical assessment and examination findings.

Imaging

- X-rays of the hip and pelvis are mandatory and a loaded view of the pubic symphysis (the flamingo view) may show evidence of subtle symphyseal instability. Views to look for FAI are considered mandatory for some clinicians and certainly indicated where hip range of motion is markedly reduced.
- CT scanning can further investigate associated hip abnormalities, early osteoarthritis of the hip or changes in the symphysis pubis. Stress fractures of the femoral neck or pubic ramus may also be better seen on CT.
- Ultrasound is useful in acute injuries in particular and if any swellings are visible at examination.
- MRI scanning is usually an inevitable investigation in these patients and many will bring such imaging with them that has been interpreted in a variety of ways by a variety of physicians they have seen previously. Positive findings on MRI scan that correlate with clinical findings are definitely supportive information for the clinician and patient, however, abnormal reported findings that do not have a close clinical correlate should be treated with caution. Features such as edema in the parasymphyseal region of the pubic symphysis may warrant reexamination of the patient, taking these findings into consideration. The diffuse nature of the pain on presentation can make localization of the pathology and diagnosis difficult, so having a structured examination system and correlating findings with MRI changes is likely to produce the highest clinical accuracy.
- A bone scan can be useful in isolating problems to the symphysis or revealing a stress fracture around the groin such as pubic rami or femoral neck. A CT scan to show the detail of the bony injury is then indicated (Table 25-3 and Box 25-2).

Differential Diagnosis

- Hip joint pathology
- Stress fractures (inferior rami and femoral neck)
- Internal or external snapping hip
- Avulsion fractures (sartorius and rectus femoris)
- Bursitis (traumatic or inflammatory)
- Nerve entrapment (obturator, ilioinguinal, and genitofemoral nerve branches)
- Gynecological or urological disorders
- Neoplasms (osteosarcomas, chondrosarcomas, other tumors)

Treatment

Nonoperative Management

Groin injuries can be difficult to treat and are often ignored by athletes and trainers, thus developing into a

Table 25-3 Checklist for MRI Evaluation of Adductor Injury

Muscle and Tendon	Sign/Symptom
Adductor longus	- tendinous (superficial) and muscular (deep) origin on anterior pubic bone (bone without perisoteum) - avulsion usually associated with bone fragment
Adductor brevis	- muscular origin posterior to adductus longus
Adductor tendon injury	- myotendinous injury—proximal (or distal)
Pectineus	- origin lateral public symphysis and superior pubic crest
Obturator externus	- origin postero-lateral pubic systems
Gracilis	- origin anteroinferior pubic symphysis and superior pubic arch
Grading of Injury	
Adductor muscle strain	
Acute	- increased T2 signal
Chronic	- Hypertrophic - Atrophic

BOX 25-2 MRI and Radiology of Groin Injury Associated Pathologies

Rectus Abdominis

- Attachment to superior pubic ramus
- Medial and lateral heads

RECTUS ABDOMINIS/ADDUCTOR APONEUROSIS

- Attachment to antero-inferior pubic bone

RECTUS ABDOMINIS/ADDUCTOR APONEUROSIS INJURY

- Ipsilateral rectus abdominis distal detachment + adductor aponeurosis partial or complete detachment
- Unilateral rectus abdominis atrophy
- Unilateral or bilateral adductor aponeurosis injury

RECTUS ABDOMINIS/ADDUCTOR APONEUROSIS PLATE DISRUPTION

- Secondary Cleft Sign
- Antero-inferior pubic bone curvilinear increased T2 signal

Symphysis Pubis

Bone marrow edema
Location:

- Superior = rectus abdominis
- Antero-inferior = RA/AA
- Lateral = pectineus
- Postero-lateral = obturator externus

Unilateral or bilateral
Degenerative change

- Subchondral cystic change
- Subchondral sclerosis
- Erosions

Acquired Inguinal Wall Deficiency

Frequent coexistent adductor tendon injury
Anterior inguinal ring insufficiency
Tear medial aspect external oblique, resulting in patulous external inguinal ring
Proposed that pain is caused by entrapment of cutaneous branches of the ilioinguinal nerve and genital branch of genitofemoral nerve
Clinical diagnosis
Rare to have findings on MR or US
MR—may see hyperintensity of external inguinal ring

Posterior Inguinal Wall Insufficiency

Conjoint tendon or transversalis fascia attachment tear or weakness
Use of imaging debated for diagnosis
US Posterior inguinal wall bulging—not sensitive or specific sign, as can be present in asymptomatic population
MR dynamic imaging
Asymmetrical focal protrusion of the posterior inguinal wall without a hernia

chronic stage before being recognized as affecting a player's or patient's performance and function. The primary treatment of choice for both acute and longstanding conditions in musculoskeletal groin injuries is an active treatment approach consisting of mobilization and exercise. Treatment is based on a systematic examination and an exact identification of the painful structure(s). This examination is based upon thorough history-taking and identification of the specific injury by palpation and isometric contractions where specific structures are isolated and specific pain responses are elicited. Diagnostic imaging can be relevant to exclude differential diagnoses, and in determining severe structural injury, such as complete and partial ruptures, but it is not advisable to be to obsessed with discrete imaging findings in isolation, as the exact understanding of such findings is not established. Therefore, treatments should primarily be based on clinical findings and their related dysfunctions, instead.

Guidelines for Choosing Among Nonoperative Treatments

The use of adjuvant modalities such as cortisone and more recently platelet enriched plasma injections has little support with scientific study and should be used with caution. Use of cortisone injections carries the same issues as other tendon injuries treated this way. It has a role in allowing short-term improvement but often the symptoms recur unless the "window" of reduced symptoms is used with rigorous rehabilitation to restore strength. An intraarticular anesthetic injection under radiological guidance can be helpful in determining the role any intraarticular hip pathology may be playing in the source of the patient's symptoms. Similarly, injection into the pubic symphysis can provide relief of symptoms where this joint is the main source of pain but repeated injections can lead to significant joint damage and increased symptoms.

The likelihood of a sustained improvement from any passive adjuvant modality is directly related to the regaining of strength and function.

- **Acute muscle-tendinous groin injuries**
  The acute treatment includes the Rest, Ice, Compression and Elevation protocol, then introducing gentle mobilization. Increasing range of motion can be commenced after the acute phase. Progression to isometric and then increasing resistance exercises can follow in a graduated regime. Sports-specific drills can be progressively commenced when isometric and eccentric strength is nearly normalized. Return to sport (competition) can be commenced as recovery improves and normal weekly training loads needs to be tolerated before return to competition is advisable.
- **Longstanding muscle-tendinous groin injury**
  For adductor-related groin pain, controlled static and dynamic exercises with focus on neuromuscular activation of the adductors, followed by increasing load and special emphasis on lengthening contractions, as well as challenging balance and co-ordination exercises has been shown to be very effective. These protocols are outlined in more detail in subsequent chapters
- **Iliopsoas-related groin pain/injury**
  The same principles are applied as with the adductor injuries. Systematic strengthening—including isometric, concentric and eccentric contractions—combined with a series of pelvic stabilization and balance

exercises are included in the treatment of the long-standing iliopsoas related groin pain. Stretching, massage, and trigger point stimulation for symptomatic relief might also be helpful, but is not the primary treatment. These injuries will have a similar favorable response as highlighted in the adductor related rehabilitation guidelines to a period of initial rest in acute injuries and then a structured strengthening program to allow full functional recovery and reduce the risk of re-injury.

- **Rectus abdominis related groin discomfort**
  Injuries that appear to involve the rectus insertion have restoration of strength after control of pain related symptoms as the ideal goal of treatment. Use of specific rectus abdominis strengthening exercises is an integral part of such a program.
- **Sports hernia**
  As the sportsman's hernia is an incipient hernia, rehabilitation should always be initiated first. A training program focusing on strength and coordination of the involved muscles provides an opportunity for the abdominal wall-lesion to heal. Using some of the exercises from the adductor-related program is of relevance as abdominal related injuries are often found in combination with adductor related injuries.
- **Stress fractures**
  A period of rest for 6 weeks and reintroduction of activity over a graduated 6-week period is a standard guideline for most stress fractures in the "adductor region" including compression sided fractures of the femoral neck and fractures of the pubic symphysis. Addressing all the contributing factors in these athletes including the diet, menstrual cycle irregularities and volume of exercise in the female athlete play an important role in this. Investigations of markers of bone metabolism including vitamin D levels are mandatory.

Preventing Groin Injury and Reinjury

Sport-specific prevention strategies to reduce the risk of groin injury in sport should include a specific focus on athletes with previous injury, and early identification of hip strength deficits. Total workload should also be specifically addressed and reduced in periods where athletes show clinical signs of hip and groin pain. In the off-season it is important for athletes to continue sports-specific activities and include strength-training exercises to stimulate muscle-tendinous health and repair.

Because previous groin injury is one of the best established risk factors, athletes displaying this risk-profile may benefit from specific attention by incorporating a specific exercise program focusing on the structures involved in their previous injury, and other related deficits, such as decreased eccentric strength, and possible lack of pelvic stability and coordination. The strength ratio between adductors and abductors seems to be important for injury prevention, as preseason strength training of the adductor muscles in ice hockey players ensuring an adductor/abductor strength ratio of 80% or more could decrease the number of adductor related groin injuries. A randomized treatment study including specific training of the adductor muscles (isometric, concentric, and eccentric), as well as exercises for the muscles related to the pelvis and torso, including 1022 male soccer players found that groin injuries were 31% less in the intervention group, compared with the control group. This difference was, however, not statistically significant, as the statistical power was too low to detect such a difference. As a possible groin injury reduction of 31% in a cohort of soccer players seems to be clinically meaningful, this program may be worthwhile to introduce in soccer teams where groin injuries constitute a significant problem.

Surgical Indications

The surgical management of groin injury depends primarily on accurately identifying the source of the pain. It cannot be emphasized too frequently that detailed clinical examination is the mainstay of making the correct diagnosis and supported by imaging studies. A subgroup of these patients have potentially multiple contributing pathologies and whether taking care of what seems the primary pathology will allow the others to recover or dealing with all apparent recalcitrant causes of pain and restriction is much argued about and seldom agreed on. For those patients with conditions identified that can be helped with nonoperative strategies outlined above, particularly adductor, rectus and psoas related problems, all patients should have undergone a supervised, rigorous, and appropriate rehabilitation schedule, as outlined in detail in following chapters, before surgery should be considered. Similarly the importance of a well-supervised, graduated, detailed progression of strengthening and proprioceptive retraining cannot be under emphasized as the key to a successful outcome. All treatment strategies, be they surgical or nonsurgical have the alleviation of pain to allow the restoration of strength as the primary goal.

Aspects of Clinical Decision Making When Surgery Is Indicated

- **Direct or indirect hernias**
  Thorough clinical examination will usually reveal a true direct or indirect hernia as the main contributing factor in a patient's symptoms. Referral for surgical treatment to an experienced laparoscopic surgeon is indicated and this condition can usually be managed around the competitive requirements of the athlete.
- **Fractures**
  Stress fractures on the tension (superior) side of the femoral neck require surgical management with compression fixation but are rare. Recalcitrant stress fractures of the femoral neck compression side or pubic ramus may require fixation usually with compression and rarely with bone grafting if sclerotic fracture ends are obvious on imaging. Again the key to identifying these diagnoses is an accurate history and physical examination and a screening bone scan if there is high index of suspicion but no obvious fracture on routine radiographs is probably the most sensitive and reliable imaging study.
- **Acute adductor tendon injury**
  As noted previously, repair of adductor tendon injuries are probably not indicated and it is often a difficult

tendon to get a robust repair. Protecting your repair is also difficult as only sustained bed rest is likely to remove tension on the repair while it heals. Unless avulsed with a surgically repairable piece of bone, surgery to repair adductor tears has been associated with significantly longer return to sport and greater risk of complications. There has been no evidence of greater strength loss without repair and as long as the structured program outlined in this section is followed, patients who have had tears treated non-operatively can achieve a similar outcome.

- **Adductor tendinopathy**
  A small subgroup of patients who have had adductor tendon pathology identified as their primary source of groin pain on history, pertinent physical examination findings and supportive imaging studies will continue to have restrictive symptoms despite attempting an appropriate rehabilitation and strengthening program. Surgical intervention in this group of patients provides a frequently rewarding relief of symptoms to allow them to successfully complete a rehabilitation program and regain strength and function. Temporary relief of symptoms with local anesthetic or cortisone, possibly injected under ultrasound control, is a helpful diagnostic adjuvant to support surgical treatment for both the clinician and the patient. It is relatively easily performed under direct vision and having the patient exercise immediately after use of any local and measuring improvement in a documented weakness in adductor strength is very helpful clinical information. Surgical release of the tendinous origin under direct visualization and possibly decompression of the obturator nerve have been associated with significant benefit in patients but long-term follow-up or randomized studies are not available in the literature.

Outcome Evaluation

Reliable, valid, and responsive outcome measures are important in the evaluation of patients with groin injury. The Copenhagen Hip And Groin Outcome Score (HAGOS) is developed specifically for younger patients with hip and groin pain. HAGOS is a patient-reported outcome measure employing five-item Likert scales. HAGOS consists of six subscales: pain, other Symptoms, physical function in daily living (ADL), Function in sport and recreation (Sport/Rec), participation in physical activities (PA), and hip-related quality of life (QOL). HAGOS can be used to assess groups and to monitor individuals, it is patient-administered and the format is user-friendly, and takes about 10 minutes to fill out. HAGOS is self-explanatory and can be administered in the waiting room or used as a mailed survey. HAGOS was found reliable, valid, and responsive in younger patients with hip and groin pain.

Isometric and eccentric strength is also important to evaluate in patients with groin injury. Reliable measures with hand-held dynamometry exist for hip adductors and hip flexors and can be used in the evaluation of when muscle strength is normalized in this region in the clinical setting. Pain during palpation and isometric maximal contraction are also good indicators of improvement in function. Different sports-specific activities, and range of motion measures, are other relevant measures that can be obtained and used for prospective evaluation of the recovery process of these injuries.

Evidence

Emery CA, Meeuwisse WH: Risk factors for groin injuries in hockey. *Med Sci Sports Exerc* 33:1423–1433, 2001.

This was a cohort study aimed at determining the level of off-season sport-specific activity, peak isometric adductor torque, and hip abduction flexibility that are predictive of groin or abdominal strain injury in the National Hockey League (NHL). The subjects were 1292 NHL players assessed during training camp. Estimated relative risks of injury were reported using six different exposures. Players who reported less than 18 sessions sport-specific training in the off-season were at greater than three times the risk of injury than those who did not (relative risk [RR]; 3.38 95% confidence interval [CI], 1.45 to 7.92). Players who reported previous history of this injury were at more than two times the risk of injury than those who did not (RR, 2.88; 95% CI, 1.33 to 6.26). Veterans were at greater than five times the risk of injury than rookies (RR, 5.69; 95% CI, 2.05 to 15.85). Peak isometric adductor torque, total abduction flexibility, and skate blade hollow measurement were not predictive of injury. Low levels of off-season sport-specific training and previous injury were identified as risks for groin injury at an elite level of hockey. (Level III evidence)

Engebretsen AE, Myklebust G, Holme E, et al: Intrinsic risk factors for groin injuries among male soccer players: A prospective cohort study. *Am J Sports Med* 38:2051–2057, 2010.

This was a prospective cohort study conducted to determine if risk factors for groin injuries among male soccer players could be identified. A total of 508 players representing 31 amateur teams were tested during the 2004 preseason for potential risk factors for groin injury through a questionnaire on previous injury and function score and a clinical examination of the groin. The total incidence of groin injuries was 0.6 injuries per 1000 playing hours, 0.3 injuries per 1000 training hours, and 1.8 injuries per 1000 match hours. Previous acute groin and weak adductor muscles as determined clinically were significantly associated with increased risk of groin injuries. A multivariate analysis based only on acute time-loss injuries revealed the 40-m sprint test and functional testing of the rectal abdominal muscles as significant risk factors. (Level III evidence)

Hölmich P, Larsen K, Krogsgaard K, et al: Exercise program for prevention of groin pain in football players: a cluster-randomized trial. *Scand J Med Sci Sports* 20:814–821, 2010.

A cluster-randomized trial including 55 football clubs representing 1211 players was performed. The clubs were randomized to an exercise program aimed at preventing groin injuries (n = 27) or to a control group training as usual (n = 28). The intervention program consisted of six exercises including strengthening (concentric and eccentric), coordination, and core stability exercises for the muscles related to the pelvis. Physiotherapists assigned to each club registered all groin injuries. Twenty-two clubs in each group completed the study, represented by 977 players. There was no significant effect of the intervention (HR = 0.69, 95% CI 0.40 to 1.19). The risk

of a groin injury was reduced by 31%, but this reduction was not significant. (Level I evidence)

Hölmich P, Uhrskou P, Ulnits L, et al: Effectiveness of active physical training as treatment for longstanding adductor-related groin pain in athletes: randomised trial. *Lancet* 353:439–443, 1999.

Sixty-eight athletes with long-standing (median 40 weeks) adductor-related groin pain—after examination according to a standardized protocol—were randomly assigned to active treatment (AT) or passive treatment (PT). The treatment period was 8 to 12 weeks. Four months after the end of treatment a standardized examination was done and 23 patients in the AT group and four in the PT group returned to sports without groin pain (odds ratio, multiple-logistic-regression analysis, 12.7 [95% CI 3.4 to 47.2]). AT with a program aimed at improving strength and coordination of the muscles acting on the pelvis, in particular the adductor muscles, is very effective in the treatment of athletes with long-standing adductor-related groin pain. (Level I evidence)

Thorborg K, Petersen J, Magnusson SP, et al: Clinical assessment of hip strength using a hand-held dynamometer is reliable. *Scand J Med Sci Sports* 20:493–501, 2010.

This was a normal subject based case control study that examined the absolute test-retest measurement variation concerning standardized strength assessments of hip abduction (ABD), adduction (ADD), external rotation (ER), internal rotation (IR), flexion (FLEX), and extension (EXT) using a hand-held dynamometer. Nine subjects (five males, four females), physically active for at least 2.5 hours a week, were included. Twelve standardized isometric strength tests were performed twice with a 1-week interval in between by the same examiner. When the maximum value of four measurements was used, test-retest measurement variation was below 10% in 11 of the 12 individual hip strength tests and below 5% in 5 of the 12 tests. Standardized strength assessment procedures of hip ABD, ER, IR, FLEX, with test-retest measurement variation below 5%, hip ADD below 6% and hip EXT below 8%, make it possible to determine even small changes in hip strength at the individual level using this method. (Level III evidence)

Tyler TF, Nicholas SJ, Campbell RJ, et al: The effectiveness of a preseason exercise program to prevent adductor muscle strains in professional ice hockey players. *Am J Sports Med* 30:680–683, 2002.

This was a prospective risk factor prevention study in 33 of 58 players from the same National Hockey League team who were identified as "at risk" on the basis of preseason hip adductor strength and participated in an intervention program. The program consisted of 6 weeks of exercises aimed at functional strengthening of the adductor muscles. There were 3 adductor strains in the 2 seasons subsequent to the intervention, compared with 11 in the previous 2 seasons (0.71 vs 3.2 per 1000 player-game exposures). A therapeutic intervention of strengthening the adductor muscle group appeared to be an effective method for preventing adductor strains in professional ice hockey players. (Level II evidence)

Zoga AC, Kavanagh EC, Omar IM, et al: Athletic pubalgia and the "sports hernia": MR imaging findings. *Radiology* 247:797–807, 2008.

This study was a retrospective review of MR imaging studies in 141 patients who had been referred because of groin pain were reviewed for findings including hernia, pubic bone marrow edema, secondary cleft sign, and rectus abdominis and adductor tendon injury. MR imaging findings were compared with surgical findings for 102 patients, physical examination findings for all 141 patients, and MR imaging findings in an asymptomatic control group of 25 men of similar age. Compared with surgery, MR imaging had a sensitivity and specificity, respectively, of 68% and 100% for rectus abdominis tendon injury and 86% and 89% for adductor tendon injury. Injury in each of these structures was significantly more common in the patient group than in the control group ($p < .001$). (Level IV evidence)

Multiple-Choice Questions

QUESTION 1. What epidemiological risk factor has not been shown to have an association with increased risk of adductor related groin injury?

A. Sex
B. Type of sport played
C. Playing at an elite level for greater than 12 months
D. Previous adductor injury

QUESTION 2. During which phase of kicking are the musculotendinous structures of the adductors at their greatest risk?

A. Plant
B. Swing
C. Contact
D. Follow through

QUESTION 3. What is the greatest associated risk factor on history and examination for sustaining a future groin injury?

A. Adductor strength
B. Age
C. Iliopsoas strength
D. Previous injury

QUESTION 4. What is the most relevant clinical indication of improvement from a muscle-tendinous groin injury with a structured rehabilitation program?

A. Pain-free single leg hop repetitions
B. Improved tolerance and duration of adductor stretching
C. Pain-free return to running
D. Pain-free maximal contraction and regains of muscle strength

Answer Key

QUESTION 1. Correct answer: **A**. (see Epidemiology)

QUESTION 2. Correct answer: **B** (see Pathophysiology: Intrinsic factors)

QUESTION 3. Correct answer: **A**. (see Clinical Presentation: Table 25-1)

QUESTION 4. Correct answer: **D**. (see Treatment)

NONOPERATIVE REHABILITATION OF LONGSTANDING GROIN INJURY

Kristian Thorborg, PT, MSportsphty, PhD, and Bruce Charles Twaddle, BHB, MBChB, FRACS

- The tendon of the insertion of the abdominals and origin of the adductors often can be involved in overuse and longstanding conditions that include groin pain as the cardinal symptom.
- Characteristically this pain is aggravated by loading of the musculotendinous tissues with some pain or discomfort at rest that may be initially eased by activity only to return and with increased intensity once the activity is increased or after the activity has ceased.
- The iliopsoas muscle can also be injured through repetitive overuse. The overused iliopsoas tendon will sometimes appear with a spindle shape on ultrasound examination, near the insertion point on the lesser trochanter minor.
- One high-quality clinical randomized trial of longstanding adductor-related groin pain has described a specific exercise program found to be highly effective in the treatment of this condition.[1] The exercise program consists of two phases:
  - The first phase is a period of 2 weeks of careful static and dynamic exercises to teach the patient to reactivate the adductor muscles. In most cases the athlete with adductor-related groin pain has difficulties activating these muscles, probably as a result of pain and disuse.
  - In the second phase, the exercises are gradually more demanding; heavier resistance training as well as challenging balance and co-ordination exercises are added.
- Nonoperative treatment of longstanding groin injury consists of active exercises performed at least three times a week for 8 to 12 weeks. This regimen can be done alone or in a group of two to four patients exercising according to the instructions and supervision of a physiotherapist. The duration of each individual training session is about 90 minutes. Patients with longstanding groin injury are told to do the exercises from module I on the days in between the treatment days.
- Patients do not usually receive any other treatment for the groin pain before the final follow-up. No athletic activity is allowed during the treatment period. Patients are allowed to ride a bicycle or swim if it does not cause any pain.
- The adductor exercise program is performed three times a week and the exercises from module I are done on the days in between the treatment days. The total length of the exercise-training period is between 8 and 12 weeks. Sports activities are not allowed in the treatment period. Riding a bicycle is allowed if it does not cause any pain.
- After 6 weeks, running is allowed as long as it does not provoke any groin pain.
- The exercise rehabilitation program is stopped when neither the exercise program nor the jogging causes any pain. The athlete is then allowed to increasingly progress to demanding sports-specific training towards final sports participation.

Exercise Treatment for Athletes With Longstanding Adductor-Related Groin Pain

Phase I: Muscle Activation (weeks 0 to 2)

- Static adduction against soccer ball placed between feet when lying supine; each adduction 30 seconds, 10 repetitions
- Static adduction against soccer ball placed between knees when lying supine (Figure 25-5); each adduction 30 seconds, 10 repetitions
- Abdominal sit-ups both in straightforward direction and in oblique direction; 5 series of 10 repetitions
- Combined abdominal sit-up and hip flexion, starting from supine position and with soccer ball placed between knees (folding knife exercise); 5 series of 10 repetitions
- Balance training on wobble board for 5 minutes
- One-foot exercises on sliding board (Figure 25-6), with parallel feet as well as with 90° angle between feet; five sets of 1-minute continuous work with each leg, and in both positions

Phase II: Muscle Strengthening and coordination (weeks 3+)

Phase II exercises were done twice at each training session.

- Leg abduction and adduction exercises lying on side; 5 series of 10 repetitions of each exercise

FIGURE 25-5. Adduction exercise with a soccer ball between the knees lying supine.

FIGURE 25-6. Adduction exercises on a sliding board.

- Low-back extension exercises prone over end of couch; 5 series of 10 repetitions
- One-leg weight-pulling (can include an elastic band) abduction/adduction standing (Figure 25-7); 5 series of 10 repetitions for each leg
- Abdominal sit-ups (Figure 25-8) both in straightforward direction and in oblique direction; 5 series of 10 repetitions
- One-leg coordination exercise flexing and extending knee and swinging the arms in same rhythm (cross country skiing on one leg); 5 series of 10 repetitions for each leg
- Training in sideward motion on a "Fitter" (rocking base curved on top and bottom; user stands on platform that rolls laterally on tracks on top of rocking base) for 5 minutes
- Balance training on wobble board for 5 minutes

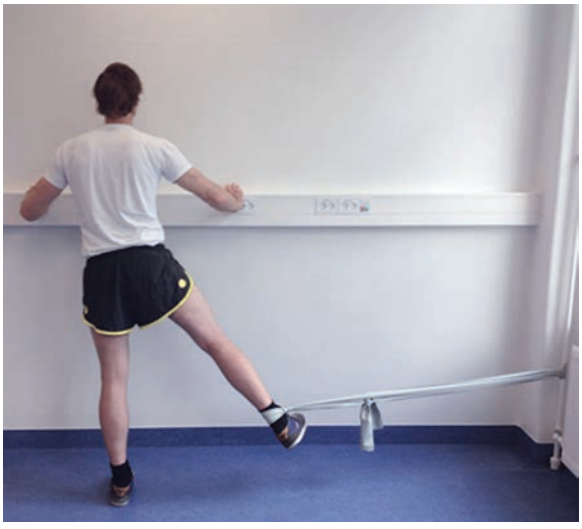

FIGURE 25-7. Elastic band "pulling" exercise to strengthen the adductor muscles.

FIGURE 25-8. Abdominal strengthening exercises using a "Swiss" ball.

- Skating movements on sliding board; five times 1-minute continuous work

Exercise Treatment for Athletes with Longstanding Iliopsoas- and Abdominal-Related Groin Pain

- The authors preferred an initial treatment suggestion for athletes with longstanding iliopsoas- and abdominal-related groin pain following the same principles as with the adductor-related program of systematic strengthening—including both isometric, concentric and eccentric contractions—combined with a series of pelvic stabilization and balance exercises.
- A bias toward specific and injured structures such the iliopsoas and abdominals (rectus abdominis for rectus abdominis tendinopathy or obliques and transversus abdominis for sports hernia) should be included in programs for athletes with these problems.
- Since the sports hernia by nature is an incipient hernia, often involving the abdominal wall (inguinal canal and conjoined tendon injury), rehabilitation should always be tried as a first step. A regular hernia has not yet developed, and a training program including pelvic strengthening and coordination exercises might provide the abdominal wall-lesion a chance to heal. These suggested treatments are, however, not yet supported by scientific evidence.

Supplementary Treatment

- Stretching exercises for the adductor muscle in patients with longstanding adductor-related groin pain is not recommended. The program nonetheless has showed to have the same increase of hip-joint range of motion as a passive treatment protocol that includes stretching.
- Usually, pain is initially a limiting factor to maximum contraction and range of motion activities, but, as the

muscle coordination and strength increased and the groin pain usually decreases and the load and the range of motion is also increased. Tolerance towards an increased range of motion might thereby be achieved.
- Two examples of this type of exercise are performed on the sliding board (see Figure 25-6) and the weight-pulling exercise (see Figure 25-7). Stretching of the adductor muscles in athletes with adductor-related groin pain is not recommended because this may stress the insertions at the pubic bone, which sometimes worsen the injury.
- NSAID and steroid injections for athletes with musculotendinous overuse groin injury are generally not recommended, before or during exercise rehabilitation. In our experience, there is no long-term beneficial effect of these modalities, and if the NSAID or injections affect the pain temporarily, it only makes it more difficult to monitor the training program needed to cure the groin pain. Rarely, NSAID or steroid injections can be used as an adjunctive treatment in patients who have so much pain during training that usual muscle activation and progress with increased symptom relief during the first initial 6 weeks is not possible.

Criteria for Abandoning Nonoperative Treatment and Proceeding to Surgery or more Intense Intervention

- No improvement in musculotendinous symptoms during sporting activity after adhering to a 8 to 12 weeks exercise program, exercising 3 times a week (90 minutes each session)
- Persisting symptoms that indicate subsequent involvement of hip joint, symphysis joint or inguinal canal/conjoined tendon lesion, which do not respond to the exercise program

Specific Criteria for Return to Sports Participation

- No pain on palpation of adductor longus tendon/insertion

FIGURE 25-9. Dynamic core/abdominal and adductor strengthening exercise.

- No pain on adductor longus tendon/insertion on bilateral isometric contraction with straight legs
- No pain during sporting activity

Preventing Reinjury

- To prevent recurrence of previous groin injuries, treatment aiming at healing the structural damage should be combined with the continuance of the exercise program to maintain strength and reduce the risk of recurrence.
- In another randomized controlled trial including 1022 male soccer players, the possible preventive value of such an exercise program has been examined.[2] The exercises consisted of the following:
  - Isometric adduction exercises, squeezing a soccer ball between the feet and between the knees in the supine position
  - Dynamic adductor and abductor strengthening exercises (concentric and eccentric) (Figure 25-9) done with a partner
  - Coordination of the hip joint related muscles and the muscles of the pelvis and torso using a dynamic exercise combining sit-up, hip flexion and adduction
  - Dynamic proprioceptive exercise stimulating both concentric and eccentric strength, and utilizing the principles of pelvic and core coordination and strength

TIMELINE 25-1: **Nonoperative Treatment of Longstanding Adductor-Related Groin Pain**

PHASE I (weeks 1 to 2)	PHASE II (weeks 3 to 5)
• Adductor muscle activation exercises initiated • Abdominal and hip flexor strengthening initiated • Gentle sliding exercises in abduction and adduction on smooth surface • Balance exercises • Passive stretching exercise (psoas) • Walking, aerobic fitness and strength training for upper extremity as tolerated	• Progressive adductor strengthening continued • Progressive core/abdominal strengthening program initiated • Sliding exercises in abduction and adduction on smooth surface • Balance and coordination exercises • Passive stretching exercise (psoas) • Walking, aerobic fitness and strength training for upper extremity as tolerated

  - Stretching exercises for the iliopsoas muscle given the nature of secondary involvement of this muscle in the presence of groin pain
- The trial found groin injuries were 31% less in the intervention group, compared to the control group, but the difference was not statistically significant, as the statistical power was too low to detect such a difference. Despite the inconclusiveness of this study, the 31% reduction in the risk of getting a groin injury would be a considerable advantage, which probably would make it worthwhile for the soccer players to do the program.
- Simple measures of symptoms, pain, and sporting function can help to monitor the athlete after full return to sport. The Copenhagen Hip and Groin Outcome Score (HAGOS) was developed specifically for younger patients with hip and groin pain.[3] This questionnaire refers to the patient's hip and/or groin pain and is therefore also useful in patients with musculoskeletal problems who are treated with exercises or other conservative interventions.
- HAGOS consists of six subscales:
  - Pain
  - Symptoms
  - Physical function in activities of daily living (ADLs)
  - Function in sport and recreation (Sport/Rec)
  - Participation in physical activities (PA)
  - Hip-related quality of life (QOL)
- The past week is taken into consideration when answering the questions. Standardized answer options are given five Likert boxes and each question gets a score from 0 to 4. A normalized score (100 indicating no symptoms and 0 indicating extreme symptoms) is calculated for each subscale. The result can be plotted as an outcome profile. HAGOS is meant to be used over both short and long time intervals. HAGOS can be used to assess groups and to monitor individuals. It is patient-administered and the format is user friendly. It takes about 10 minutes to fill out. HAGOS is self-explanatory and can be administered in the waiting room or used as a mailed survey.
- HAGOS was found to be reliable, valid and responsive in younger patients with hip and groin pain. Median scores close to maximum are present in healthy athletes, and reference values have shown that scores below 75 points seem to indicate problems with the hip and groin in most of the subscales. HAGOS can be used as a monitoring tool for athletes with hip and groin problems to assess the severity and monitor the load of these athletes in relation to their scores as this may be an effective way of reducing the risk of recurrence.

Evidence

Hölmich P, Larsen K, Krogsgaard K, et al: Exercise program for prevention of groin pain in football players: a cluster-randomized trial. *Scand J Med Sci Sports* 20:814–821, 2010.

A cluster-randomized trial including 55 football clubs representing 1211 players was performed. The clubs were randomized to an exercise program aimed at preventing groin injuries (n = 27) or to a control group training as usual (n = 28). The intervention program consisted of six exercises including strengthening (concentric and eccentric), coordination, and core stability exercises for the muscles related to the pelvis. Physiotherapists assigned to each club registered all groin injuries. Twenty-two clubs in each group completed the study, represented by 977 players. There was no significant effect of the intervention (HR = 0.69, 95% CI 0.40 to 1.19). The risk of a groin injury was reduced by 31%, but this reduction was not significant. (Level I evidence)

Hölmich P, Uhrskou P, Ulnits L, et al: Effectiveness of active physical training as treatment for long-standing adductor-related groin pain in athletes: randomised trial. *Lancet* 353:439–443, 1999.

Sixty-eight athletes with long-standing (median 40 weeks) adductor-related groin pain—after examination according to a standardized protocol—were randomly assigned to active treatment (AT) or passive treatment (PT). The treatment period was 8 to 12 weeks. Four months after the end of treatment a standardized examination was done and 23 patients in the AT group and four in the PT group returned to sports without groin pain (odds ratio, multiple-logistic-regression analysis, 12.7 [95% CI 3.4 to 47.2]). AT with a program aimed at improving strength and coordination of the muscles acting on the pelvis, in particular the adductor muscles, is very effective in the treatment of athletes with long-standing adductor-related groin pain. (Level I evidence)

Thorborg K, Hölmich P, Christensen R, et al: The Copenhagen Hip and Groin Outcome Score (HAGOS): development and validation according to the COSMIN checklist. *Br J Sports Med* 45:478–491, 2011.

TIMELINE 25-1: Nonoperative Treatment of Longstanding Adductor-Related Groin Pain (Continued)

PHASE III (weeks 6 to 8)	PHASE IV (weeks 9 to 12)	PHASE V (weeks 13+)
• Progressive adductor strengthening continued • Progressive core/abdominal strengthening program continued • Sliding exercises in abduction and adduction on smooth surface • Running, aerobic fitness and strength training for upper extremity as tolerated • Balance and coordination exercises • Passive stretching exercise (psoas)	• Gradual return to sport if tolerated • Progressive adductor strengthening continued • Progressive core/abdominal strengthening program continued • Sliding exercises in abduction and adduction on smooth surface • Running as tolerated • Aerobic fitness and strength training for upper and lower extremity as tolerated • Balance and coordination exercises • Passive stretching exercise (psoas) • Sport-specific exercises	• Gradual or full return to sport if tolerated • Maintenance of active and passive range of motion • Maintenance of adductor/hip flexor and core/abdominal strength • Maintenance of balance and coordination.

In a prospective study the purpose was to develop and validate a new PRO (HAGOS) in accordance with the COnsensus-based Standards for the selection of health Measurement INstruments (COSMIN) recommendations for use in young to middle-aged, physically active patients with longstanding hip and/or groin pain. Test-retest reliability was substantial, with intraclass correlation coefficients ranging from 0.82 to 0.91 for the six subscales of HAGOS. Construct validity and responsiveness were confirmed. HAGOS has adequate measurement qualities for the assessment of symptoms, activity limitations, participation restrictions and QOL in physically active, young to middle-aged patients with longstanding hip and/or groin pain. (Level II evidence)

Multiple-Choice Questions

QUESTION 1. Exercise treatment of longstanding groin injury usually takes?

A. 2 to 3 weeks
B. 3 to 4 weeks
C. 5 to 8 weeks
D. 8 to 12 weeks

QUESTION 2. What is the duration for a single session for the exercise program for treatment of longstanding groin injury?

A. 30 minutes
B. 60 minutes
C. 90 minutes
D. 120 minutes

QUESTION 3. When is pain-free running allowed in exercise treatment of longstanding groin injury?

A. Immediately
B. 2 weeks
C. 6 weeks
D. 12 weeks

QUESTION 4. What are the criteria for return to full sports participation?

A. No pain during daily activities
B. Normalized muscle strength
C. No pain during sport
D. No pain on palpation of adductor longus tendon/insertion and no pain of adductor longus tendon/insertion on bilateral isometric contraction with straight legs and no pain during sporting movements

QUESTION 5. How can groin symptoms in athletes be measured and monitored?

A. By using the HAGOS
B. By using a visual analog scale
C. By palpation
D. By a squeeze test

Answer Key

QUESTION 1. Correct answer: **D** (see Guiding Principles)

QUESTION 2. Correct answer: **C** (see Guiding Principles)

QUESTION 3. Correct answer: **C** (see Guiding Principles and Phase III)

QUESTION 4. Correct answer: **D** (see Specific Criteria for Return to Sports Participation)

QUESTION 5. Correct answer: **A** (see Preventing Reinjury)

POSTOPERATIVE REHABILITATION AFTER ADDUCTOR RELEASE

Bruce Charles Twaddle, BHB, MBChB, FRACS, and Kristian Thorborg, PT, MSportsPhty, PhD

Indications for Surgical Treatment

- Reliable history and examination findings to support adductor tendonosis as the likely cause of the groin pain (see previous section Clinical Presentation).
- Confirmed supporting changes on an imaging modality (MRI, Ultrasound, SPECT bone scan, and/or favorable response to local anesthetic injection and "stress test")
- Failure of a supervised appropriate rehabilitation program (see previous section Surgical Indications).

Brief Summary of Surgical Treatment

Major Surgical Steps

- Positioning of patient supine in "frog leg" position
- Appropriate draping of the groin area
- Palpation and identification of adductor longus tendon as it originates from the inferior aspect of the pubic ramus
- Transverse groin crease incision
- Split superficial fascia longitudinally in the line of the adductor longus
- Identify the tendon of the adductor longus as it originates from the pubis (Figure 25-10)
- Transversely divide the tendinous part of the adductor longus as close to the origin as possible
- Debride any abnormal tendon or scar tissue
- Careful hemostasis
- Close the superficial fascia
- Close the skin incision
- Infiltrate local anesthetic
- Apply a small padded dressing with a waterproof covering

Factors That May Affect Rehabilitation

Anesthetic

- No specific anesthetic issues are likely to affect rehabilitation apart from those related to any unanticipated complication.

Surgical

- In patients with neuralgic type symptoms affecting the anterior division of the obturator nerve, some authors recommend exposure and neurolysis of this nerve after the adductor longus has been released.
- In patients with multiple suspected pathologies, other surgical procedures may be required. Such procedures as arthroscopic treatment of suspected symptomatic femoro-acetabular impingement (FAI) may be considered, as may surgery for associated Pubic Symphysis pathology. Invariably any other surgical procedure will have a more prolonged period of initial restricted weight bearing and mobilization.

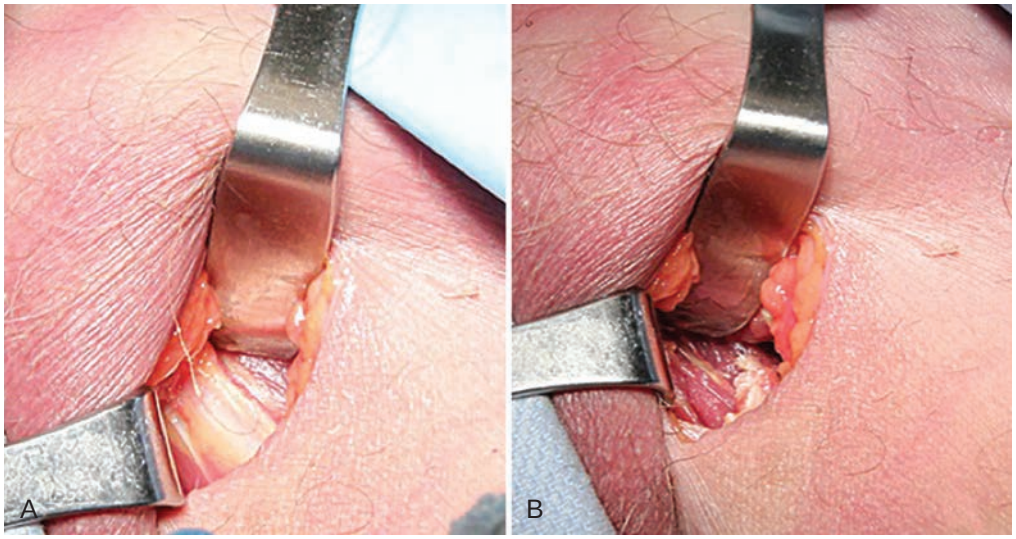

FIGURE 25-10. Surgical exposure and release of the adductor longus tendon. **A,** Transverse groin incision with longitudinal release of the fascia and exposure of the muscle and tendon at its origin off the pelvis. **B,** Release of the tendinous part only leaving the muscle fibers intact.

Other Surgical Techniques and Options

Before Surgery: Overview of Goals, Milestones, and Guidelines[1]

GUIDING PRINCIPLES OF POSTOPERATIVE REHABILITATION

- Initial limited activity and exercise to allow uncomplicated healing of the incision.
- Begin passive range exercises and active range of motion eliminating gravity until mobilizing comfortably off crutches.
- Introduce static adduction muscle activating exercises and controlled motion exercises without full weight bearing on a sliding board, as well as core/abdominal strength and balance/coordination exercises.
- Progress to strengthening exercises including concentric, isometric, and eccentric actions, with more sophisticated movement exercises incorporating eccentric adductor activation, continued core/abdominal and balance/coordination exercises.
- Sport-specific exercises and high-intensity training in specific focused activities

Phase I: Immediate Postoperative Period (days 0 to 14)

Clinical Pearls

Avoid infection: Due to the nature of the region where adductor release surgery is performed, use of removable nylon sutures and careful attention to groin and wound hygiene will prevent an early wound infection slowing beginning more active rehabilitation

Goals

Protection

- The patient can begin weight bearing with crutches as soon as possible and can progress to using one crutch then no crutches as pain allows over the first 10 days.

Management of Pain and Swelling

- Long acting local anesthetic is infiltrated into the surgical site after wound closure and combined use of nonnarcotic oral analgesia and an oral antiinflammatory agent if tolerated is usually all that is required. Avoid use of antiinflammatory medication in the first 2 weeks if possible as these impair healing processes
- Attention to ensuring all bleeding sites are cauterized prior to wound closure is the most important part of controlling swelling.

Techniques for Progressive Increase in Range of Motion

Manual Therapy Techniques

- Passive range of motion exercises for maintaining hip range of motion with cautious introduction of passive assisted abduction are appropriate.

Stretching and Flexibility Techniques for the Musculotendinous Unit

- Stretching/flexibility techniques for the musculotendinous unit: Use of the sliding board to allow the patient to begin some active abduction/adduction exercises lying supine to remove the resistance of gravity can be commenced after the first 3 to 4 days using the patient's own comfort as a guide.

Other Therapeutic Exercises

- Core/abdominal exercises with focus on isometric and concentric contractions can begin at the same time as the patient is comfortable enough to begin supine sliding board exercises (4 to 5 days post surgery).
- General body strength and conditioning can continue as pain allows.

Activation of Primary Muscles Involved in Injury Area or Surgical Structures

- Use of the sliding board to allow the patient to begin some active ab/adduction exercises lying supine to

TIMELINE 25-2: **Postoperative Rehabilitation after Open Adductor Longus Release**

PHASE I (weeks 1 to 2)	PHASE II (weeks 3 to 4)
• Crutches • PT modalities • Gentle supine sliding board exercises • Static adduction muscle activating exercises and controlled motion • Core/abdominal activation exercises can begin • TBS/TAS/TLS activities as recommended and tolerated	• Reduce use of crutches • PT Modalities • Continue sliding board exercises • Core/abdominal strengthening program initiated • Graduated resisted adductor strengthening • TB/TAS/TLS activities as recommended and tolerated

[1]*Prehabilitation, if appropriate, is described in the Nonoperative Rehabilitation section of this chapter.*

remove the resistance of gravity can be commenced after the first 3 to 4 days using the patient's own comfort as a guide.

Sensorimotor Exercises

- Commencing heel-to-toe weight bearing pattern with crutches, progressing to one then no crutches should be part of early rehabilitation.
- Balance/coordination exercises with single leg balance can commence on the nonoperative leg.

Open and Closed Kinetic Chain Exercises

- Use of the sliding board with the patient supine as noted above

Milestones for Progression to the Next Phase

- Establish a heel-to-toe walking pattern without crutches.
- Abduct comfortably beyond 20 degrees on the sliding board.

Phase II: Intermediate Postoperative Phase (weeks 3 to 4)

Clinical Pearls

Use of a low resistance sliding board/slippery surface is an ideal tool to allow initial range of motion activities and exercises with the patient lying supine in the early phase of postoperative rehabilitation and recovery. More sophisticated "skating motion" and upright exercises can be introduced utilizing the same apparatus as rehabilitation progresses and becomes more sophisticated. Ideally, the patient will have had a preoperative program that utilized these exercises so that this kind of training has already taken place to ensure these exercises are done correctly

Goals

- Comfortable heel-to-toe walking pattern without crutches
- Introduction of sliding board abduction/adduction exercises lying supine
- Progression to standing abduction/adduction exercises and elastic band type resistance strengthening exercises
- One foot sliding exercises, without weight bearing, on the sliding board as comfort allows

Protection

- Treatment for pain/analgesia: Oral analgesics as tolerated; avoid antiinflammatory medication as it can slow tendon healing in the first 4 weeks.

Management of Pain and Swelling

- Decrease swelling as necessary with ice, rest, analgesia.

Techniques for Progressive Increase in Range of Motion

Manual Therapy Techniques

- Continued increase in passive assisted range of motion exercises of the hip working particularly on range of abduction using pain as a guide

Soft Tissue Techniques

- As required for wound healing and scar formation treatment with massage, taping and application of vitamin E or evening primrose oil-based topical applications

Stretching and Flexibility Techniques for the Musculotendinous Unit

- Use of the sliding board to allow the patient to continue active abduction/adduction exercises lying supine. Progression to standing sliding board exercises can commence.

TIMELINE 25-2: **Postoperative Rehabilitation after Open Adductor Longus Release** (Continued)

PHASE III (weeks 5 to 8)	PHASE IV (weeks 9 to 12)	PHASE V (weeks 13 to 52)
• Running and striding activity begins • PT modalities as needed • Assisted adductor and hip flexor stretching program • Continued resisted adductor strengthening • TBS/TAS/TLS activities as recommended and tolerated • Progressive abdominal/core strengthening exercises • Standing sliding board exercises • Plyometric exercises begin • Introduction of sport-specific training	• Gradual return to full training and sport participation • PT modalities as needed • Progressive strengthening adductor and abductor muscles with elastic band • Active and passive stretching exercises • Continued abdominal/core strengthening • Increased plyometric and change of direction exercise program • Sport-specific training • TBS/TAS/TLS activities as recommended and tolerated • Sport-specific exercises can be tailored to the individuals needs	• Full training and sport participation • PT modalities as needed • Maintenance of abdominal/core strengthening • Maintenance program of strengthening and sliding exercises • TBS/TAS/TLS activities as recommended and tolerated • Sport-specific exercises can be tailored to the individuals needs

Other Therapeutic Exercises

- Reintroduction of other strengthening and sport-specific strengthening as possible, avoiding active resistance or secondary firing of the adductor muscles.
- Unlimited upper body strength work is possible

Activation of Primary Muscles Involved in Injury Area or Surgical Structures

- Static adduction against soccer ball placed between feet when lying supine; each adduction 30 seconds, ten repetitions
- Static adduction against soccer ball placed between knees when lying supine (see Figure 25-5); each adduction 30 seconds, 10 repetitions
- Abdominal sit-ups both in straightforward direction and in oblique direction; 5 series of 10 repetitions
- Combined abdominal sit-up and hip flexion, starting from supine position and with soccer ball placed between knees (folding knife exercise); 5 series of 10 repetitions
- One-foot exercises on sliding board, with parallel feet as well as with 90° angle between feet (see Figure 25-6); five sets of 1-minute continuous work with each leg, and in both positions.

Sensorimotor Exercises

- Balance training on wobble board for 5 minutes

Open and Closed Kinetic Chain Exercises

- Exercises as noted above

Techniques to Increase Muscle Strength, Power, and Endurance

- One-leg elastic band abduction/adduction standing (see Figure 25-7); for each leg using progressive exercise principles. Progress from 30 to 20 repetitions maximum.
- Neuromuscular dynamic stability exercises

Neuromuscular Dynamic Stability Exercises

- Skating movements on sliding board; five times 1 min continuous work.

Plyometrics

- Introduced in the next phase

Functional Exercises

- Introduced in the next phase

Sport-Specific Exercises

- Introduced in the next phase

Milestones for Progression to the Next Phase

- Pain-free heel-to-toe walking pattern
- Comfortable with supine sliding board exercises in full ROM
- Able to tolerate resisted adductor strengthening exercises from 30 to 20 RM
- Ready for introduction of walking and jogging

Phase III: Late Postoperative Phase (weeks 5 to 8)

Clinical Pearls

Use of an elastic band exercise program helps specifically gain adductor functional strength recovery on both the standing and the moving leg. The muscle activity is less but still substantial on the standing leg, and training can be progressed by increased resistance and by changing from standing to moving leg. Ten repetition maximum with similar resistance as performed on the uninjured leg needs to be performed before progressing into more sport-specific training.

Goals

- Increase strength with resistance using repetition maximum (20 to 10 RM) and dynamometer as a guide
- Introduction of upright sliding dynamic exercise
- Initiating change of direction exercises
- Progression to sport-specific training and exercises

Management of Pain and Swelling

- Oral analgesia as required

Techniques for Progressive Increase in Range of Motion

Manual Therapy Techniques

- As felt necessary with passive assisted and active range of motion exercises

Soft Tissue Techniques

- Local deep tissue massage as required

Stretching and Flexibility Techniques for the Musculotendinous Unit

- Introduce adductor stretching as part of the rehab and include general hip stretches, in particular rectus femoris stretches

Other Therapeutic Exercises

- General conditioning in preparation for return to sport with reintroduction of a sport-specific strengthening program for the other muscle groups as per their usual strength training
- Low-back extension exercises prone over end of couch; 5 series of 10 repetitions
- Abdominal sit-ups both in straightforward direction and in oblique direction (see Figure 25-8); 5 series of 10 repetitions

Activation of Primary Muscles Involved in Injury Area or Surgical Structures

- Muscle activation exercises should be well advanced as discussed in previous sections working towards a reintroduction to sport-specific training

Sensorimotor Exercises

- Advanced sensorimotor retraining can be introduced including single leg landing balance exercises

Open and Closed Kinetic Chain Exercises

- Leg abduction and adduction exercises lying on side; 5 series of 10 repetitions of each exercise
- One-leg weight-pulling abduction/adduction standing; 5 series of 10 repetitions for each leg

Techniques to Increase Muscle Strength, Power, and Endurance

- Progression of strength and power exercises modulated by the individual patients symptoms

Neuromuscular Dynamic Stability Exercises

- One-leg coordination exercise flexing and extending knee and swinging arms in same rhythm (cross-country skiing on one leg); 5 series of 10 repetitions for each leg

Plyometrics

- Introduction of plyometric exercise can begin during this rehabilitation period as long as hand-held dynamometer adduction strength is 80% to 90% of the normal side

Functional Exercises

- Skating movements on sliding board; five times 1-minute continuous work
- Training in sideways motion on a sliding board type area for 5 minutes

Sport-Specific Exercises

- Introduction of sport-specific exercises (see next phase) can begin during this rehabilitation period as long as hand-held dynamometer adduction strength is 80% to 90% of the normal side

Milestones for Progression to the Next Phase

- Hip adduction strengthening with ten repetition maximum and of similar resistance as performed on the uninjured leg needs to be performed before progressing into more sport-specific training.
- Minimal pain with progression of activity with symptoms the following day being the most accurate guide as to how well increases in rehabilitation exercises and duration were tolerated.

Phase IV: Late Oostoperative Phase (weeks 9 to 12)

Clinical Pearls

Use of the hand-held dynamometer as an accurate measure of strength recovery using the nonoperated side as a guide allows progression of more plyometric type activities and return to sport-specific training to be based on clear, accurate milestones. Reduced adductor strength after tenotomy is to be expected but adductor strength recovery should be 80% to 90% of nonoperated side before sport-specific progression.

Goals

- Adduction strength 80% to 90% of the uninjured side (using a hand-held dynamometer if available)
- Full progression to sport-specific training
- Return to play using performance and comfort in training as a guide
- Introduction of maintenance exercises to reduce risk of recurrence

Protection

- Not required

Management of Pain and Swelling

- Oral analgesia as required

Techniques for Progressive Increase in Range of Motion

Manual Therapy Techniques

- As necessary using passive assisted and active range of motion exercises

Soft Tissue Techniques

- Local deep tissue massage as required

Stretching and Flexibility Techniques for the Musculotendinous Unit

- Continue active adductor flexibility and include passive hip flexor stretches as return to sport begins

Other Therapeutic Exercises

As noted previously the following exercises are seen as being useful:

- Low-back extension exercises prone over end of couch; 5 series of 10 repetitions.
- Abdominal sit-ups both in straightforward direction and in oblique direction; 5 series of 10 repetitions. Progressed into abdominal sit-ups performed on exercise ball, including eccentric, isometric and concentric contractions of abdominals from near full active lumbar extension over the ball into near full active lumbar flexion.

Sensorimotor Exercises

- Advanced sensorimotor retraining continue including single leg landing balance exercises

Open and Closed Kinetic Chain Exercises

- Both open and closed kinetic chain strengthening are unrestricted

Techniques to Increase Muscle Strength, Power, and Endurance

- One-leg elastic band abduction/adduction standing; 8 to 12 RM
- Progression of strength and power exercises modulated by the individual patients symptoms

Neuromuscular Dynamic Stability Exercises

- One-leg coordination exercise flexing and extending knee and swinging arms in same rhythm (cross-country skiing on one leg); 5 series of 10 repetitions for each leg.

Plyometrics

- Continued plyometric exercise during this rehabilitation period as long as hand held dynamometer adduction strength is 80% to 90% of the normal side

Functional Exercises

- Skating movements on sliding board; five times 1 min continuous work.
- Reintroduction of running, sprinting and kicking training and progression if part of specific sport requirements

Sport-Specific Exercises

- Progression of sport-specific exercises continues during this rehabilitation period as long as hand-held dynamometer adduction strength remains at 80% to 90% of the normal side with minimal pain.
- Reintroduction of running, sprinting, and kicking as part of training progression

Milestones for Progression to the Next Phase

- Hand-held dynamometer adduction strength is still 80% to 90% of the normal side, also in days after plyometric and sport-specific drills
- Minimal pain with progression of activity with symptoms the following day being the most accurate guide as to how well increases in rehabilitation exercises and duration were tolerated

Phase V: Late Postoperative Phase (weeks 13 to 52)

Goals

- Unrestricted activity and training and return to full participation
- Maintenance of a preventative strengthening and stretching program

Protection

- Not required

Management of Pain and Swelling

- Oral analgesia as required

Techniques for Progressive Increase in Range of Motion

Manual Therapy Techniques

- As felt necessary with passive assisted and active range of motion exercises

Soft Tissue Techniques

- Local deep tissue massage as required

Stretching and Flexibility Techniques for the Musculotendinous Unit

- Continue active adductor flexibility and include passive hip flexor stretches as return to sport begins

Other Therapeutic Exercises

As noted previously the following exercises are seen as being useful:

- Low-back extension exercises prone over end of couch; 5 series of 10 repetitions.
- Abdominal sit-ups both in straightforward direction and in oblique direction; 5 series of 10 repetitions. Progressed into abdominal sit-ups performed on exercise ball, including eccentric, isometric and concentric contractions of abdominals from near full active lumbar extension over the ball into near full active lumbar flexion.

Sensorimotor Exercises

- Advanced sensorimotor retraining continue including single leg landing balance exercises

Open and Closed Kinetic Chain Exercises

- Both open and closed kinetic chain strengthening are unrestricted

Techniques to Increase Muscle Strength, Power, and Endurance

- One-leg elastic band abduction/adduction standing; 8 to 12 RM
- Progression of strength and power exercises modulated by the individual patients symptoms

Neuromuscular Dynamic Stability Exercises

- One-leg coordination exercise flexing and extending knee and swinging arms in same rhythm (cross-country skiing on one leg); 5 series of 10 repetitions for each leg

Plyometrics

- Continued plyometric exercise during this rehabilitation period as long as hand-held dynamometer adduction strength is 80% to 90% of the normal side

Functional Exercises

- Skating movements on sliding board; five times 1-minute continuous work
- Reintroduction of running, sprinting, and kicking training and progression if part of specific sport requirements

Sport-Specific Exercises

- Progression of sport-specific exercises continues during this rehabilitation period as long as hand-held dynamometer adduction strength remains 80% to 90% of the normal side with minimal pain.
- Reintroduction of running, sprinting, and kicking as part of training progression

Milestones for Progression to Advanced Sport-Specific Training and Conditioning

- Hand-held dynamometer adduction strength is still 80% to 90% of the normal side, also in days after plyometric and sport-specific drills, training and game/competition-related activity.
- Minimal pain with progression of activity with symptoms the following day being the most accurate guide as to how well increases in rehabilitation exercises and duration were tolerated.

Criteria for Return to Sport

General

- Some discomfort at time of returning to sport is acceptable as long as there is no pain and full pain-free training participation is possible the following day
- Monitoring of adductor strength with the hand-held dynamometer ensuring strength is comparable (within 90%) of the nonoperated side
- Symptom-free cutting and change of direction drills as part of practice and participation
- Able to maximally sprint, cut, and kick a ball if required as part of sport-specific training with no discomfort and/or decreased performance in keeping with the athletes preinjury performance

Sport-Specific

- Soccer is covered in other parts of the section.
- Ice hockey and skating sports:
  - Pain-free motion on the sliding board doing upright skating type exercises; graduated reintroduction of ice-based skating; and change of direction exercises including game-related activities, such as passing, shooting, and dribbling with the puck.
- American football, rugby and other lower extremity strength-based sports: graduated reintroduction of running, sprinting, and change of direction exercises including game-related activities, such as passing, kicking.

After Return to Sport

Continuing Fitness or Rehabilitation Exercises

- Continued resistance adductor and core/abdominal strengthening as maintenance work.
- Use of the range of exercise noted in the previous sections that specifically focus on adductor strength and rehabilitation such as the sliding board exercises if there is any recurrence of symptoms

Exercises and Other Techniques for Prevention of Recurrent Injury

- Focused adductor stretching program as part of warmups in practice and training
- Ongoing and focused abdominal/core strengthening
- Weekly sets of adductor and abductor elastic exercise program, plyometric jumping from side to side, and/or upright sliding board "skating"

Evidence

Akermark C, Johansson C: Tenotomy of the adductor longus tendon in the treatment of chronic groin pain in athletes. *Am J Sports Med* 20:640–643, 1992.

This is a cohort study of 18 tenotomies of the adductor longus tendon performed in 16 consecutive male athletes (aged 20 to 42) as treatment for chronic groin pain. The criteria for surgery was a history of longstanding (range, 2.5 to 48 months) and distinct pain at the origin of the adductor longus muscle, refractory to conservative treatment. At follow-up 35 months (range, 4 to 84) after surgery, all patients were improved or free of symptoms. All but 1 of the athletes returned to the same sport within a mean of 6.6 weeks, and 12 of 16 returned to competitive sports within a mean of 14 weeks after surgery. A majority of the patients (10 of 16) returned to full athletic activity, whereas 5 of 16 performed at a reduced level. A decreased muscle strength was observed in this study and did not seem to influence participation in sports. (Level IV evidence)

Davis JA, Stringer MD, Woodley SJ: New insights into the proximal tendons of adductor longus, adductor brevis and gracilis. *Br J Sports Med* 46:871–876, 2012.

In this anatomical dissection study the entheses and proximal musculotendinous junctions (MTJs) of adductor longus (AL), adductor brevis (AB) and gracilis were dissected bilaterally in 10 embalmed cadavers (7 females, mean age at death 79 years [range 57 to 93 years]), focusing on the type of enthesis, and architecture of the proximal tendons and MTJs. Histology was used to determine if the entheses contained fibrocartilage and to semiquantitatively assess the vascularity of each proximal tendon. All entheses were fibrocartilaginous. The proximal tendons of AB and gracilis were fused, forming a common tendinous insertion in all specimens. AL and AB both contained extensive intramuscular tendons of variable length (AL 11.1 ± 1.5 cm; AB 5.4 ± 1.1 cm). The vascularity of AL and AB tendons decreased significantly towards the enthesis ($p < 0.05$), and their entheses were significantly less vascular than that of gracilis ($p < 0.05$). The arrangement and fusion of these muscles, their fibrocartilaginous entheses and differences in vascularity of their proximal tendons, may be important anatomical considerations in the pathogenesis and pattern of adductor-related groin pain. (Level IV evidence)

Mei-Dan O, Lopez V, Carmont MR, et al: Adductor tenotomy as a treatment for groin pain in professional soccer players. *Orthopedics* 36:e1189–e1197, 2013.

This is a retrospective cohort study that reported the outcome of adductor tenotomy and hernioplasty for professional soccer players with groin pain. Between 2000 and 2006, a total of 155 professional and recreational soccer players with

recalcitrant groin pain (with or without lower abdominal pain) and resistance to conservative treatment were treated surgically. Ninety-six patients were treated with adductor tenotomy and 59 patients were treated with combined adductor tenotomy and hernioplasty. No difference in pre- or postoperative parameters was detected between groups, apart from abdominal wall muscle defects revealed during ultrasound for patients in the combined group. The RTP time and subjective and objective outcome measures were compared. Mean RTP was 11 weeks (range, 4 to 36 weeks). Postoperative Tegner score remained 8.2 (same as the preinjury Tegner score). Subjective outcome was rated 4.3 of 5. Surgical intervention allowed RTP at the same level in professional soccer players following failure of nonoperative treatments. The authors' concluded that athletes with adductor syndrome and accompanying sportsman's hernia may benefit from adductor tenotomy alone.(Level XX evidence)

Robertson IJ, Curran C, McCaffrey N, et al: Adductor tenotomy in the management of groin pain in athletes. *Int J Sports Med* 32:45–48, 2011.

This study is a retrospective case series that evaluates the efficacy of adductor longus tenotomy for chronic tendinopathy refractory to conservative management of 109 male athletes all of whom responded to a detailed questionnaire. The criterion for tenotomy was chronic adductor origin pain which prevented training or playing (Level 4), limited training or playing (Level 3), or affected performance (Level 2) and which had failed to respond to conservative management including rest, rehabilitation and/or local steroid injection. Level 1 performance is classified as optimal performance with no pain. Ninety-nine of the 109 patients (91%) reported improvement. Best results were achieved in patients with maximum discomfort preoperatively (Level 4) with 32 of 38 (84%) patients returning to Level 1 performance. (Level IV evidence)

Schilders E, Dimitrakopoulou A, Cooke M, et al: Effectiveness of a selective partial adductor release for chronic adductor-related groin pain in professional athletes. *Am J Sports Med* 41:603–607, 2013.

This is a retrospective cohort study of the use of selective partial adductor longus release as treatment for recalcitrant chronic adductor longus enthesopathy in 43 professional athletes (39 soccer and 4 rugby) with chronic adductor-related groin. All athletes were assessed in a standard way for adductor dysfunction. They received radiographs and a specifically designed magnetic resonance imaging groin study protocol. Pain and functional improvement were assessed with the visual analog scale (VAS) pain score and time to return to sport. The average follow-up time was 40.2 months. Forty-two of 43 athletes returned to their preinjury level of sport after an average of 9.21 weeks. The preoperative VAS score improved significantly (Wilcoxon signed-rank test, $p < .001$) from 5.76 ± 1.08 (range, 3 to 8) to 0.23 ± 0.61 (range, 0 to 3) postoperatively In this study a selective partial adductor longus release provided excellent pain relief for chronic adductor enthesopathy in professional athletes with a high rate of return to the preinjury level of sport. (Level IV evidence)

Multiple-Choice Questions

QUESTION 1. The most important goal of early (two weeks) postoperative care is:

A. Able to be walking without crutches
B. Commencement of strengthening exercises
C. Uncomplicated wound healing
D. To be able to single leg balance on the operated side

QUESTION 2. In the early postoperative period the range of motion exercise likely to be well tolerated by the patient is

A. Able to walk without crutches
B. Use of the low resistance sliding board with the patient lying supine
C. Resisted band strengthening exercises
D. Single leg balance and motion exercise

QUESTION 3. Which of the following exercises is **not** recommended in the first 8 weeks of rehabilitation?

A. Abdominal sit-up combined with hip flexion exercises
B. One foot standing and sliding exercises on the sliding board
C. Sport-specific exercises after appropriate strength testing
D. None of the above

QUESTION 4. In determining return to sport criteria for an athlete:

A. Number of abdominal sit-up type exercises able to be completed is important.
B. Pain the following day after full training should delay return to playing.
C. Return of maximum sprint speed is not an important criteria.
D. Hand-held dynamometer strength has to be 60% of the noninjured side.

Answer Key

QUESTION 1. Correct answer: **C** (see Immediate postoperative period)

QUESTION 2. Correct answer: **B** (see Phase II)

QUESTION 3. Correct answer: **D** (see Phase III)

QUESTION 4. Correct answer: **B** (see Criteria for return to sport)

BEYOND BASIC REHABILITATION: RETURN TO FOOTBALL (SOCCER) AFTER TREATMENT OF ACUTE GROIN INJURY

Kristian Thorborg, PT, MSportsphty, PhD, and Bruce Charles Twaddle, BHB, MBChB, FRACS

Introduction

ASPECTS OF SOCCER THAT REQUIRE SPECIAL ATTENTION IN REHABILITATION

- Soccer is a sport that includes many short passages of high-intensity work.
- The high intensity is caused by repetitive sprints, and repeated sprint ability is especially of high importance in soccer.
- Maximum hip adductor activities, such as sprinting, acceleration, deceleration, including many stops, turns, and changes of direction, should be specifically addressed when returning an athlete for all types of football from a groin injury
- Maximum hip adductor activities, such as kicking, require specific attention for athletes participating in football forms where kicking is performed regularly and when the athletes needs to return to this kind of activity
- The acute groin strain usually involves one or more musculotendinous structures. The lesion can be in the musculotendinous junction itself, but in some cases it is in the tendon itself or the entheses where the tendon inserts into the bone that is the site of the injury.
- These injuries happen during forceful actions such as in kicking, sprinting, sudden change of direction, and other sporting movements where the muscle is being stretched during forceful contraction.
- If the initial injury is not treated appropriately in the first place or if a player is returned to the sport too quickly, these injuries might become longstanding or chronic. If the athlete does not get appropriate treatment and instead continues to participate in soccer, the injury can become very challenging to treat, and the injury pattern will start to resemble overuse-type adductor-related groin pain where more and more soccer-specific activities become problematic, and finally all soccer activities start to cause pain.
- This type of injury can take months to recover from, and what started out as minor acute strain can develop into a longstanding problem, where important and decisive sporting movements in soccer such as maximum kicking, acceleration, deceleration, twisting and turning becomes so problematic and painful that the player's performance is significantly impaired.

Literature

- In soccer about 10% of adductor-related injuries, which is by far the most common groin injury in this sport, last more than 4 weeks. It is not known how many of these injuries become longstanding or chronic. However, it has been reported that if players sustain a re-injury of their groin, the re-injury recovery period is almost twice as long compared with the index injury, emphasizing the importance of proper care initially.[1]
- In athletes with longstanding adductor-related groin pain, the average time before being fully returned to sport was 18.5 weeks, after treatment with an active exercise program.[2] Furthermore, it has been documented in sub-elite soccer that combined adductor and abdominal groin problems add to injury time, by quadrupling injury time compared with other types of groin injuries.[3]
- The groin injuries in soccer are mostly overuse injuries. In the UEFA study 27% were traumatic injuries[1] and the sub-elite study found 39% were traumatic injuries.[3] Very interestingly only in one of five situations, contact with another player was involved in the injury mechanism of the traumatic injuries, implying that the majority (80%) of the traumatic injuries are probably happening as the result of kicking, sprinting, or sudden changes of direction, movements where the groin-related muscles are involved at high speed, often with a forceful eccentric element.[4]
- Complete adductor ruptures are not common, but in the American National Football league (AFL) mean time for return to play in players treated conservatively for an acute adductor longus rupture has been reported to be 6 ± 3 weeks (range, 3 to 12 weeks).[4]
- A recent study of two different adductor ruptures in a soccer player suggests that adductor longus ruptures can have very different recovery times. In this study normal hip adductor strength was obtained after 52 weeks for the first injury, but after 10 weeks for the second injury (Figure 25-11). This highlights the importance of measuring hip adductor strength by using a hand-held dynamometer, as this gives important information on the actual recovery process of the adductors, which cannot be obtained from diagnostic imaging.[5]

The Advanced Rehabilitation Program

- The rehabilitation program after an acute groin injury is divided into four phases by including linear

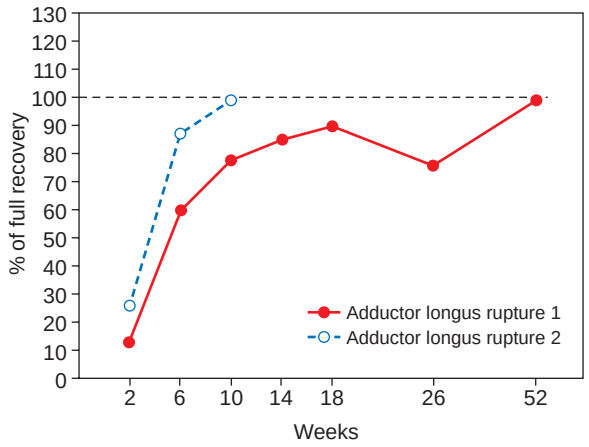

FIGURE 25-11. Variability of strength recovery after adductor groin injury. *(From Thorborg* et al. *Hip adduction strength recovery after adductor longus ruptures.* BMC Research Notes *6:205, 2013.)*

periodization principles within each period, each with a different rehabilitation focus. In general the rehabilitation program works from focus and isolation of the specific tissues involved in the injury towards integration of the specific structures into sports-specific function and return to sport based upon individual and continuous assessment of (1) injury (structural) status, (2) functional status, and (3) performance status, and finally (4) sports participation status, at specific time points during the rehabilitation period.

- In addition supplementary training specific for each phase is important for optimizing recovery and for maintenance of soccer-specific fitness is also included, and can be performed on a daily/weekly basis, depending on the specific intervention.

Phase I: Acute/Subacute Injury Focus (weeks 1 to 2)

- Includes the acute and subacute phase and is characterized by musculotendinous pain and/or inflammation at the musculotendinous junction (MTJ), in the tendon or at the pubic insertion point, usually of the adductor longus and/or the rectus abdominis muscle.
- This phase focuses on the initiation of tissue repair and/or regeneration, but also includes effects of possible disuse, detraining, loss of muscle performance because of potential immobilization as a result of the actual musculotendinous injury.

Goals

- Protection of the adductor and/or abdominal musculotendinous complex
- Control of pain and inflammation
- Normalization of flexibility within restrictions
- Preventing excessive muscular inhibition by isometric contractions (see Figure 25-5) with no or minimal pain provocation

Supplementary Training

- Aerobic fitness maintained on exercise bike. General strength maintained by upper extremity strength training seated rows and chest press exercises, as long as pain is not provoked from adductors and abdominals as a result of maximum co-contractions.
- Isolated quadriceps and calf strengthening and adductor and abductor strengthening of the uninvolved side (sidelying adductions and abductions) for general strength and stimulating cross-over effects to decrease possible inhibition of injured side by central nervous system activation strategies.

Criteria for Progression to the Next Phase

- No or minimal pain with all Phase I exercises
- Clear muscle activation during isometric contractions of adductor and abdominal muscles
- Active hip abduction ROM should be at least 50% of non-injured side

Phase II: Tissue Conditioning Focus (weeks 3 to 4)

- Focuses on tissue repair and/or regeneration. In this phase gradual and progressive loading of adductors and abdominal muscles is commenced while still respecting the structural injury and underlying healing

TIMELINE 25-3: **Return to Football (Soccer) after Treatment of Acute Groin Injury**

PHASE I (weeks 1 to 2)	PHASE II (weeks 3 to 4)
• Protection of injured structures (crutches, compression) • PT modalities for pain relief • Gentle supine active flexibility exercises • Core/adductor/abdominal activation exercises initiated • Walking, aerobic fitness and strength training as tolerated	• PT modalities • Continue gentle supine active flexibility exercises • Progressive core/abdominal strengthening program initiated • Progressive adductor strengthening initiated • Walking, aerobic fitness and strength training as tolerated • Running and sports specific activities as tolerated • Plyometric exercises if tolerated

FIGURE 25-12. Abdominal strengthening as part of Phase II.

processes depending on the location of the injury (MTJ, tendon, aponeurosis or insertion) at this early stage.
- Gentle dynamic muscle exercises are commenced starting with a low load from 30 to 20 repetitions maximum. Strength training machines, sidelying using the weight of the leg and standing exercises with elastic bands can be used for targeting the adductor longus muscle (see Figure 25-7), and at least two different exercise types should be used with 3 × 20 repetitions of each. The musculotendinous conditioning should focus on concentric, isometric and eccentric contractions during these exercises.
- Abdominal crunches in supine (Figure 25-12), frontal rolling exercises with a Swiss ball (see Figure 25-8), or training in a machine should also be performed using the same principles as applied for the adductors. All these exercises should be performed 3 times a week with at least 1 day of rest from these exercise types in between. Pain during exercises must not be neglected, but some discomfort and pulling may be felt during early initiation of these exercises. A general rule of thumb is that pain and discomfort should be less than 3 on a numerical rating scale, during exercise, and that initial pain levels before exercise are reached shortly after exercises are finished. Increasing morning pain and stiffness, compared to the initial state, is also a good indicator of when exercises have been progressed too quickly.

Supplementary Training

- Aerobic fitness maintained on exercise bike, changing functional muscle work demands by alternating between standing and sitting bike drills.
- Finally also anaerobic drills can be incorporated by increasing resistance. Walking and jogging can be commenced when pain-free.
- General strength maintained by upper extremity strength training seated row and chest press, as long as pain is not generated from adductors and abdominals during maximum contractions.
- Isolated quadriceps and calf and gluteus medius strengthening for both sides, and sidelying adductor exercises for the uninvolved side.

Criteria for Progression to the Next Phase

- No or minimal pain with all Phase II exercises, and normal execution (no compensation strategies to avoid loading injured structures) of dynamic exercises of adductor and abdominal muscles.
- Active ROM at least 80% of non-injured side and adductor strength at least 60% of non-injured side, able to do 20 repetitions maximum by using the same resistance based upon 20 repetitions maximum from the uninjured side, and/or able to do 20 sidelying adductor lifts and 20 abdominal crunches lying supine on the floor with proper form, and with no or minimal pain.

Phase III: Sports-Specific Focus (weeks 5 to 8)

- The primary goals during this phase are restoration of musculotendinous endurance and strength, aerobic and anaerobic capacity, and neuromuscular control/balance/coordination.
- Dynamic muscle strengthening exercises in standing using elastic bands as resistance are continued starting with a load of 20 repetitions maximum progressing towards 10 repetitions maximum.
- The same principle is applied for abdominal exercises where a Swiss ball is used (Figure 25-13). The musculotendinous conditioning should focus on slow heavy concentric, isometric and eccentric contractions during these exercises.
- Exercises on a sliding board are commenced by introducing 5 to 10 times 1 minute of skating from side to side. All these exercises should be performed 3 times a

TIMELINE 25-3: **Return to Football (Soccer) after Treatment of Acute Groin Injury** (Continued)

PHASE III (weeks 5 to 8)	PHASE IV (weeks 9 to 12)	PHASE V (weeks 13 to 52)
• PT modalities as needed • Active and passive stretching exercise • Progressive core/abdominal strengthening exercises continued • Progressive adductor strengthening continued • Aerobic fitness and strength training as tolerated • Running and sport-specific activities as tolerated • Plyometric exercises if tolerated	• PT modalities as needed • Active and passive stretching exercise • Progressive core/abdominal strengthening exercises continued • Progressive adductor strengthening continued • Aerobic fitness and strength training as tolerated • Increase sport-specific training as tolerated • Increase plyometric exercises and change of direction if tolerated	• PT modalities as needed • Maintenance of active and passive stretching exercise • Maintenance program of adductor/abdominal/core strengthening • Maintenance program of plyometric and change of direction exercises

FIGURE 25-13. Frontal rolling exercise to improve core strength.

week with at least 1 day of rest from these exercise types in between pain during exercises and must not be neglected, but some discomfort and pulling may be felt during early initiation of these exercises. A general rule of thumb is that pain and discomfort should be less than 3 on a numerical rating scale, during exercise, and that initial pain levels before exercise are reached shortly after exercises are finished. Increasing morning pain and stiffness, compared to the initial state, is also a good indicator of when exercises have been progressed too quickly.

Supplementary Training

- Aerobic fitness maintained/increased by running drills, and anaerobic fitness increased by running drills.
- General strength maintained by strength training of both upper and lower extremity. Strength training including high intensity strength training, and also low to high intensity power exercise progression (Figure 25-14).

FIGURE 25-14. Progression to high-intensity strength training.

FIGURE 25-15. Phase III: Twisting turning exercises on the trampoline.

- Plyometric drills and agility drills using stairs. Repeated sprint ability including maximal and forceful actions such accelerating, decelerating, twisting turning starting in trampoline (Figure 25-15).
- Soccer specific ball drills including juggling, dribbling, progressed into passing and receiving passes, progressed into kicking drills from short to long pass with maximum crosses and shoots on goals (Figure 25-16) as the final and most demanding and stressing exercise for the adductor-abdominal musculotendinous complex. Again, all exercises should be performed with no or minimal pain/discomfort during execution and the morning after.

FIGURE 25-16. Shots on goal: Final level of adductor activation before full return to sport participation.

Criteria for Progression to the Next Phase

- No or minimal pain with all Phase III exercises, and normal execution (no compensation strategies to avoid loading injured structures) of dynamic exercises of adductor and abdominal muscles.
- Active ROM of nearly 100% of the non-injured side and adductor strength of at least 80% of the non-injured side, able to do 3 × 10 repetitions maximum, by using the same resistance based upon 10 repetitions maximum from the uninjured side, or able to do 3 × 10 sidelying adductor lifts with external load of at least 6 kg, and able to do 3 × 10 abdominal crunches lying over Swiss ball with proper form, and with no or minimal pain. Demonstration of initial agility drills with proper form, with no clear and visible compensation strategies during maximal and forceful actions such as accelerating, decelerating, twisting turning and kicking, again with no or minimal pain/discomfort during execution and the morning after.

Phase IV: Return-to-Sport Focus (weeks 9 to 12)

- Characterized by activities that focus on returning the athlete to full sporting function and soccer participation. The primary goals to be addressed during this phase are successful return to previous functional and sporting level, and prevention of reinjury. The primary goals to be addressed during this phase are maintenance of musculotendinous endurance and strength, aerobic and anaerobic capacity, and improving neuromuscular control/balance/coordination.
- Dynamic muscle exercises using the elastic bands are continued with a load of 8 to 10 repetitions maximum, with focus of different and increasing speeds of eccentric contractions.
- Exercises on a sliding board are continued by introducing 10 to 20 times 1 minute of skating from side to side. All these exercises should be performed 2 to 3 times a week with at least 1 day of rest from these exercise types in between.

Supplementary Training

- Anaerobic fitness increased by running drills.
- General strength maintained by strength training of both upper and lower extremity. Strength training including high intensity strength training, and also low to high intensity power exercise progression for abdominals..
- Agility drills and repeated sprint ability including maximal and forceful actions such accelerating, decelerating, twisting turning (Figure 25-17).

Criteria for Return to Play at the Preinjury Competitive Level

- Participation in soccer training with the rest of the team (Figure 25-18), progressing from 45 minutes to 90 minutes of soccer training, and participating in 1 to 3 weeks of full soccer training before full return to sport (match activity) can be commenced, depending on the severity of the initial injury (the more severe the longer participation period before full return).
- Playing 45 minutes or less of second half is recommended to start with until soccer fitness is improved and full game can be performed at preinjury level.
- Again, all training and matches should be performed with no or minimal pain/discomfort during execution and the morning after.

FIGURE 25-17. Phase IV: Forceful change of direction drills.

Sports Performance Testing

General Information

- Medical history
- Sports injury history
- Surgical history
- Chronic conditions/medication

FIGURE 25-18. Full team training participation.

Objective Tests to Determine Readiness For Soccer

Phase I: Structure-specific location of injury
- Palpation
- Ultrasound/MRI

Phase I: Range of motion
- Hip abduction range of motion (supine with goniometer)
- Hip extension range of motion (Thomas test with goniometer)

Phase II: Hip strength
- Isometric hip strength, hip adduction/abduction ratio (HHD)
- Isometric hip strength, hip adduction strength recovery, compared to uninjured side (HHD)
- Eccentric hip adduction strength recovery, compared to asymptomatic side (HHD)

Phases III and IV:
- Self-reported objective measures of pain and function
  - Copenhagen Hip And Groin Outcome score (HAGOS), six subscales
  - Copenhagen groin pain test (groin pain evaluated on a numerical analogue scale 0 to 10, during maximum static hip adduction in the supine position with straight legs)
- Soccer fitness
  - Yo-yo test
  - Repeated sprint ability test

Evidence

Hölmich P, Thorborg K, Dehlendorff C, et al: Incidence and clinical presentation of groin injuries in sub-elite male soccer. *Br J Sports Med* 2013. doi: 10.1136/bjsports-2013-092627. [Epub ahead of print].

Prospective cohort study of 44 soccer clubs at the sub-elite level had recorded baseline characteristics and groin injuries sustained by a cohort of 998 sub-elite male soccer players during a full 10-month season. Adductor-related groin injury was the most common entity found followed by iliopsoas-related and abdominal-related injuries. Age and previous groin injury were significant risk factors for sustaining a groin injury. Having both adductor and abdominal pain also increased the injury time significantly when compared to injuries with no adductor and no abdominal pain (RIT = 4.56, 95% CI 1.91 to 10.91, p = 0.001). (Level II evidence)

Hölmich P, Uhrskou P, Ulnits L, et al: Effectiveness of active physical training as treatment for long-standing adductor-related groin pain in athletes: randomised trial. *Lancet* 353:439–443, 1999.

Sixty-eight athletes with long-standing (median 40 weeks) adductor-related groin pain—after examination according to a standardized protocol—were randomly assigned to active treatment (AT) or passive treatment (PT). The treatment period was 8 to12 weeks. Four months after the end of treatment a standardized examination was done and 23 patients in the AT group and four in the PT group returned to sports without groin pain (odds ratio, multiple-logistic-regression analysis, 12.7 [95% CI 3.4 to 47.2]). AT with a program aimed at improving strength and coordination of the muscles acting on the pelvis, in particular the adductor muscles, is very effective in the treatment of athletes with long-standing adductor-related groin pain. (Level I evidence)

Schlegel TF, Bushnell BD, Godfrey J, et al: Success of nonoperative management of adductor longus tendon ruptures in National Football League athletes. *Am J Sports Med* 37:1394–1399, 2009.

Using the National Football League Injury Surveillance System, adductor tendon ruptures documented by magnetic resonance imaging were identified in 19 National Football League players from 1992 to 2004. Fourteen players were treated nonoperatively, and five players were treated with surgical repair using suture anchors. In both groups, all players eventually returned to play in the National Football League. Mean time for return to play was 6.1 ± 3.1 weeks (range, 3 to 12 weeks) for the nonoperative group and 12.0 ± 2.5 weeks (range, 10 to 16 weeks) for the operative group (p = .001). Nonoperative treatment of proximal adductor tendon rupture results in a faster return to play than does operative treatment in athletes competing in the National Football League. (Level IV evidence)

Thorborg K, Petersen J, Nielsen MB, et al: Clinical recovery of two hip adductor longus ruptures: a case-report of a soccer player. *BMC Res Notes* 6:205, 2013.

A 22-year old male soccer player (white) sustained two subsequent acute adductor longus ruptures, one in each leg. He was evaluated using hip-strength assessments, self-report and ultrasonography until complete muscle-strength recovery of the hip adductors had occurred. The player was able to participate in a full soccer training session without experiencing pain 15 weeks after the first rupture, and 12 weeks after the second rupture. Full hip adductor muscle-strength recovery was obtained 52 weeks after the first rupture and 10 weeks after the second rupture. From this case we can conclude that two apparently similar hip adductor longus ruptures, verified by initial ultrasonography (10 days postinjury), can have very different hip adductor strength recovery times. (Level IV evidence)

Werner J, Hägglund M, Waldén M, et al: UEFA injury study: a prospective study of hip and groin injuries in professional football over seven consecutive seasons. *Br J Sports Med* 43(13): 1036–1040, 2009.

Prospective cohort study of European professional football. During the 2001/2 to 2007/8 seasons, between nine and 17 clubs per season (23 clubs in total) were investigated, accounting for 88 club seasons in total. Time loss injuries and individual exposure during club and national team training sessions and matches were recorded. A total of 628 hip/groin injuries were recorded, accounting for 12% to 16% of all injuries per season. The total injury incidence was 1.1/1000 h (3.5/1000 match hours vs 0.6/1000 training hours, p < 0.001) and was consistent over the seasons studied. (Level II evidence)

Multiple-Choice Questions

QUESTION 1. An acute musculotendinous injury is often caused by?

A. A lengthening contraction
B. A shortening contraction
C. An isometric contraction
D. By being overstretched

QUESTION 2. A reinjury of the groin in soccer players takes how long to recover compared to the initial injury

a. Shorter time than initial injury
b. Same amount of time as initial injury
c. Twice as long as the initial injury
d. Three times as long as initial injury

QUESTION 3. Quantifying hip adductor muscle strength recovery is best performed by?

A. Ultrasound
B. MRI
C. Manual assessment
D. Hand-held dynamometry

QUESTION 4. Phase II of the rehabilitation program for acute adductor injuries should focus on

A. Neuromuscular control
B. Tissue conditioning
C. Muscle power
D. Settling inflammation

QUESTION 5. One of the most stressful sporting movements for the hip adductors is?

A. Running
B. Jumping
C. Kicking
D. Short passing

Answer Key

QUESTION 1. Correct answer: **A** (see Introduction)

QUESTION 2. Correct answer: **C** (see Literature)

QUESTION 3. Correct answer: **D** (see Literature)

QUESTION 4. Correct answer: **B** (see Phase II)

QUESTION 5. Correct answer: **C** (see Introduction)

Chapter 26

Femoroacetabular Impingement and Labral Injuries

INTRODUCTION

John C. Clohisy, MD

Epidemiology

Age

- Average age 35 yrs (range, 16 to 91)

Sex

- 57% male
- 43% female

Sport

- Any sport with repetitive hip flexion, bending and squatting (soccer, hockey, football, baseball, basketball, etc.)
- One recent study indicated:
  - 59% participated in regular sporting activities.
  - 59% classified participation intensity as high.
  - 28% reported intensity as moderate.
  - Average UCLA was 7.1 ± 2.8, consistent with patients participating in activities like fast walking, golfing, and bowling.
  - 29% participated in impact activities like jogging, tennis and ballet on regular basis.

Position

- Athletic activities/positions with repetitive hip flexion are at highest risk.

Pathophysiology

Intrinsic Factors

- Hip pathomorphology—Acetabular overcoverage (Figure 26-1)
- Hip pathomorphology—Femoral head-neck offset deformities (Figure 26-2)
- Soft tissue laxity with excessive hip motion

FIGURE 26-1. Acetabular overcoverage—deep socket, preoperative view.

FIGURE 26-2. Femoral head-neck offset deformity, preoperative frogleg view.

Extrinsic Factors

- Repetitive hip flexion activities including occupational and athletic activities
- Athletics: hockey, soccer, basketball, football, and others that involve repetitive hip flexion activities

Traumatic Factors

- Forced hip flexion can result in acute labrochondral injury
- Forced hip flexion with combined adduction and internal rotation can result in subluxation or hip dislocation.
- Patients with femoroacetabular impingement (FAI) anatomy may be more susceptible to subluxation/dislocation episodes due to levering from anterior impingement.

Classic Pathological Findings

- Structural abnormalities of the acetabulum and proximal femur consistent with femoroacetabular impingement (FAI; see Figure 26-2)
- Acetabular labral abnormalities including detachment, degeneration, and ossification
- Chondral abnormalities specifically of the acetabular rim including delamination, articular cartilage flap formation and full thickness defect (Figure 26-3).
- The most common intraarticular abnormality includes injury to the acetabular labrochondral complex.

Clinical Presentation

History

- Groin pain
- Activity-related symptoms
- Activity limitation owing to hip symptoms
- Locking, catching of the hip
- Groin pain with prolonged sitting or hip flexion activities
- History of recurrent groin pulls, compensatory symptoms (low back pain, SI joint pain, trochanteric bursitis, adductor strain)

Physical Examination

Abnormal Findings

- Limited hip flexion
- Limited internal rotation in flexion
- Positive impingement test (sensitive but not specific for FAI).
- Positive flexion, abduction, external rotation (FABER) test

Pertinent Normal Findings

- Normal external rotation/motion
- Normal gait
- Athletes may have normal muscle strength and function

Imaging

- Plain radiographs including the anteroposterior (AP) pelvis, frog lateral, and 45° Dunn view
- Parameters consistent with acetabular overcoverage
- Femoral head-neck offset abnormalities are present.
- Magnetic resonance imaging (MRI) and magnetic resonance arthrography can demonstrate labrochondral disease, structural anatomy, and secondary articular cartilage changes.
- CT scan with three-dimensional images provides detailed information regarding deformity characteristics.

Differential Diagnosis

- Hip dysplasia
- Secondary hip osteoarthritis
- Lumbar spine dysfunction
- Sacral Iliac joint dysfunction
- Athletic hernia
- Muscle imbalance syndromes
- Stress fractures
- Adductor strain

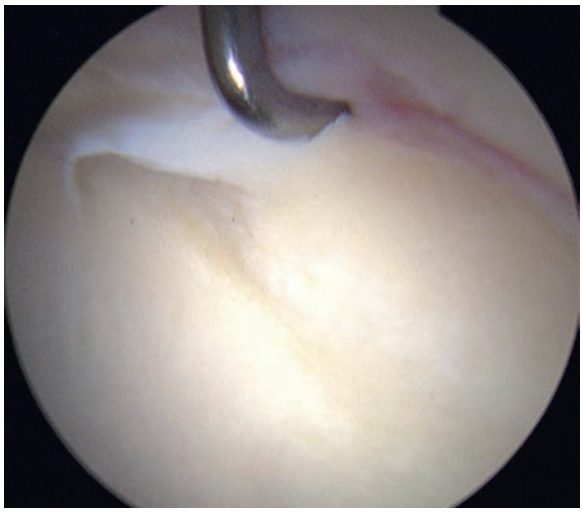

FIGURE 26-3. Chondral abnormality, labral disruption.

- Symphysis pubalgia
- Comprehensive history, physical exam, and imaging evaluation of the patient distinguish the above conditions from a symptomatic femoroacetabular impingement. Compensatory disorders are common and many of the above diagnoses can occur simultaneously with femoroacetabular impingement.

Treatment

Nonoperative Management

- Activity modification and patient education
- Nonsteroidal antiinflammatory medicines
- Physical therapy with muscle strengthening and balancing
- Intraarticular corticosteroid injection

Guidelines for Choosing Among Nonoperative Treatments

- A panel of nonsurgical treatment options to block the pain cycle and optimize function about the hip is preferred.
- Corticosteroid injections are mostly used in patients greater than 40 years of age with early osteoarthritis.

Surgical Indications

- Patients less than 50 years of age
- Symptomatic hip impingement disease
- Failure of nonsurgical treatment methods
- Defined hip impingement deformity
- Imaging studies demonstrate lack of moderate to advanced osteoarthritis of the hip.
- Body mass index (BMI) less than 35
- Positive response to intraarticular injection (with pain relief)

Aspects of History, Demographics, or Exam Findings that Affect Choice of Treatment

- Age
- Physical health
- Deformity characteristics
- Articular cartilage integrity

Aspects of Clinical Decision Making When Surgery Is Indicated

- Open versus closed surgical correction
- Treatment of the acetabular labrum (partial resection or repair)
- Correction of the impingement deformity (acetabuloplasty, femoral plasty or both) (Figures 26-4, 26-5)
- Treatment of acetabular articular cartilage disease including chondromalacia, delamination, articular cartilage flap and full thickness defects.

Evidence

Beaule P: Prevalence of associated deformities and hip pain in patients with cam-type femoracetabular impingement. *J Bone Joint Surg* 91-B:589–594, 2009.

FIGURE 26-4. Deep socket, postoperative view.

One hundred and thirteen patients, 82 male and 31 females aged 55 or less, with symptomatic cam-type impingement of at least one hip were evaluated for this study. Bilateral cam deformity was seen in 77.8% of the population, whereas only 26% had pain in both hips. Hips with alpha angles greater than 60° had an odds ratio 2.59 for being painful. Pincer deformity was seen in 42% of the cases. (Level IV evidence)

Byrd J: Arthroscopic femoroplasty in the management of cam-type femoroacetabular impingement. *Clin Orthop Relat Res* 467:739–746, 2008.

Prospective assessment of 200 patients (207 hips) undergoing arthroscopic treatment for cam-type impingement. Patient cohort consisted of 138 men and 62 women with mean age 33 years. One hundred and sixty-three hips underwent femoroplasty, whereas 44 hips received a concomitant procedure to correct for pincer impingement. The Harris hip score improved an average of 20 points at a minimum of 1 year, whereas 0.5% went on to total hip arthroplasty. (Level IV evidence)

Clohisy JC, Knaus ER, Hunt DM, et al: Clinical presentation of patients with symptomatic anterior hip impingement. *Clin Orthop Relat Res* 2467:638–644, 2009.

This prospective study of 51 patients with a diagnosis of FAI evaluated clinical history, physical exam, previous treatments performed, and patient outcome scores. Patients indicated a

FIGURE 26-5. Head-neck offset postoperative frogleg view.

relatively high level of activity, yet had restrictions of function and overall health. (Level II evidence)

Ellis T: Efficacy of surgery for femoroacetabular impingement. *Am J Sports Med* 38:2337–2345, 2010.

Systematic review of 970 cases included 1 level II, 2 level III, and 20 level IV studies. Patients improved in all studies based on outcome scores. Patients with intraoperative Outerbride classification of III or IV or preoperative radiographic Tonnis grade greater than 1 showed less improvement. Longer follow-up will be needed to determine if onset or progression of osteoarthritis is delayed. (Level III evidence)

Philippon MJ, Briggs KK, Yen Y-M, et al: Outcomes following hip arthroscopy for femoroacetabular impingement with associated chondrolabral dysfunction: minimum two-year follow-up. *J Bone Joint Surg (Br)* 91(1):16–23, 2009.

One hundred and twelve patients underwent arthroscopy for femoroacetabular impingement with a mean age of 40.6 years. Twenty-three patients were treated with osteoplasty for cam impingement only, 3 had acetabular rim trimming for pincer type impingement, and 86 underwent both procedures for mixed type impingement. At a mean follow-up of 2.3 years, the mean modified Harris hip score improved from 58 to 84, and median satisfaction score of 9. Ten patients underwent total hip arthroplasty at mean of 16 months. Predictors of better outcome were preoperative Harris hip score, joint space narrowing, and labral repair versus labral debridement. (Level II evidence)

Siebenrock KA, Ferner F, Noble PC, et al: The cam-type deformity of the proximal femur arises in childhood in response to vigorous sporting activity. *Clin Orthop Relat Res* 469:3229–3240, 2011.

This retrospective review compared 72 hips in 37 male basketball players and 76 asymptomatic hips of 38 nonathletic volunteers. Findings suggest high- intensity sports activities performed in adolescence are likely to increase the risk of cam-type impingements. (Level II evidence)

Multiple-Choice Questions

QUESTION 1. What is the most common pain location of symptomatic hip impingement?

A. Groin
B. Lateral
C. Buttock
D. Thigh

QUESTION 2. What is the most common location of intraarticular damage in patients with femoroacetabular impingement?

A. Acetabular labrum
B. Acetabular labrochondral complex
C. Acetabular articular cartilage
D. Femoral head articular cartilage

QUESTION 3. Nonsurgical management of hip impingement should focus on the following combination of modalities:

A. Hip range of motion and activity modification
B. Hip strengthening and hip range of motion
C. Hip strengthening, muscle balancing, and activity modification
D. Nonsteroidal antiinflammatory medicines, hip strengthening and balancing, and range of motion.

QUESTION 4. What is the most common physical examination finding in patients with symptomatic hip impingement?

A. Reduced hip flexion and external rotation
B. Reduced hip abduction and external rotation
C. Reduced hip flexion and internal rotation
D. Limited extension and external rotation

QUESTION 5. Which of the following disease characteristics is a relative contraindication for hip preservation FAI surgery?

A. Severe deformity
B. History of injury to the joint
C. Symptoms of catching and locking
D. Moderate (50%) joint space narrowing

Answer Key (identify where in text the answer can be found)

QUESTION 1. Correct answer: **A** (see Pathophysiology: Clinical presentation)

QUESTION 2. Correct answer: **B** (see Pathological Findings)

QUESTION 3. Correct answer: **C** (see Nonoperative Management)

QUESTION 4. Correct answer: **C** (see Physical Exam Findings)

QUESTION 5. Correct answer: **D** (see Surgical Indications)

NONOPERATIVE REHABILITATION OF HIP STIFFNESS AND HIP IMPINGEMENT (CAM/PINCER LESIONS)

Erik P. Meira, PT, SCS, CSCS, and Mark B. Wagner, MD

GUIDING PRINCIPLES OF NONOPERATIVE REHABILITATION

- Avoid exacerbating the anterior hip pain associated with femoroacetabular impingement (FAI).
- Range of motion may be limited by bony deformity—DO NOT FORCE MOTION.
- Focus on increasing strength and coordination within pain-free range of motion.
- Specific attention should be made to controlling dynamic knee valgus.
- Activation of hip abductors should be reinforced during each phase of rehab.
- Modify lifestyle to accommodate FAI as able.

Phase I (weeks 0 to 2)

Protection

- Weight bearing as tolerated.
- Limit motion to pain-free range.
- Minimize activation of the iliopsoas.

Management of Pain and Swelling

- Nonsteroidal antiinflammatory drugs (NSAIDs)
- Cryotherapy with compression to the joint

Techniques for Progressive Increase in Range of Motion

Manual Therapy Techniques

- Long axis traction and gentle lateral glides in supine for pain control

Soft Tissue Techniques

- Gentle massage to anterior hip with the focus on relaxation of regional musculature, specifically pectineus and iliopsoas

Stretching and Flexibility Techniques for the Musculotendinous Unit

- Gentle stretching to the iliopsoas (Figure 26-6) and lumbar extensors

Other Therapeutic Exercises

- Upright exercise bike with elevated seat to minimize hip flexion
- Total leg strength (TLS) may be initiated as tolerated.

Activation of Primary Muscles Involved

- Hip abductors
  - Gluteus medius
  - Gluteus minimus
- Hip external rotators
  - Gluteus maximus
  - Piriformis
  - Gemellus superior
  - Gemellus inferior
  - Obturator internus
  - Obturator externus
  - Quadratus femoris
- Hip extensors
  - Gluteus maximus
- Hip adductors
  - Adductor magnus
  - Adductor longus
  - Adductor brevis
  - Pectineus
  - Gracilis

Sensorimotor Exercises

- Single leg stance as tolerated

Open and Closed Kinetic Chain Exercises

- Clamshells in pain-free range (OKC)
- Bridging (CKC)

FIGURE 26-6. Iliopsoas stretch. Maintain posterior pelvic tilt during the stretch.

FIGURE 26-7. Rhythmic stabilization in side-lying. Be cautious applying resistance to flexion during Phase I.

Techniques to Increase Muscle Strength, Power, and Endurance

- Prone heel squeeze
- Isometric adductor squeeze

Neuromuscular Dynamic Stability Exercises

- Manual resistance hip stability (rhythmic stabilization) in side lying (Figure 26-7)

Milestones for Progression to the Next Phase

- No pain at rest
- Pain free with all rehab activities
- Able to perform one straight leg raise without pain

Phase II (weeks 2 to 4)

Protection

- Limit motion to pain-free range.

Management of Pain and Swelling

- Continue with nonsteroidal antiinflammatory drugs (NSAIDs), and cryotherapy with compression to the joint as needed.

Techniques for Progressive Increase in Range of Motion

Manual Therapy Techniques

- Continue long axis traction and gentle lateral glides in supine for pain control.

Soft Tissue Techniques

- Continue gentle massage to anterior hip with the focus on relaxation of regional musculature as needed.

Stretching and Flexibility Techniques for the Musculotendinous Unit

- Progress iliopsoas and low back extensor stretching as tolerated.
- Gentle stretching into combined flexion abduction external rotation as tolerated

Other Therapeutic Exercises

- May progress to elliptical trainer as tolerated.
- Continue to progress TLS.
- May begin core stability training being cautious of excessive load to the iliopsoas.

Activation of Primary Muscles Involved

- Hip abductors
  - Gluteus medius
  - Gluteus minimus
- Hip external rotators
  - Gluteus maximus
  - Piriformis
  - Gemellus superior
  - Gemellus inferior
  - Obturator internus
  - Obturator externus
  - Quadratus femoris
- Hip extensors
  - Gluteus maximus
  - Biceps femoris
  - Semitendinosus
  - Semimembranosus
- Hip adductors
  - Adductor magnus
  - Adductor longus
  - Adductor brevis
  - Pectineus
  - Gracilis

Sensorimotor Exercises

- Single leg stance on uneven surface

Open and Closed Kinetic Chain Exercises

- Clamshells in pain-free range against resistance (OKC)
- Standing hip abduction, adduction, and extension against resistance (OKC)
- Bridging with marching (CKC)
- Double and single leg press in pain-free range (CKC)

Techniques to Increase Muscle Strength, Power, and Endurance

- Begin Romanian Deadlift (RDL) with focus on lumbopelvic coordination.

Neuromuscular Dynamic Stability Exercises

- Single leg lunge on wall with physioball (Figure 26-8) with focus on controlling knee valgus and hip adduction

FIGURE 26-8. Wall lunge with physioball. Avoid knee valgus and Trendelenburg position.

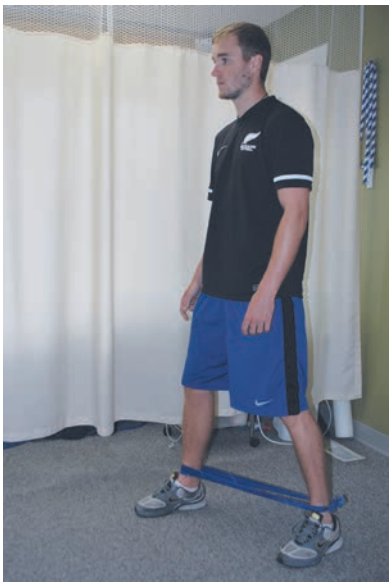

FIGURE 26-9. "Monster walking."

Plyometrics

- Submaximal jumps on shuttle
- Double leg bouncing while maintaining contact on mini-trampoline

Functional Exercises

- Hip band ambulation
  - Forward/backward
  - Side-to-side
  - "Monster walking" (Figure 26-9)

Milestones for Progression to the Next Phase

- No pain with activity of daily living (ADL)
- Pain free with all rehab activities
- Able to hold straight leg raise at 45° hip flexion in supine against minimal manual resistance without pain.
- Able to maintain hip height within 2 cm of uninvolved side during single leg stance phase test.

Phase III (weeks 4 to 8)

Protection

- Continue to limit motion to pain-free range.

Management of Pain and Swelling

- Continue with nonsteroidal antiinflammatory drugs (NSAIDs) and cryotherapy with compression to the joint as needed.

TIMELINE 26-1: **Nonoperative Rehabilitation of Femoroacetabular Impingement**

PHASE I (weeks 0 to 2)	PHASE II (weeks 2 to 4)
• WBAT • PT Modalities • Mobilizations as needed for pain control • Gentle iliopsoas and lumbar extensor stretching • Exercise bike with elevated seat • Total body strengthening/total leg strength (TBS/TLS) activities as recommended & tolerated • Single leg stance as tolerated • OKC Rhythmic stabilization exercises • Prone heel squeezes • Isometric adductor squeeze • Clamshells (OKC) • Bridging (CKC)	• FWB • PT Modalities as needed • ROM-limited to pain-free motion • Mobilizations as needed • Elliptical trainer • TBS/TLS activities as recommended & tolerated • Hip band ambulation • Core stability • Continue OKC/CKC exercises • Standing hip abduction/adduction/extension (OKC) • Bridging with marching (CKC) • Leg press in pain-free range (CKC) • Single leg lunge on wall with physioball (CKC) • Romanian Deadlift (RDL) with focus on lumbopelvic coordination (CKC) • Submaximal jumps on shuttle (Plyo) • Double leg bounces on mini-trampoline (Plyo)

Techniques for Progressive Increase in Range of Motion

Manual Therapy Techniques

- Long traction with progressive range of motion in all directions as tolerated

Soft Tissue Techniques

- Continue gentle massage to anterior hip with the focus on relaxation of regional musculature as needed.

Stretching and Flexibility Techniques for the Musculotendinous Unit

- Progress iliopsoas and low back extensor stretching as tolerated. Continue gentle stretching into combined flexion abduction external rotation as tolerated.

Other Therapeutic Exercises

- Continue elliptical trainer as tolerated.
- Continue to progress TLS.
- Progress core stability training, being cautious as tolerated.

Activation of Primary Muscles Involved

- Hip abductors
  - Gluteus medius
  - Gluteus minimus
- Hip external rotators
  - Gluteus maximus
  - Piriformis
  - Gemellus superior
  - Gemellus inferior
  - Obturator internus
  - Obturator externus
  - Quadratus femoris
- Hip extensors
  - Gluteus maximus
  - Biceps femoris
  - Semitendinosus
  - Semimembranosus
- Hip adductors
  - Adductor magnus
  - Adductor longus
  - Adductor brevis
  - Pectineus
  - Gracilis

Sensorimotor Exercises

- Single leg stance on uneven surface
- Lunges in multiple planes with focus on maintaining proper knee position

Open and Closed Kinetic Chain Exercises

- Continue clamshells in pain-free range against resistance (OKC).
- Continue standing hip abduction, adduction, and extension against resistance (OKC).
- Continue bridging with marching (CKC).
- Side plank (CKC)
- Progress double and single leg press in pain-free range (CKC).

Techniques to Increase Muscle Strength, Power, and Endurance

- Progress Romanian Deadlift (RDL) with focus on lumbopelvic coordination.
- Squatting, first in Smith machine progressing to back squats in pain-free range (CKC)
- Begin deadlifts from floor with focus on proper form (CKC).
- Begin single leg squats in Smith machine with focus on maintaining proper knee position (CKC).

Neuromuscular Dynamic Stability Exercises

- Continue single leg lunge on wall with physioball (Figure 26-8) with focus on controlling knee valgus and hip adduction.

TIMELINE 26-1 **Nonoperative Rehabilitation of Femoroacetabular Impingement** (Continued)

PHASE III (weeks 4 to 8)	PHASE IV (weeks 8+)
• PT Modalities as needed • ROM-limited to pain-free motion • Mobilizations as needed • Elliptical trainer • TBS/TLS activities as recommended & tolerated • Hip band ambulation • Core stability • Side planks • Single leg stance on unstable surface with perturbations • Continue OKC/CKC/Plyo exercises • Lunges in multiple planes with focus on knee control (CKC) • Squats/deadlifts in pain-free range (CKC) • Single leg squats in Smith machine with focus on knee position (CKC) • Resisted sit to stand with kettle bell or dumbbell (CKC) • Double leg jumps on stable surface (Plyo) • Single leg bounces on mini-trampoline (Plyo)	• ROM-limited to pain-free motion • Mobilizations as needed • Progression to running as tolerated • TBS/TLS activities as recommended & tolerated • Hip band ambulation • Core stability • Continue OKC/CKC/Plyo exercises • Power lifts as indicated for specific sports • Double and single leg jumps on stable and unstable surfaces • Sport-specific exercises progressed

FIGURE 26-10. Resisted sit-to-stand with hips abducted and externally rotated (sumo squat) with dumbbell or kettle bell weight.

Plyometrics

- Double leg jumps on stable surface in pain-free range
- Single leg bouncing while maintaining contact on mini-trampoline

Functional Exercises

- Continue hip band ambulation
  - Forward/backward
  - Side-to-side
  - "Monster walking"
- Resisted sit-to-stand with hips abducted and externally rotated (sumo squat) with dumbbell or kettle bell weight (Figure 26-10)

Milestones for Progression to Advanced Sport-Specific Training and Conditioning

- No pain with ADL
- Pain free with all rehab activities
- Able to consistently perform single leg squat into full functional range without pain while controlling dynamic knee valgus without verbal cues
- Able to consistently perform vertical drop jump from 18 inches without pain while controlling dynamic knee valgus without verbal cues

Phase IV (weeks 8+)

Protection

- Continue to limit motion to pain-free range.

Management of Pain and Swelling

- Continue with nonsteroidal antiinflammatory drugs (NSAIDs) and cryotherapy with compression to the joint as needed.

Techniques for Progressive Increase in Range of Motion

Manual Therapy Techniques

- Continue for pain relief if indicated.

Soft Tissue Techniques

- Continue gentle massage to anterior hip with the focus on relaxation of regional musculature as needed.

Stretching and Flexibility Techniques for the Musculotendinous Unit

- Progress iliopsoas and low back extensor stretching as tolerated.
- Continue gentle stretching into combined flexion abduction external rotation as tolerated.

Other Therapeutic Exercises

- Progressive running program as tolerated
  - Begin with 10 minute jog, stopping if painful.
  - If pain free during run and over next 24 hours, progress by 5 minutes the next day; if not, stay at 10 minutes.
  - Continue to monitor and progress as above.
- Continue to progress TLS.
- Progress core stability training as tolerated.

Activation of Primary Muscles Involved

- Hip abductors
  - Gluteus medius
  - Gluteus minimus
- Hip external rotators
  - Gluteus maximus
  - Piriformis
  - Gemellus superior
  - Gemellus inferior
  - Obturator internus
  - Obturator externus
  - Quadratus femoris
- Hip extensors
  - Gluteus maximus
  - Biceps femoris
  - Semitendinosus
  - Semimembranosus
- Hip adductors
  - Adductor magnus
  - Adductor longus
  - Adductor brevis
  - Pectineus
  - Gracilis

Sensorimotor Exercises

- Progress single leg stance on uneven surface to incorporate perturbations.
- Lunges in multiple planes with focus on maintaining proper knee position while adding dynamic component such as twisting

Open and Closed Kinetic Chain Exercises

- Continue clamshells in pain-free range against resistance (OKC).
- Continue standing hip abduction, adduction, and extension against resistance (OKC).
- Continue bridging with marching (CKC).
- Continue side plank (CKC).
- Progress double and single leg press in pain-free range (CKC).

Techniques to Increase Muscle Strength, Power, and Endurance

- Progress resistance during RDL with focus on lumbopelvic coordination.
- Free squats in pain-free range with higher intensity (CKC).
- Continue deadlifts from floor with higher intensity and focus on proper form (CKC).
- Progress single leg squats in Smith machine with focus on maintaining proper knee position (CKC).
- Power lifts such as clean, jerk, snatch as indicated for specific sports

Neuromuscular Dynamic Stability Exercises

- Continue single leg lunge on wall with physioball with focus on controlling knee valgus and hip adduction, adding dumbbell resistance as needed.

Plyometrics

- Double and single leg jumps on stable and unstable surfaces in pain-free range

Functional Exercises

- Continue hip band ambulation.
  - Forward/backward
  - Side-to-side
  - "Monster walking"
- Squat to run medicine ball throws (Figure 26-11)

Sport-Specific Exercises

- Begin sport-specific drills as indicated including:
  - Running
  - Cutting
  - Jumping

Milestones for Progression to Advanced Sport-Specific Training and Conditioning

- Has full, functional, and pain-free range of motion as necessary for the athlete's particular sport during training activities
- Lower body strength is within 90% of the involved side during single leg squats in Smith machine.
- Lower body power is within 90% of the uninvolved side.
  - Single hop
  - Triple hop
  - Crossover hop
  - 6-minute timed hop
- Athlete has achieved proper scores in validated functional tests that challenge range of motion, strength, and coordination as appropriate for his or her sport such as the Lower Extremity Functional Test.

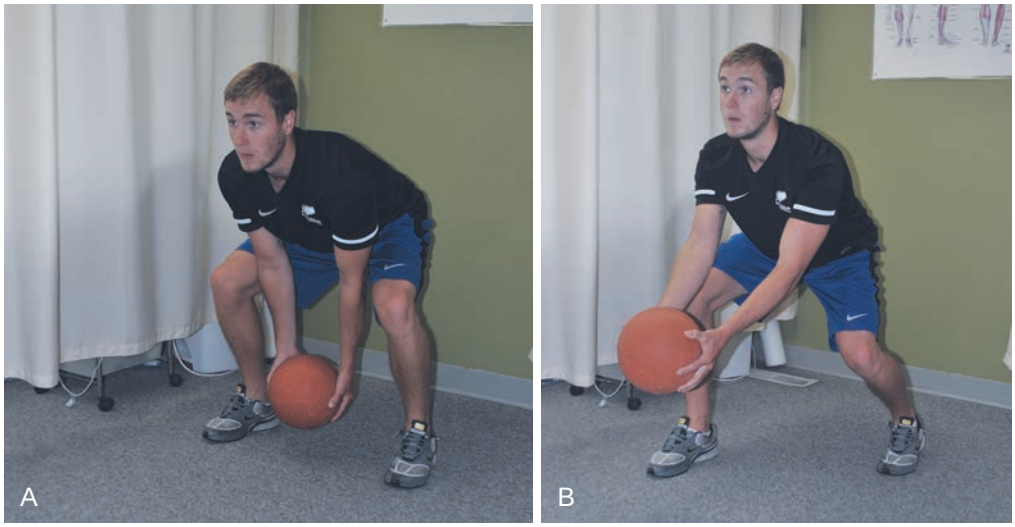

FIGURE 26-11. Squat to run medicine ball throws. Squat (**A**) then throw (**B**) as initiating run.

Criteria for Abandoning Nonoperative Treatment and Proceeding to Surgery or More Intensive Intervention

- Pain-free ROM does not improve to within functional limits of the athlete's particular sport.
- Unable to progress strength or coordination owing to range of motion limitations
- Significant restrictions based on bony morphology observed on radiographs

Tips and Guidelines for Transitioning to Performance Enhancement

- Progress training in a progressive fashion to make sure that the muscles and supporting structures have sufficient time to adapt to the loads unique to the sport.
  - Start with simple controlled sport specific drills in single plane.
  - Progress to more complex multidirectional drills.
  - Advance to more unpredictable activities such as partial and then complete scrimmages.

Performance Enhancement and Beyond Rehabilitation: Training/Trainer and Optimization of Athletic Performance

- Make modifications in training to reduce the amount of internal rotation, adduction, and/or flexion at the hip.
  - Limit squat depth.
  - Convert to sumo squat (see Figure 26-10).
- Focus on controlling dynamic knee valgus during training by avoiding hip adduction and internal rotation during activities.
- If unable to make necessary modifications, the athlete may need surgical intervention to reduce the impingement.

Specific Criteria for Return to Sports Participation: Tests and Measurements

- No pain during gym activities
- No pain during sport-specific drills
- No pain during practice including scrimmages and game simulation for 2 weeks

Evidence

Austin AB, Souza RB, Meyer JL, et al: Identification of abnormal hip motion associated with acetabular labral pathology. *J Orthop Sports Phys Ther* 38:558–565, 2008.

This case study presents a patient with a diagnosis of femoroacetabular impingement who responded well by training to reduce hip adduction and internal rotation. (Level IV evidence)

Bedi A, Dolan M, Hetsroni I, et al: Surgical treatment of femoroacetabular impingement improves hip kinematics: a computer-assisted model. *Am J Sports Med* 39:43S, 2011.

This case series of 10 patients compared preoperative and postoperative hip range of motion using computer-assisted 3-dimensional analysis. Concluded that osteoplasty reliably improves hip kinematics, specifically in internal rotation in a flexed position. (Level IV evidence)

Ekstrom RA, Donatelli RA, Carp KC: Electromyographic analysis of core trunk, hip, and thigh muscles during 9 rehabilitation exercises. *J Orthop Sports Phys Ther* 37:754–762, 2007.

This prospective, single-group, repeated-measures study of 30 subjects compared the EMG activity of core trunk, hip, and thigh muscles during 9 rehabilitation exercises. Concluded that side plank had the highest activity in the gluteus medius. (Level III evidence)

Grindem H, et al: Single-legged hop tests as predictors of self-reported knee function in nonoperatively treated individuals with anterior cruciate ligament injury. *Am J Sports Med* 39:2347–2354, 2012.

This study evaluated the predictive abilities of single leg hop tests for return to sport after ACL injury without reconstruction. It found that they were good predictors, and suggests that they may be useful tests in other nonoperative lower extremity injuries. (Level II evidence, but not in the way we apply it)

Hewett TE, et al: Biomechanical measures of neuromuscular control and valgus loading of the knee predict anterior cruciate ligament injury risk in female athletes: a prospective study. *Am J Sports Med* 33:492–501, 2005.

This study looked for predictors of ACL injury and found that the vertical drop jump demonstrates dynamic knee valgus tendencies during functional activities and is a predictor of ACL injury. This suggests that the same test may predict dynamic knee valgus in other subjects. (Level II evidence, but not in the way we apply it)

Johnston TL, Schenker ML, Briggs KK, et al: Relationship between offset angle alpha and hip chondral injury in femoroacetabular impingement. *Arthroscopy* 24:669–675, 2008.

This study compared surgical findings with preoperative measurements of range of motion and alpha angle in 82 patients. It concluded that increased offset alpha angle was correlated with increased chondral damage, labral injury, and decreased range of motion. (Level II evidence)

Kapron AL, et al: Hip internal rotation is correlated to radiographic findings of cam femoroacetabular impingement in collegiate football players. *Arthroscopy* 28:1661–1670, 2012.

This study compared hip IR range of motion limitations and alpha angle measurements on x-ray. It concluded that there was a strong correlation. (Level IV evidence)

Krause DA, Jacobs RS, Pilger KE, et al: Electromyographic analysis of the gluteus medius in five weight-bearing exercises. *J Strength Cond Res* 23(9):2689–2694, 2009.

This study compared activation of the gluteus medius in 20 healthy subjects during five weight-bearing exercises. It concluded that single leg activity was greater than double leg. Although balance cushion showed increased activity, it was not significantly greater than on solid surfaces. (Level III evidence)

Martin HD, et al: The pattern and technique in the clinical evaluation of the adult hip: the common physical examination tests of hip specialists. *Arthroscopy* 26:161–172, 2010.

The purpose of this study was to systematically evaluate the technique and tests used in the physical examination of the adult hip performed by multiple clinicians who regularly treat patients with hip problems and identify common physical examination patterns. This article describes many intraarticular tests including single leg stance phase and SLR against resistance. (Level IV)

McCurdy K, O'Kelly E, Kutz M, et al: Comparison of lower extremity EMG between the 2-leg squat and modified single-leg squat in female athletes. *J Sport Rehabil* 19:57–70, 2010.

This study compared EMG activity during 2-leg squat and single-leg modified squat in 11 female athletes. It concluded that the modified single-leg squat produced significantly higher EMG in gluteus medius, hamstrings, and quadriceps than 2-leg squat. (Level III evidence)

Rylander JH, Shu B, Andriacchi TP, et al: Preoperative and postoperative sagittal plane hip kinematics in patients with femoroacetabular impingement during level walking. *Am J Sports Med* 39:36S, 2011.

This case series used motion capture to analyze kinematics and kinetics of gait preoperatively and one year after arthroscopic osteoplasty in eleven subjects. This article suggests that patients with FAI present with abnormal gait kinematics and that surgery may be required to restore normal patterns. (Level IV evidence)

Yazbek PM, Ovanessian V, Martin RL, et al: Nonsurgical treatment of acetabular labrum tears: a case series. *J Orthop Sports Phys Ther* 41:346–353, 2011.

This cases series described a treatment program with positive outcomes in four patients with acetabular labral tears. The authors suggest that controlling knee valgus may be the most effective nonsurgical treatment for these patients. (Level IV evidence)

Multiple-Choice Questions

QUESTION 1. Into what direction should range of motion be aggressively pushed?

A. Flexion
B. Adduction
C. Internal Rotation
D. None of the above. May be restricted by bony morphology

QUESTION 2. What muscle activation should be minimized during Phase I?

A. Gluteus medius
B. Quadriceps
C. Iliopsoas
D. Hamstrings

QUESTION 3. What motion should be controlled during return to sport activities?

A. Dynamic knee valgus
B. Hip extension
C. Trunk extension
D. None of the above

QUESTION 4. During which phase can simple plyometrics such as submaximal jumps on a shuttle be initiated?

A. Phase I
B. Phase II
C. Phase III
D. Phase IV

QUESTION 5. Activation of which muscle group should be reinforced during each phase of rehab?

A. Hip flexors
B. Quadriceps
C. Hip abductors
D. Hamstrings

Answer Key

QUESTION 1. Correct answer: **D** (see Guiding Principles of Nonoperative Rehabilitation)

QUESTION 2. Correct answer: **C** (see Phase I)

QUESTION 3. Correct answer: **A** (see Phase IV)

QUESTION 4. Correct answer: **B** (see Phase II)

QUESTION 5. Correct answer: **C** (see Box A)

POSTOPERATIVE REHABILITATION AFTER FEMOROACETABULAR IMPINGEMENT TREATMENT, LABRAL REPAIR, AND LABRAL DEBRIDEMENT

Nancy J. Bloom, PT, DPT, MSOT, John C. Clohisy, MD, and Marcie Harris-Hayes, PT, DPT, MSCI, OCS

Indications for Surgical Treatment

- Nonoperative treatment for at least 3 to 6 months has failed to resolve hip pain. Optimal nonoperative treatment would include corrections for impairments in:
  - Sitting and standing alignment
  - Precision of motion during functional activities, exercise and sport
  - Muscle performance of the proximal hip muscles

  The time frame for nonoperative care may be affected by value of the athletic participation for the individual. For example, a professional athlete may choose surgery earlier than a recreational athlete because return to sport is critical to their life.
- Persistent pain associated with basic functional activities, such as walking or sitting
- There is no pain with basic functional activities, but pain is persistent with athletic activities.
- Physical examination and hip imaging consistent with hip impingement disorder

Brief Summary of Surgical Treatment

Major Surgical Steps

- Hip exposure via arthroscopy or open technique (mini-open or surgical dislocation)
- Correction of acetabular rim disease (rim osteoplasty, labral repair, partial labral resection, articular cartilage procedures)
- Correction of femoral disease/deformity (head-neck osteoplasty, relative neck lengthening, trochanteric osteotomy

Factors That May Affect Rehabilitation

See Table 26-1.

- Less invasive (arthroscopy or limited anterior approaches) or open surgical dislocation
- Open dislocation is performed with a trochanteric osteotomy, which may extend the partial weight-bearing phase (4 weeks).

Table 26-1 Postoperative Precautions for Hip Arthroscopy and Surgical Dislocation

Procedure	Weight Bearing	Movement			
		Hip Flexion	Hip Extension	Hip Rotation	Hip Abduction
Labral resection	50% WB* × 2 weeks then progress to full WB	Active and Passive w/in comfort level but no >90° × 4 weeks	No >0° × 4 weeks	As tolerated	As tolerated
Labral repair	FF × 2 weeks then progress to full WB	Active and Passive w/in comfort level but no >90° × 4 weeks	No >0° × 4 weeks	10° MR and LR × 4 weeks	As tolerated
Osteoplasty chondroplasty osteochondroplasty	50% WB × 2 weeks then progress to full WB	Active and Passive w/in comfort level but no >90° × 4 weeks	No >0° × 4 weeks	As tolerated	As tolerated
Microfracture	FF** × 8 weeks then progress to full WB	Active and Passive w/in comfort level but no >90° × 4 weeks	No >0° × 4 weeks	As tolerated	As tolerated
Surgical dislocation w/trochanteric osteotomy	FF × 4 weeks then progress to full WB	Active and Passive w/in comfort level but no >90° × 4 weeks	No >0° × 4 weeks	As tolerated	4 weeks: No active abduction 8 weeks: add resistance
Arthroscopy + limited open osteochondroplasty	The addition of a limited anterior open procedure to correct CAM impingement does not add any additional precautions. Follow precautions for procedures performed in the scope.				
Combinations	Review procedures and follow most conservative precautions. Exp 1: Labral repair and osteoplasty: TTWB × 2 weeks, no MR or LR or hip flexion >90° Exp 2: Labral repair, osteoplasty, and microfracture: TTWB × 8 weeks, no MR or LR or hip flexion >90°				

*WB, weightbearing;**FF, foot flat.
Capsulorraphy: 6 weeks in brace. No CPM.

- Labral repair (as opposed to partial resection) may extend partial weight-bearing phase (2 weeks).
- Microfracture will increase time of protected weightbearing.

Before Surgery: Overview of Goals, Milestones, and Guidelines[1]

Assuming nonoperative treatment has not satisfactorily resolved the hip symptoms, the patient needs to be readied for surgery. Treatment should include:

- Education regarding positioning, mobility and equipment required postsurgically.
  - Lying down
  - Sitting
  - Crutch training: gait, stairs, sit to and from standing
  - Bed mobility
  - Transfers: car, commode, tub/shower
- Basic strengthening for upper extremities and nonsurgical lower extremity (LE)
- Strengthening for primary hip muscles of the surgical LE without increasing pain
- Encourage cardiovascular fitness to build endurance. Select activities or equipment that minimize forces due to weightbearing and avoid extreme ranges of hip motion. The activity should not increase symptoms.
- Education of potential precautions and postoperative activity level

GUIDING PRINCIPLES OF POSTOPERATIVE REHABILITATION

- Recognize that surgical techniques can be combined; therefore follow the most conservative protocol. For example, labral tear and osteochondroplasty will need to follow labral tear precautions.
- Understand the surgical procedure or combination of procedures and associated precautions (see Table 26-1).
- Understand the specific tissues affected in the surgery (e.g., labrum, acetabulum, femoral head, femoral head-neck junction, cartilage, muscles) and the healing rate of tissues and the moderators affecting healing, such as age, anthropomorphics, and health of patient. Understand the alignment, positions, and movements that may increase stress to the involved structures.
- Most hip pain problems exist several months before surgery, which results in significant tissue adaptations. The longer the duration of symptoms, the more likely it is to find significant impairments in ROM; strength and flexibility and recovery may be slower. Exercise selection should be carefully graded to match the condition of the tissues.
- Avoid pushing end ROM. Normal ROM is highly variable and individual differences need to be respected.
- Emphasis should be placed on precision of movement and proper muscle activation during all therapeutic exercise, functional activities, and sporting skills.
- Understand structural variations and their impact on goals for treatment.
- Musculoskeletal impairments in the nonoperative lower extremity and lumbar spine are common and need to be addressed.

[1]*Prehabilitation, if appropriate, is described in the Nonoperative Rehabilitation section of this chapter.*

Phase I (days 0–2, 4, or weeks 8 postoperatively depending on procedure): Immediate Postoperative Period, Minimal Weightbearing (Foot Flat)

See Table 26-1.

Clinical Pearls

- Movement impairments may be observed during attempted exercise performance. For example, hip medial rotation (MR) may be observed during hip flexion exercises. Observed impairments should be corrected.
- In general, do not push hip ROM too soon or too aggressively.
- Very often a continuous passive movement system is prescribed for passive range of hip flexion and extension. Do not rely on the machine setting alone for ROM. To avoid hip flexion beyond 90°, educate the patient to consider the influence of the trunk/pelvic position on hip flexion when setting up to use the CPM device. When out of the device, precise hip flexion is most easily achieved when combining hip and knee flexion.
- An active straight leg should not be used for hip flexor or quadriceps strengthening or hamstring stretching in this population.
- Pain in the adductor region is often felt during hip abduction exercises. In those cases, cue to activate the gluteus medius and downgrade the movement until it can be performed without a sensation in the adductors.

Goals

- Minimize stress to the affected structures during basic mobility and exercise.
- Decrease pain and inflammation.
- Minimize the effects of immobilization (joint, muscle, and circulation).
- Begin cardiovascular activities within precautions.

Protection

- Instruction in precautions for exercise and daily activities (see Table 26-1)

- Two crutches for ambulation
- Bracing if prescribed by surgeon

Equipment

- Raised toilet seat
- Tub bench and hand held shower
- Long-handled devices: reacher, shoehorn, sponge
- Continuous passive motion (CPM) device
- Assistive device: crutches
- Compressive stocking or mechanical compressive device

Basic Functional Mobility and Positions

- Lying down:
  - Supine (most frequently used): pillow under knees for first few days only. May also place bolsters/towel roll/pillow on the outside of thigh to control lateral rotation (LR).
  - Side lying on uninvolved side (once patient is able to log roll while maintaining precautions, see bed mobility): pillows between knees. Avoid side lying on involved side.
  - Prone (less commonly used for resting position): pillow under hips.
- Sitting: Assess use and type of chair at home. Make recommendations to achieve the following:
  - Hips should be higher than knees (may need wedge or pillow on chair or use of recliner).
  - Weightbearing should be symmetrical
  - Avoid low surfaces.
  - Feet and spine should be supported.
  - Avoid prolonged periods (>20 to 30 minutes) of sitting upright.
  - Do not cross legs.
- Standing with crutches: Allow the foot on the involved side to rest flat on the ground, but avoid putting too much weight through the involved limb. Foot flat is preferred over toe-touch weightbearing to avoid prolonged positioning of hip flexion. Avoid leaning on axillae. Avoid prolonged periods of standing.

FIGURE 26-12 Sit to and from stand. The goal is to avoid hip flexion greater than 90° and place minimal weight on the involved lower extremity. Scoot to edge of chair, place involved lower extremity in front of body with knee straight, and use upper extremities to assist.

- Bed mobility:
  - Rolling: Assume hook lying, place pillow between knees, and log roll toward the nonsurgical side.
  - Supine to sitting: Perform log rolling as above. Once on side, use upper extremities or uninvolved LE to assist in moving the surgical LE to the edge or push up to sitting.
- Sit to and from stand: Scoot forward in the chair. Place involved LE in front of body with knee straight and the opposite foot underneath the seat. Place hands on armrests and use upper extremities to assist standing or sitting. Control the descent when sitting down (Figure 26-12).
- Gait: Use two crutches and minimal weightbearing. Encourage heel to toe pattern to foster normal hip, knee, and ankle motion without placing more than the weight of limb on the foot.
- Stairs: Instruct in a step to cadence, lead with the involved LE when descending stairs, and lead with the uninvolved LE when ascending stairs. The use of two crutches or one crutch and a railing is dependent on the safety and comfort of the patient.

TIMELINE 26-2: **Postoperative Rehabilitation After Femoroacetabular Impingement Treatment, Labral Repair, and Labral Debridement**

PHASE I (weeks 0 to 2, 4, or 8)

- Hip ROM:
  - Flexion/extension: No hip flexion >90°, no hip extension >0°, CPM to 60°
  - MR and LR: 10° for labral repair, otherwise as tolerated
  - Abduction: no active abduction with surgical dislocation for 4 weeks to protect the trochanteric osteotomy site for bony healing
  - Bracing if desired by surgeon
- Function:
  - Gait: Use two crutches and encourage heel-to-toe pattern while maintaining WB precaution
  - Stairs: Step to pattern
  - Adjust positioning for sitting and lying to maintain hip precautions
- Ice, compressive stockings, elevation
- Gentle active range of motion (AROM) for all allowed hip motions: on mat, in pool, upright bike
- Gentle stretching and ROM for other body regions
- Fitness: Upper-body ergometer or cycling with uninvolved LE

PHASE II (weeks 2 to 12)

- Hip ROM: Increase in all directions as tolerated after 4 weeks
- Gait:
  - Progress WB to 50%, then gradually to full WB
  - Reduce use of crutches balanced with increased walking distance
  - Water walking
- Stairs: continue step to pattern
- Ice, compressive stockings, elevation
- Strength:
  - AROM against gravity for all key hip manual muscle (mm) tests; no active straight leg raise (SLR)
  - Increased WB in standing exercises
- Stretching and active exercise for other body regions as tolerated
- Fitness: Upper-body ergometer or cycling on upright bike

- Car transfers: Seat should be moved back and reclined. Back up toward the seat, using car or crutch to assist in sitting down. Lean back into car and use hands or opposite foot to assist moving the LE on the surgical side into the car.

Management of Pain and Swelling

- Ice
- Oral pain medications as prescribed by physician
- Elevation of LE in supine position
- Compressive stocking or mechanical compression devise

Techniques for Progressive Increase in Range of Motion, Muscle Activation, and Other Therapeutic Exercises

Exercises may have multiple purposes such as increasing joint ROM, muscle activation, strengthening, endurance, or flexibility.

Exercises Primarily for the Hip

- Hip flexion: (Precaution: no hip flexion >90°, no active straight leg raises[1])
  Cue to stabilize pelvis by using the lower abdominals[2]
  - Supine or sitting semi reclined: use of CPM to 60°
  - Supine: heel slide
    - Slide foot along surface to the hook-lying position and return. Keep hip in neutral rotation. If painful, a cue to dig the heel in slightly to increase the use of the hamstrings may help. Cue to relax between repetitions.
      - Initially may need to place a pillow under the knees for comfort, but eventually the pillow should be removed to achieve hip extension to 0°.
  - Supine hook-lying: active-assistive hip flexion toward 90°
    - Use towel or upper extremities (UEs) to assist with lifting thigh (Figure 26-13)
    - Progress to active hip flexion without assistance.

FIGURE 26-13 Supine/hook lying: active-assistive hip flexion toward 90°. Use towel to assist with lifting thigh. Gradually progress the exercise by reducing the amount of assistance.

  - Quadruped: partial rocking backward
    - Start with the hips in 60° of flexion. Cue to push with the hands while rocking backward toward 90°. Avoid flexing the lumbar spine as the hip flexes.
  - Standing on uninvolved LE: active hip flexion through partial range motion
- Hip extension: *(Precaution: no hip extension >0°)*[3]
  - Any position: gluteal isometric contractions.
  - Standing on uninvolved LE:
    - Active hip extension (knee extended): lift lower extremity from starting position to 0° (hamstrings)
    - Active hip extension (knee flexed to 90°): lift lower extremity from starting position to 0° (gluteus maximus)
  - Prone with a pillow placed under the hips to avoid increased hip joint force during active hip extension[3] (may need to avoid until after removal of ankle pumps or in general rolling over is safe given rotation precaution). Cue to contract abdominals before performing hip extension.

TIMELINE 26-2 Postoperative Rehabilitation After Femoroacetabular Impingement Treatment, Labral Repair, and Labral Debridement (Continued)

PHASE III (weeks 2 to 16)	PHASE IV (weeks 12 to 24)

• Hip ROM: Increase in all directions as tolerated
• Gait:
  • Increase distance to 10,000 steps/day using optimal gait pattern
  • Include hills and uneven surfaces
• Stairs: step over pattern
• Driving: adjust car seat to avoid excessive hip flexion or MR
• Strength:
  • Add resistance for key hip mm
  • Standing exercises in full WB with double or single limb support
• Stretching and active exercise for other body regions: introduce partial squats and lunges
• Introduce drills for sports readiness: form first, then speed and duration
• Balance and neuromuscular training exercises
• Fitness: Swim, biking, running, use of elliptical
	• Hip ROM, strength, and flexibility: Continue to perform specific exercises targeted at precise joint motion, activation of key hip mm, and stretching one and two joint muscles without substitution or associated faulty motion.
	• Fitness: Increase speed and endurance with swimming, biking, running, or use of the elliptical
	• Advanced exercises and drills: jumping, shuttle runs, cutting
	• Sport-specific exercises and drills: use of equipment, partners, sport cord

FIGURE 26-14 Prone: active hip extension with the knee flexed. **A,** Correct performance because the hip extends toward 0 degrees but not beyond. **B,** Incorrect performance because there is too much hip extension.

  - Active hip extension (knee flexed to 90°): lift lower extremity from starting position to 0° (gluteus maximus). Cue to contract the gluteals and avoid pushing down with the nonmoving LE (Figure 26-14)
  - Active hip extension (knee extended): lift lower extremity from starting position to 0° (hamstrings) (Figure 26-15).
  - Active knee flexion: Although the motion is not hip extension, this exercise is a low level hamstring strengthening and stretch for tensor fascia lata-iliotibial band (TFL-ITB) and rectus femoris. Hip should be in neutral abduction/adduction and rotation. Knee should be fully flexed. If patient has a short TFL-ITB and has trouble keeping the pelvis stable as the knee is flexed, allow the hip to be positioned in slight abduction for this exercise. As flexibility increases, the hip may be positioned in midline.
- Hip abduction/adduction: (Precaution with surgical dislocation: No active abduction × 4 weeks)
- Cue to activate gluteus medius and avoid lateral pelvic tilt as a substitution with the following exercises:

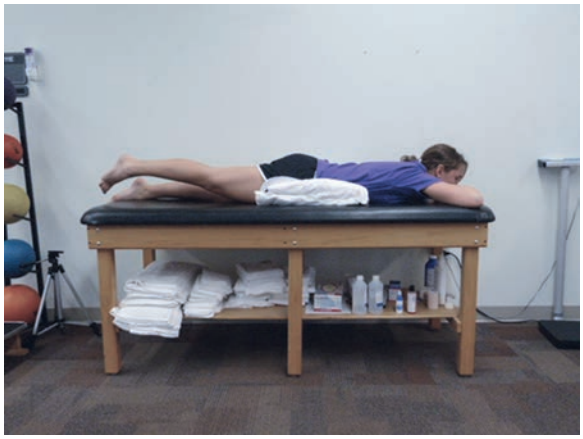

FIGURE 26-15 Prone: Active hip extension with the knee extended. Lift lower extremity from starting position toward 0° hip extension.

  - Standing on uninvolved LE: Abduct hip with slight extension and neutral rotation. Cue to keep pelvis stable and avoid lateral pelvic tilt (Figure 26-16).
  - Supine: Abduct and adduct hip while maintaining neutral rotation.
  - Prone with a pillow placed under the hips: (May need to avoid until after removal of ankle pumps or in general rolling over is safe given rotation precaution.)
  - Active hip abduction and adduction maintaining neutral rotation.
  - Side lying: Keep hips and knees flexed and pillow between the knees. (Precaution: Avoid these exercises which include LR if a labral repair has been performed.)
    - Active abduction and LR (knees separate and feet stay together) (Figure 26-17)
    - Progress to active abduction and LR by lifting the lower extremity off the pillow. *If a labral repair has been performed, cue to abduct the hip in neutral rotation.* Avoid lateral pelvic tilt. Focus on muscle activation of gluteus medius not on performing high numbers of repetitions (Figure 26-18).
- Hip rotation: (Precaution with labral repairs: avoid >10° medial rotation (MR) and LR (LR) × 4 weeks) Perform partial ROM with the following exercises.
  - Supine: Hips and knees extended
    - Roll whole lower extremity in and out. (Cue to move knee and foot together, not just the foot.)
  - Supine hook lying:
    - Allow whole LE to rotate outward and inward (Figure 26-19).
  - Standing on uninvolved LE with involved foot resting on heel, forefoot lifted.
    - Active MR and LR. (Cue to move knee and foot together, not just the foot.) Also avoid lateral pelvic rotation as a substitution (Figure 26-20).
  - Prone with a pillow placed under the hips and knee flexed to 90°.
    - Active MR and LR. (May need to avoid until after removal of ankle pumps or in general rolling over is safe given rotation precaution.)

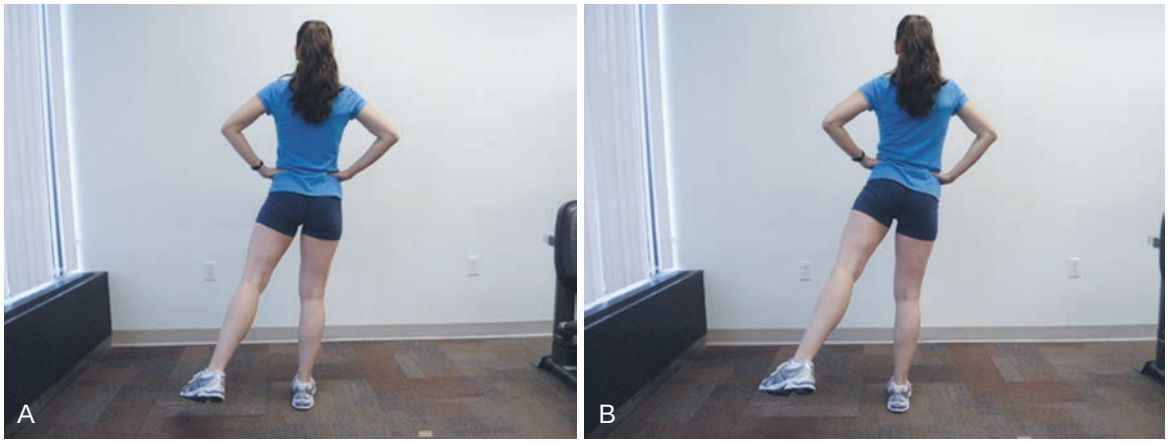

FIGURE 26-16 Standing hip abduction. *A,* Correct: using the posterior gluteus medius, abduct the involved hip in slight extension and neutral rotation. *B,* Incorrect: lateral pelvic tilt as substitution of for hip abduction.

- Other (aquatic and bike)
  - Aquatic exercise: May begin after adequate incision healing and physician permission.
    - Use of flotation device to suspend self while performing
      - Active ROM of the hip within precautions
      - Bicycle motion
    - Use of kick board for flutter kick. (Keep legs below the surface of the water to avoid excessive hip and back extension.)
    - No breast stroke
  - Upright biking:
    - 10 to 20 minutes
    - Adjust height of seat to avoid hip flexion greater than 80°.
    - Low resistance

Exercises for Other Body Regions

- Ankle pumps
  - May be progressed to resistance with elastic band
- Sitting and leaning back on upper extremities: active knee extension with active ankle dorsiflexion (low level quadriceps strength and gentle stretch of hamstrings and gastrocnemius)
- General upper extremity strengthening as allowed while maintaining precautions.

Cardiovascular Fitness

- Upper body ergometer
- Stationary cycling with uninvolved lower extremity only. Uninvolved lower extremity propped so that it is relaxed and not being used to pedal.

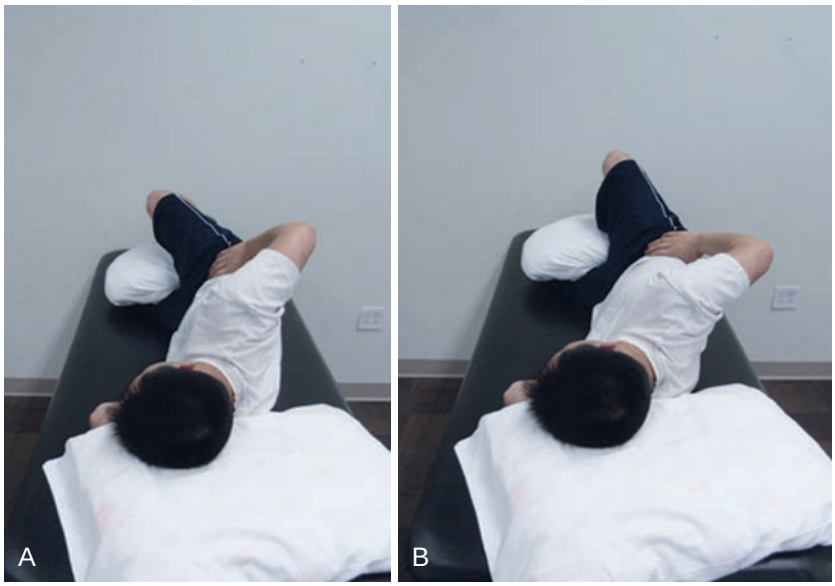

FIGURE 26-17 Side-lying hip abduction (low level). *A,* Correct: active abduction and lateral rotation (knees separate and feet stay together). *B,* Incorrect: pelvic rotation as substitution for hip lateral rotation

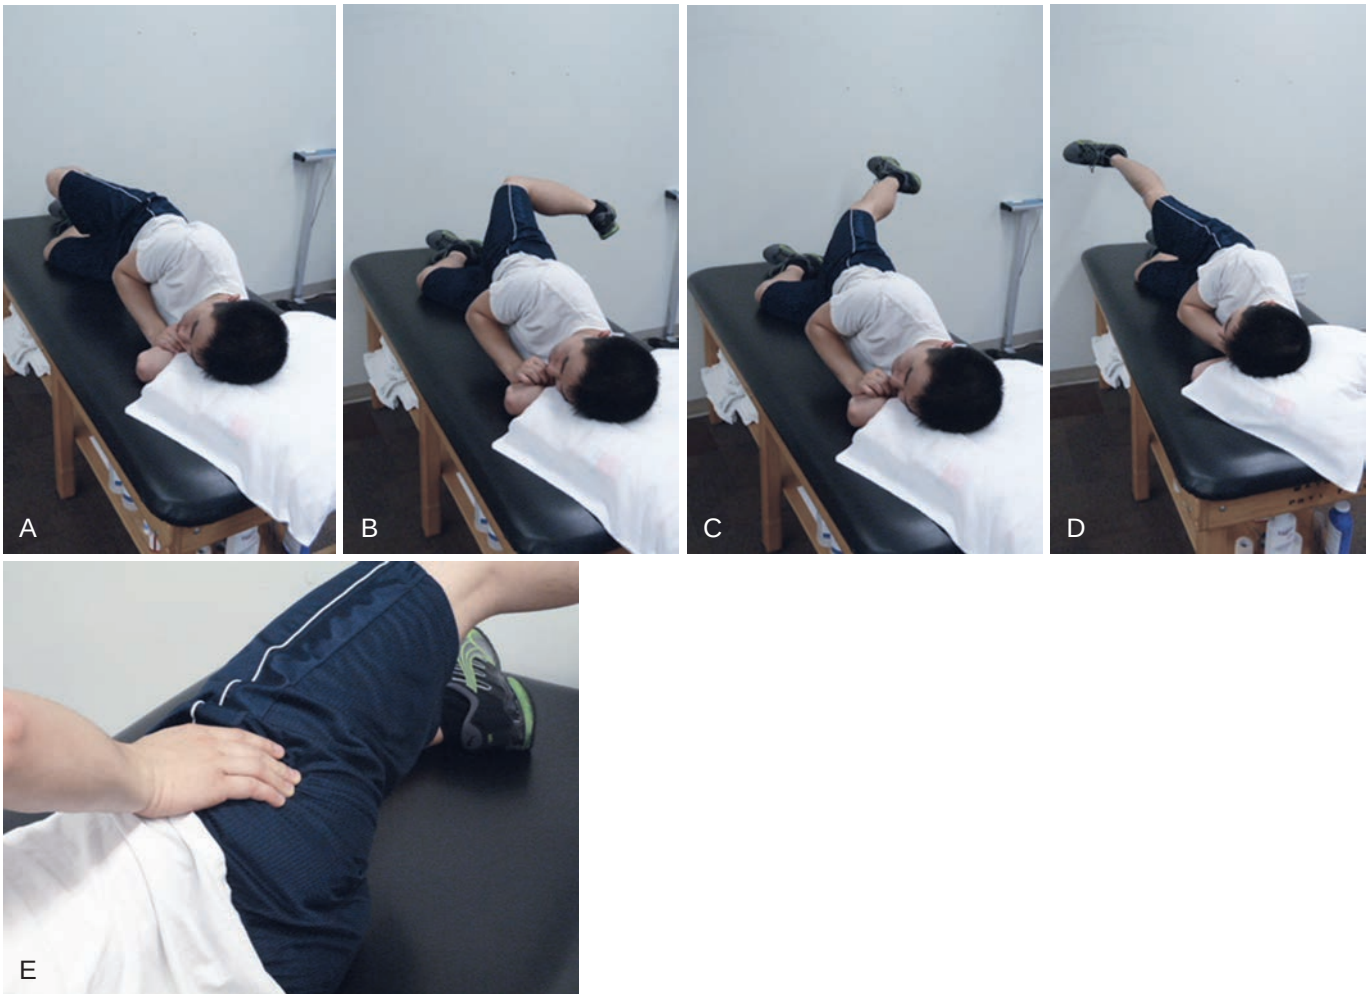

FIGURE 26-18 Side-lying hip abduction (higher level). *A,* Active abduction and lateral rotation. *B,* Abduct and extend hip with knee flexed; maintain neutral to slight lateral rotation. *C,* Extend knee. *D,* Incorrect: abduction in too much flexion. *E,* Placement of hand to monitor muscle contraction.

FIGURE 26-19 Supine hip rotation through partial range of motion. *A,* Medial rotation. *B,* Lateral rotation.

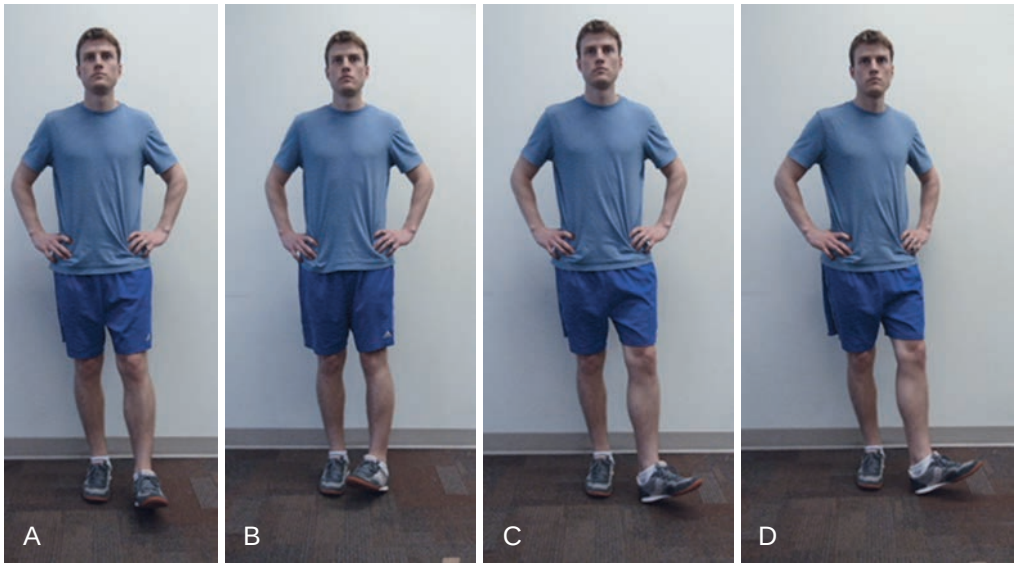

FIGURE 26-20 Standing hip rotation. *A,* Starting position. *B,* Medial rotation. *C,* Lateral rotation. *D,* Incorrect: lateral tibial rotation as substitution for hip lateral rotation (also avoid pelvic rotation).

Milestones for Progression to the Next Phase

- Adequate pain control
- Weight-bearing precautions changed

Phase II (weeks 2 to 12 postoperatively depending on procedure): Partial to Full Weightbearing

See Table 26-1.

Clinical Pearls

- Movement impairments may be observed during performance of daily activities. For example, side bending of the trunk or hip drop may be observed during stance phase of gait. Observed impairments should be corrected.
- Muscle performance during activity is determined by the pattern of movement. Correction of faulty patterns is best achieved by training the correct pattern and not isolated "strengthening" of a muscle.[2] For example, training to perform sit to stand with the knees aligned over the feet is needed in addition to strengthening of the hip abductors and lateral rotators.
- Although cleared for weightbearing, the joint and surrounding soft tissue muscles may not be ready. Avoid gait deviations by using an appropriate assistive device for the proper amount of time, ie transition from walking with two crutches to one crutch part-time to no crutches.
- As hip rotation ROM is increased, consider structural variations in acetabular or femoral versions. For example, if someone has femoral anteversion, the neutral position for hip rotation may appear medially rotated. This patient should be careful with pushing lateral hip rotation and flexion and extension should be performed with the appearance of slight MR. In general males tend to be more retroverted and females more anteverted in the femur.
- People often have problems in both hips so be cautious in using the strength and ROM of the nonsurgical hip as the target for goal achievement.
- Pain and movement impairments in the hip are often combined with problems in the lumbar spine. Therefore, it is important to observe and address the relative flexibility between the hip and the lumbopelvic region. For example, when flexing the involved hip, monitor the lumbar spine to avoid lumbar flexion or rotation.
- Muscle performance of the primary hip muscles is key. Cues to activate the iliopsoas, deep lateral rotators, posterior gluteus medius, and gluteus maximus are important during exercise to promote precise hip motion. Be aware of overuse of the hip adductors during exercise and functional activities.
- People vary in their general joint mobility. The best indication is obtained by assessing the ease of movement during passive motion. Sometimes non-weightbearing strengthening exercises, particularly for the abductors, can be uncomfortable for those with increased joint mobility. In those cases avoid sidelying as a position for strengthening and promote strength through functional activities, such as sit to stand, single leg stance and sidestepping.

Goals

- Within precautions, decrease dependence on assistive device for ambulation and gradually increase distance walked while optimizing gait pattern.
- Progress ROM within patient comfort level, particularly for hip flexion, MR, and LR. Moving precisely through the range frequently is more important than pushing end-range motion.
- Control pain and edema as activity level gradually increases (return to work or school).
- Prepare for return to work/school.
- Progress cardiovascular activities within precautions.

Protection

- Instruction in precautions for exercise and daily activities (see Table 26-1).
- Assistive device for ambulation

Equipment

- Continue use of equipment listed in phase I if appropriate

Basic Functional Mobility and Positions

- Lying down
  - Supine encourage limited use of pillow under knees. May place bolsters/towel roll/pillow on the outside of thigh to control LR.
  - Side lying on uninvolved side: Recommend continued use of pillows between the knees. May begin side lying on involved side. This position may be more tolerable if towel rolls or small pillows are placed above and below the greater trochanter.
  - Prone: May be more tolerable if pillow placed under the hips.
- Sitting: May tolerate increased time in sitting. Assess use and type of chair at home and work/school. Patient may tolerate sitting with hips at 90°. Otherwise, continue to follow recommendations described in Phase I.
- Standing with crutches: Maintain weight-bearing precautions during stance. Avoid excessive hip extension, which may be caused by forward sway of the pelvis or hyperextension of the knee. The hip should be maintained in neutral rotation. Use the distal femur, not the foot, as a guide for the hip rotation position.
- Bed mobility: Encourage continued use of log roll to protect lumbopelvic region. Recommendations from Phase I may continue to be used as needed for patient comfort.
- Sit to and from stand: Maintain weight-bearing precautions during the movement. To avoid too much hip flexion, scoot to the edge of seat maintaining a neutral lumbar spine alignment. Straddle feet so that the foot of involved side is back and the other is forward. During standing and sitting, keep the knees aligned over the second toe and use quadriceps and gluteals to control motion (Figure 26-21).
- Gait:
  - Pre-gait: To determine 50% weightbearing, divide patient's weight in half and use scale to monitor amount. Place the opposite foot on a step of equal height of the scale surface and place foot on involved side on the scale. Transfer weight to scale until the desired amount of weight is achieved. Practice weightshifting to target weight several times.
- Initial gait: Practice gait with 50% weightbearing using two crutches. Monitor symptoms and reduce weightbearing if 50% is too painful. Some soreness is expected; however, pain should not be sharp or persist so that weightbearing is limited for the rest of the day. Encourage heel to toe pattern to foster normal hip, knee, and ankle motion without violating precautions.
- Gait progression: Over the next 4 weeks, gradually increase weightbearing, reduce use of assistive device, and increase distance walked while maintaining optimal gait pattern. For example:
  - 50% WB, two crutches, household distances
  - 100% WB, two crutches, household and community distances
  - 100% WB, one crutches in household, two crutches in community
  - 100% WB, one crutch for all walking,
  - 100% WB, no crutch short distances, one crutch for longer distances
  - 100% WB, no assistive device for limited distances

Avoid prolonged hip extension during the stance phase to reduce stress on the anterior hip joint structures. A helpful cue is to lift the heel sooner after midstance which will allow earlier hip and knee flexion.

May use pedometer to quantify the amount of walking. As patient is progressed monitor symptoms and modify weightbearing, use of assistive device or distance walked accordingly. **Do not progress gait until gait pattern is optimal.** (No trunk sidebending, hip drop, or excessive hip rotation.)

FIGURE 26-21 Sit to stand. To avoid too much hip flexion, scoot to the edge of seat maintaining a neutral lumbar spine alignment. Straddle feet so that the foot of involved side is back and the other is forward. During standing and sitting, keep the knees aligned over the second toe and use quadriceps and gluteals to control motion.

FIGURE 26-22 Posterior glide provided during passive hip flexion. Apply a gentle posterior force over the proximal femur to achieve precise motion in those with limited and painful hip flexion.

  - Water walking may be used during this phase to progress weightbearing. Start by walking with water level chest high. Gradually reduce water level to increase the challenge.
  - Turning: Avoid pivoting on involved side. Pick up foot and turn using a series of small steps.
- Stairs: Continue with step to cadence until 100% weightbearing, and then decrease dependence on AD. Progress to step over step pattern according to patient's ability and symptoms.
- Car transfers: Recommendations from Phase I may continue to be used as needed for patient comfort. Driving is not typically recommended until 100% WB. If driving during this phase, see instructions in the Driving section in Phase III.

Management of Pain and Swelling

- Ice
- Oral pain medications as prescribed by physician or over the counter as needed
- Elevation of lower extremity in supine position
- Use of compressive shorts, such as spandex, may be used to assist with control of swelling

Techniques for Progressive Increase in Range of Motion, Muscle Activation, and Other Therapeutic Exercises

Exercises are described based on the assumption that the precautions for hip MR or LR have been lifted. (Exercises may have multiple purposes such as increasing joint ROM, muscle activation, strengthening, endurance or flexibility.)

Exercises Primarily for the Hip

- Hip Flexion: (No active straight leg raises)
- ROM may increase from Phase I, but should not be forced. For example, 120° may not be an appropriate target for hip flexion ROM after FAI surgery.
- Cue to use lower abdominals to stabilize pelvis[2,4]
  - Supine or hook lying: hip flexion to comfortable range
    - Active hip flexion: If patient reports anterior hip pain as hip flexion approaches 90°, patient can apply a gentle posterior force over the proximal femur to achieve precise motion
    - Passive hip flexion with mobilization: Patient applies a gentle posterior force over the proximal femur while passively flexing the hip with the opposite hand (Figure 26-22)
  - Quadruped:
    - Start with the hips in 70° to 80° of flexion. Push with the hands to rock backward toward 120°. Avoid flexing the lumbar spine as the hip flexes (Figure 26-23).
  - Standing on uninvolved: active hip flexion to 90°
  - Sitting: Use hands to passively flex hip within pain-free range; hold end-range for three to five seconds. May need to allow slight LR as hip is flexed for comfort. Use hands to assist to lower thigh to starting position (Figure 26-24).
    - May progress to active-assistive, then to active hip flexion. If pain or popping is reported when lowering the thigh, cue to "relax the muscles [iliopsoas] and let the thigh drop down"
- Hip extension
  - Prone with a pillow placed under the hips: continue exercises from Phase I.
  - Quadruped: Active hip extension (knee flexed to 90°): lift the involved lower extremity from starting position toward 0°. Do not lift the uninvolved side until the involved weight-bearing status has progressed to 100%. Cue to use lower abdominals to stabilize pelvis while moving the lower extremity. Because many tend to extend the knee during hip extension, cue to keep the knee flexed throughout the movement.
- Hip abduction/adduction: Make sure the patient reports feeling muscle activation in the gluteus medius and not in the lateral hamstrings, groin, or adductors during the following abduction exercises.
  - Standing on uninvolved: Abduct hip with slight extension and neutral rotation with light elastic band for resistance. Keep pelvis stable avoiding lateral pelvic tilt. ***Caution: No resistance until 8 weeks for surgical dislocation.***
  - Stand on involved extremity: Begin with UE support and control hip adduction or pelvic drop and MR. Mirror may be used to provide feedback

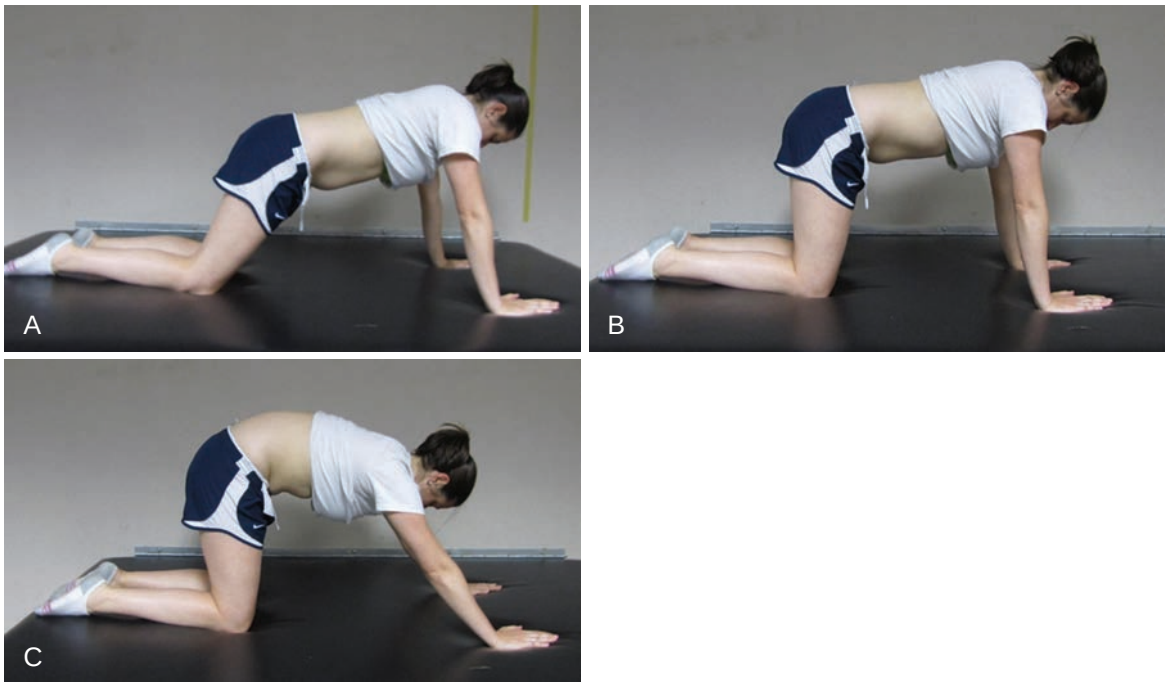

FIGURE 26-23 Hip flexion in quadruped. *A,* Starting position at 70° to 80° of hip flexion. *B,* Push with hands to flex hips from starting position toward 120° keeping the lumbar spine in a neutral position. *C,* Incorrect: lumbar flexion as substitution for hip flexion.

for maintenance of proper alignment during single leg stance. Progress to using no UE support as able.
  - Standing side stepping toward the involved hip
  - Sidelying: Hips and knees slightly flexed and pillow between the knees
    - Active abduction and LR by lifting the lower extremity off the pillow. Do not allow the knee to lock as hip abduction is being performed. Increase repetitions and sets as appropriate.
- Hip rotation:
  ROM may increase from Phase I, but should not be forced.
  - Supine hooklying:
    - Allow whole LE to rotate outward and inward through comfortable ROM. Cue to keep the pelvis stable by contracting the lower abdominals.
      - In patients with overuse and stiffness of the hip adductors, place pillows on the outside of the limb to allow the adductors to relax between repetitions if needed (Figure 26-25).
  - Standing on uninvolved side with involved foot resting on heel, forefoot lifted
    - Resisted MR and LR with light elastic band. (Cue to move knee and foot together, not just the foot) (Figure 26-26).

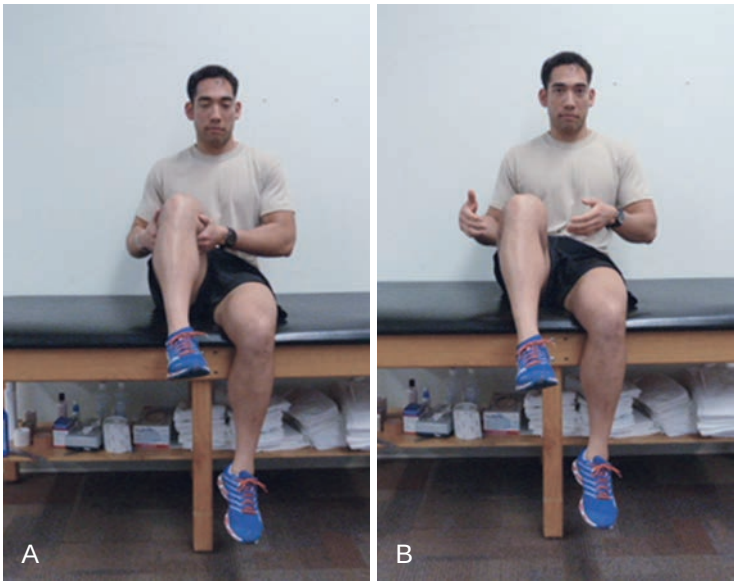

FIGURE 26-24 Hip flexion in sitting. *A,* Use hands to passively flex hip within pain-free range. May need to allow slight lateral rotation as the hip is flexed for comfort. Also use hands to assist to lower thigh to starting position. *B,* Hold end-range for 3 to 5 seconds.

FIGURE 26-25 Supine hip rotation. After performing hip lateral rotation, rest the lower extremity on pillows to allow the adductors to relax between repetitions if needed.

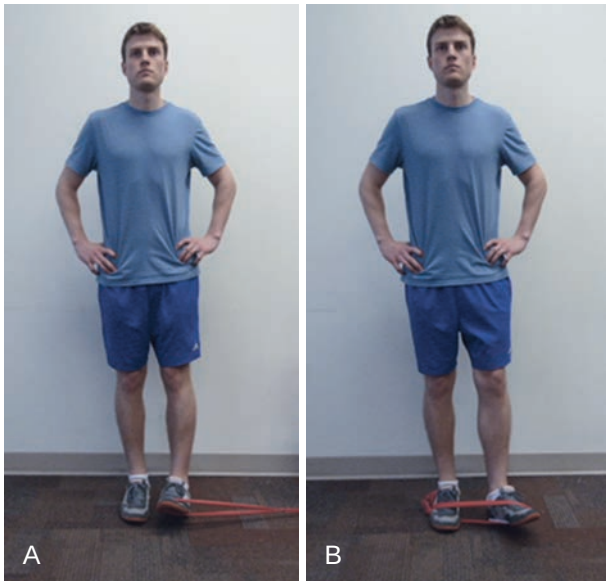

FIGURE 26-26 Standing hip rotation with resistance. *A,* Medial rotation. *B,* Lateral rotation

    - Consider both bony structure and preferred alignment when prescribing rotation exercises. Assess total rotation ROM (MR + LR) and the person's neutral position for rotation when determining the arc of motion to be performed. For example, a person with femoral anteversion may be asked to perform hip LR from a position where the foot is turned to a position that is slightly past midline.
- Prone with a pillow placed under the hips and knee flexed to 90°
  - Active MR and LR: Cue to keep pelvis stable by contracting lower abdominals.
- Sitting leaning back and resting on upper extremities to reduce hip flexion angle:
  - Active ROM for LR. Cue to keep the thigh relaxed on the chair and to activate the buttock muscles (deep lateral rotators) to perform the motion. MR is typically not comfortable or necessary to perform in this position.
  - Rotation control during sit to stand
    - Place a circular elastic band around distal femurs. Perform sit to stand while pushing out against the elastic band. The goal for alignment during performance should be to keep the knee over foot (Figure 26-27).
- Other (aquatic)
  - Continue active ROM and kickboard activities from Phase I.
  - No breast stroke

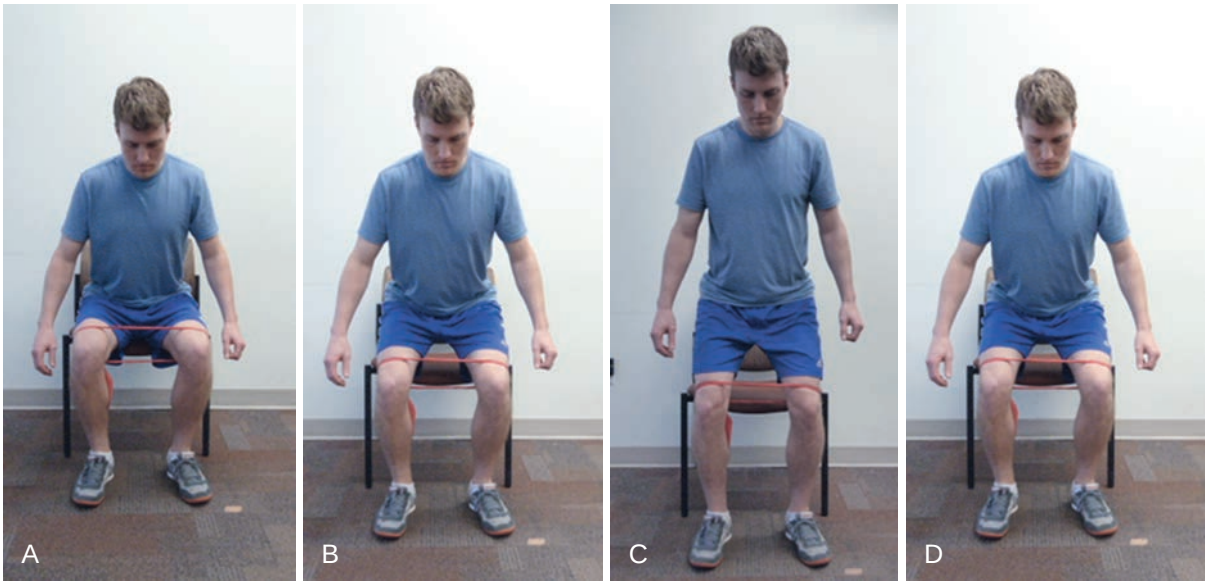

FIGURE 26-27 Sit to stand with resistance to control hip rotation. Perform sit to stand while pushing out against the elastic band. The goal for alignment during performance should be to keep the knee over foot.

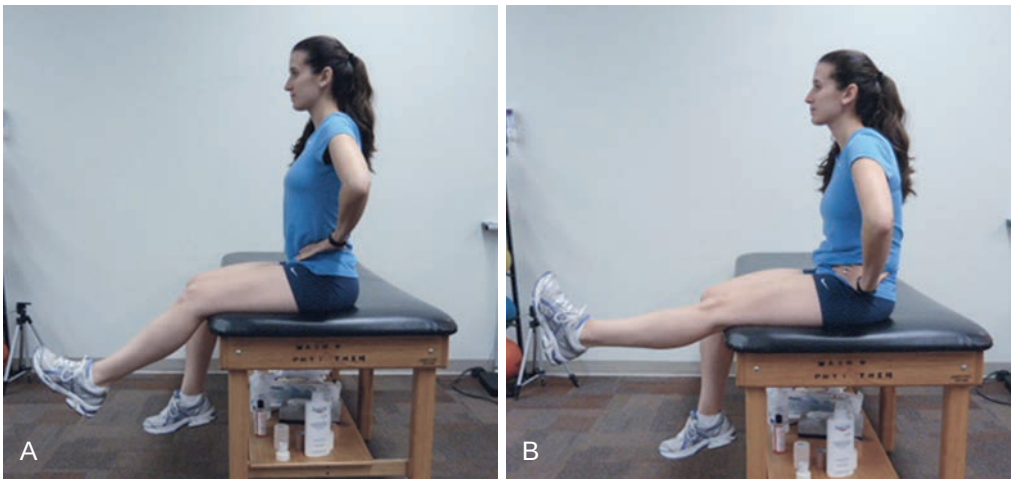

FIGURE 26-28 Sitting hamstring and gastrocnemius stretch. *A,* Correct: active knee extension and ankle dorsiflexion with stabilization of pelvis and lumbar spine. *B,* Incorrect: posterior pelvic tilt and lumbar flexion as substitution during hamstring stretch.

Exercises for Other Body Regions

- Sitting upright: Active knee extension with ankle dorsiflexion for hamstring and gastrocnemius stretching (cue to maintain pelvic and lumbar spine alignment as the knee is extended) (Figure 26-28)
- Standing: Calf stretches
- General upper extremity strengthening as allowed while maintaining precautions
- General trunk strengthening. Focus on activation of the trunk musculature isometrically while maintaining the spine in a neutral position. Avoid single or double straight leg raises as a method for strengthening abdominals.
  - Resisted upper extremity motions
  - Modified planks with base of support at the knees

Cardiovascular Fitness

- Gradually increase duration and intensity. Achieving target heart rate for cardiovascular fitness may not be achieved in early phases. The goal is to increase duration before adding resistance to the activity. May start with 10 minutes and gradually increase to tolerance. Should be able to tolerate multiple episodes at a given dose before increasing duration or intensity. Balance amount of time spent in fitness activities with walking program and work demands.
  - Upper body ergometer
  - Upright biking:
    - Increase duration gradually to 30 minutes within tolerance
    - Adjust height of seat to avoid hip flexion greater than 90°
    - May add moderate resistance

Milestones for Progression to the Next Phase

- No limitations or abnormal movement patterns in basic daily activities except stairs
- ROM necessary for function
- Optimal/normalized gait pattern without assistive device
- Single leg stance with good control of trunk, pelvis, and hip (no sidebending of the trunk, pelvic drop, or hip adduction or MR)

Phase III (weeks 2 to 16 postoperatively depending on procedure): Full Weightbearing Phase

Clinical Pearls

- Although movement impairments have been addressed in Phase I and II, they may reappear as the degree of difficulty increases when performing activities for sports readiness. The critical issue is HOW an activity is performed, not just performing the activity. Proper movement strategy can optimize performance and minimize tissue injury.[2,5]
- Continue to monitor relative flexibility between the hip and lumbopelvic region during exercise and activities.[2,4]
- As sports activities are progressed, consider the hip structure of the individual when setting targets for ROM.
- Goals for fitness and sports vary widely among individuals. Those who achieve their goals after completion of Phase III do not need to be progressed to Phase IV.
- Watch for substitution during stretching exercises. For example, when stretching the hamstrings in sitting, avoid posterior pelvic tilt and lumbar flexion as the knee is extended. Hip MR is another substitution commonly seen with this stretch.

Goals

- Gradually increase ambulation distance to 10,000 steps/day using optimal gait pattern. Include hills and uneven surfaces.

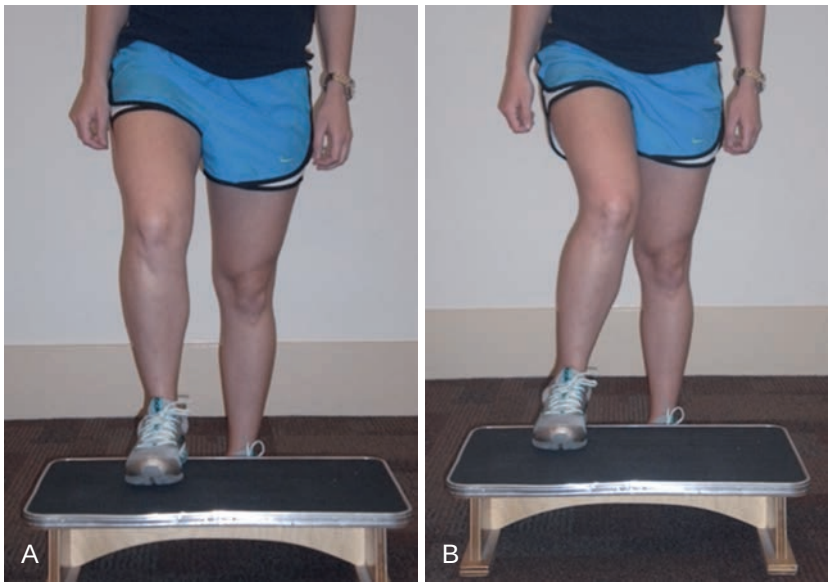

FIGURE 26-29 Ascend stairs. *A,* Correct: knee is aligned over foot. *B,* Incorrect: hip is in adduction and medial rotation resulting in knee being aligned medial to the foot.

- Provide stair training using step-over-step pattern.
- Progress strengthening and endurance of entire lower extremity.
- Progress cardiovascular activities to patient-preferred activities.
- Begin exercises for sport readiness, balance, and neuromuscular training.
- Provide feedback to athlete on performance to help with motivation and reduce fear.

Functional Mobility and Positioning

- Standing: Correct excessive hip extension achieved with forward sway of the pelvis and hyperextension of the knees. The hip should be maintained in neutral rotation. Use the distal femur, not the foot, as a guide for the hip rotation position.
- Gait:
  - Gait progression: Increase distance walked while maintaining optimal gait pattern.
  - May use pedometer to quantify the amount of walking. As patient is progressed monitor symptoms and modify distance walked accordingly if symptoms increase.
  - Initiate walking on uneven surfaces such as hills.
  - Turning: Avoid pivoting on involved side. Pick up foot and turn using a series of small steps.
- Stairs:
  - Use step-over-step method. Initially, may use rail to assist for proper control during stair ambulation. Emphasis on optimal movement pattern.
  - Upright trunk, no trunk sidebending
  - Keep knee over foot, no excessive hip rotation (Figure 26-29).
  - Maintain level pelvis during ascent, no hip drop.
  - During ascent, lean forward and use quads to raise body; avoid snapping knee back to body (Figure 26-30).
  - Control speed during descent.
- Driving: Assess type of seat in car and method of driving.
  - Position seat to avoid excessive or painful hip flexion and allow operation of pedals. Possible adjustments that may be used:
    - Recline backrest.
    - Tilt seat forward.
    - Slide seat backward.
    - Pillow/wedge may be placed on seat.
  - In cars with bucket seats, may need to fill in the bucket with pillow or towels to avoid excessive MR.
  - For those with stiff or short hamstrings, seat may be moved forward to reach the pedals more easily and to avoid excessive posterior pelvic tilt and lumbar flexion.
  - Minimize excessive hip flexion and MR when moving from gas to brake pedals. May suggest sliding foot when possible.
- Shoes
  - Wear supportive, flat shoes.
  - Gradually build tolerance to shoes with elevated heels. Avoid high heels.

Management of Pain and Swelling

- Ice or heat may be used.
- Oral pain medications as prescribed by physician or over the counter as needed.
- Use of compressive shorts, such as spandex, may be used to assist with control of swelling.
- Massage may assist with release of fluids and muscle cramps.

Techniques for Progressive Increase in Range of Motion, Muscle Activation, and Other Therapeutic Exercises

Exercises are described based on the assumption that the precautions for hip MR or LR have been lifted. (Exercises

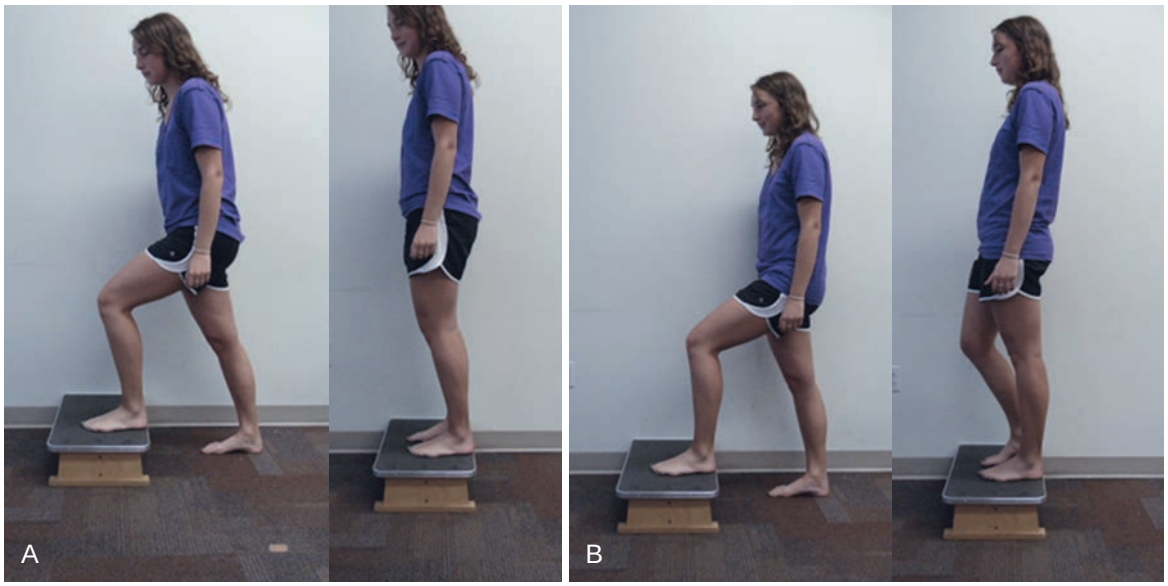

FIGURE 26-30 Ascend stairs. *A,* Correct: lean slightly forward and use quadriceps to lift body up the step. The final knee position should be neutral to slightly flexed. *B,* Incorrect: Trunk is too upright when placing foot on step and during step up. The knee snaps back during step-up and goes into hyperextension in the final position.

may have multiple purposes such as increasing joint ROM, muscle activation, strengthening, endurance or flexibility.)

Exercises Primarily for the Hip

- Hip flexion: *(No active straight leg raises)*
- ROM may increase from Phase II, but should not be forced.
- For example, 120° may not be an appropriate target for hip flexion ROM after FAI surgery.
- Cue to use lower abdominals to stabilize pelvis.
  - Quadruped:
    Exercise to increase hip flexion ROM and flexibility of posterior soft tissues
    - Start with the hips in 90° of flexion. Push with the hands to rock backward toward 120°. Avoid flexing the lumbar spine as the hip flexes.
    - If patient reports anterior hip pain as hip flexion approaches end-range, patient can apply a gentle posterior force over the proximal femur to achieve precise motion (Figure 26-31).
  - Standing on uninvolved: resisted hip flexion to 90° (ankle weights)
  - Sitting: May add resistance at end-range of hip flexion by using the hand. May need to allow slight LR as hip is flexed for comfort. If pain or popping is reported when lowering the thigh, cue to "relax the muscles [iliopsoas] and let the thigh drop down" (Figure 26-32).
- Hip extension
  - Prone with a pillow placed under the hips: Continue exercises from Phase I. May add ankle weights as needed.
  - Quadruped: Active hip extension (knee flexed to 90°): Lift the lower extremity from starting position toward 0°. Cue to use lower abdominals to stabilize pelvis while moving the lower extremity. Because many tend to extend the knee during hip extension,

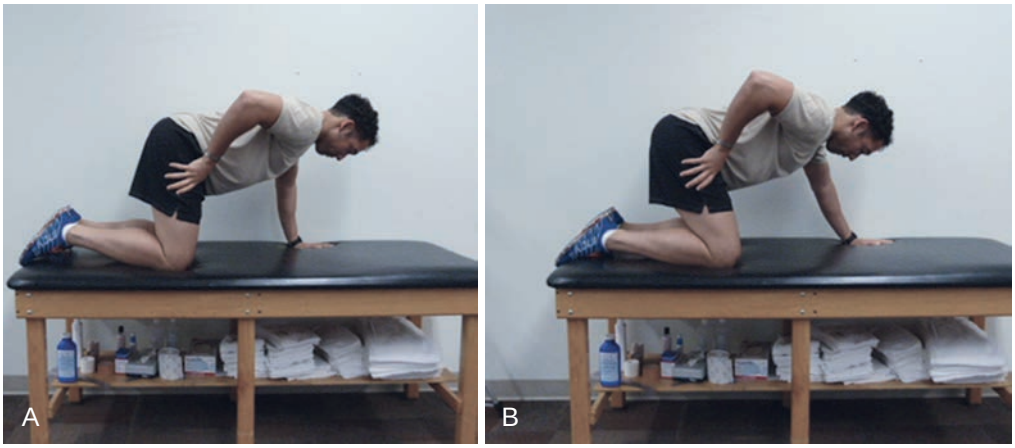

FIGURE 26-31 Posterior glide provided during quadruped rocking. *A,* Place hand over proximal femur in the starting position. *B,* Apply a gentle posterior force while rocking backward to achieve precise hip flexion in those with limited and painful hip flexion.

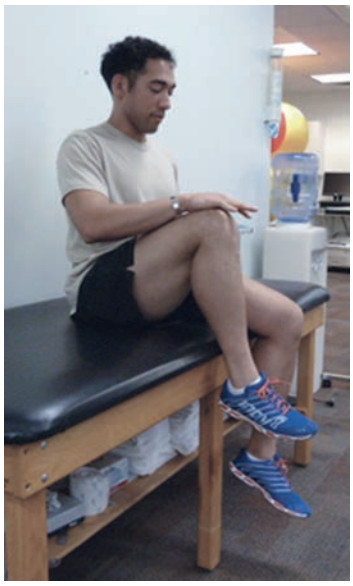

FIGURE 26-32 Hip flexion in sitting (resistance). May add resistance at end-range of hip flexion by using the hand. May need to allow slight LR as hip is flexed for comfort. If pain or popping is reported when lowering the thigh, cue to "relax the muscles [iliopsoas] and let the thigh drop down."

cue to keep the knee flexed throughout the movement. Increase repetitions and sets as appropriate.
  - Supine: Two joint hip flexor stretch. Avoid if athlete has excessive femoral anterior glide[2] during extension. Avoid tibial LR (Figure 26-33).
- Hip abduction/adduction
  Make sure the patient reports feeling muscle activation in the gluteus medius not in the lateral hamstrings, groin, or adductors during the following abduction exercises.
  - Stand on involved extremity: Control hip adduction or pelvic drop and MR. Knee should be slightly flexed to avoid hyperextension or locking the knee. Mirror may be used to provide feedback for maintenance of proper alignment during single leg stance. May be progressed by performing hip abduction against resistance with the uninvolved side.
  - Standing on uninvolved: Abduct hip with slight extension and neutral rotation with elastic band or pulley for resistance. Perform in the opposite direction for hip adduction.
  - Standing side stepping in both directions and progress with elastic band around the ankles or knees. Trunk should remain upright, pelvis level, and knee over foot during side stepping (Figure 26-34).
  - Sidelying: Hips and knees slightly flexed and pillow between the knees.
    - Active abduction, extension and LR by lifting the top lower extremity off the pillow. Slowly lower the lower extremity to neutral abduction/adduction and lift again. Increase repetitions and sets as appropriate. Knee should be relaxed (unlocked).
  - Sidelying: Active adduction of the bottom lower extremity if weak with muscle testing.
- Hip rotation:
  ROM may increase from Phase II, but should not be forced.
  - Supine hooklying:
    - Allow whole LE to rotate outward and inward through comfortable ROM (see Figure 26-19).
      - Place pillows on the outside of the limb to allow the adductors to relax between repetitions if needed (see Figure 26-25).
  - Standing on uninvolved side with involved foot resting on heel, forefoot lifted
    - Progress resisted MR and LR with moderate elastic band. (Cue to move knee and foot together, not just the foot.)
      - Consider both bony structure and preferred alignment when prescribing rotation exercises. Assess total rotation ROM (MR + LR) and the person's neutral position for rotation when determining the arc of motion to be performed.

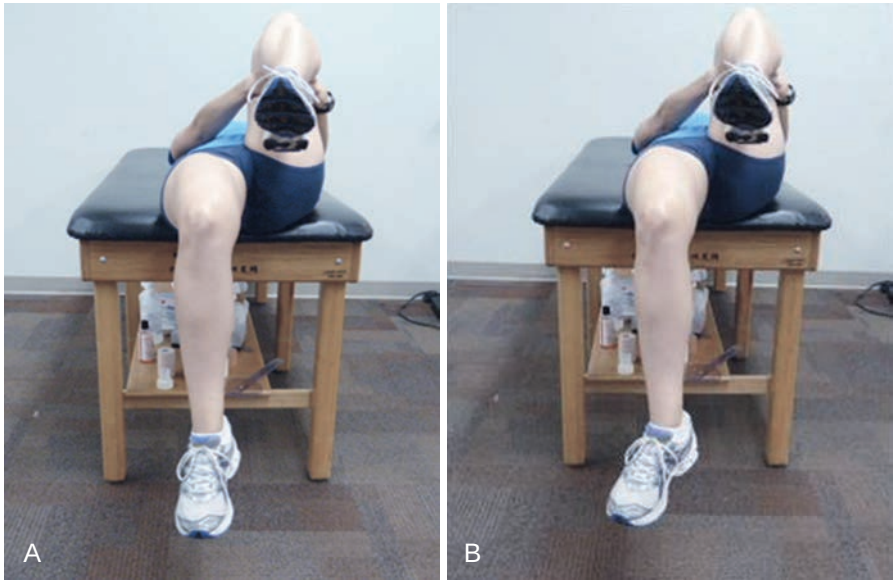

FIGURE 26-33 Two joint hip flexor stretch. *A,* Correct. *B,* Incorrect: Lateral tibial rotation occurs during hip flexor stretch owing to short or stiff tensor fascia lata-iliotibial band. Cue to hold foot in as the hip is extended being careful to avoid hip medial rotation as a substitution for holding the foot in midline.

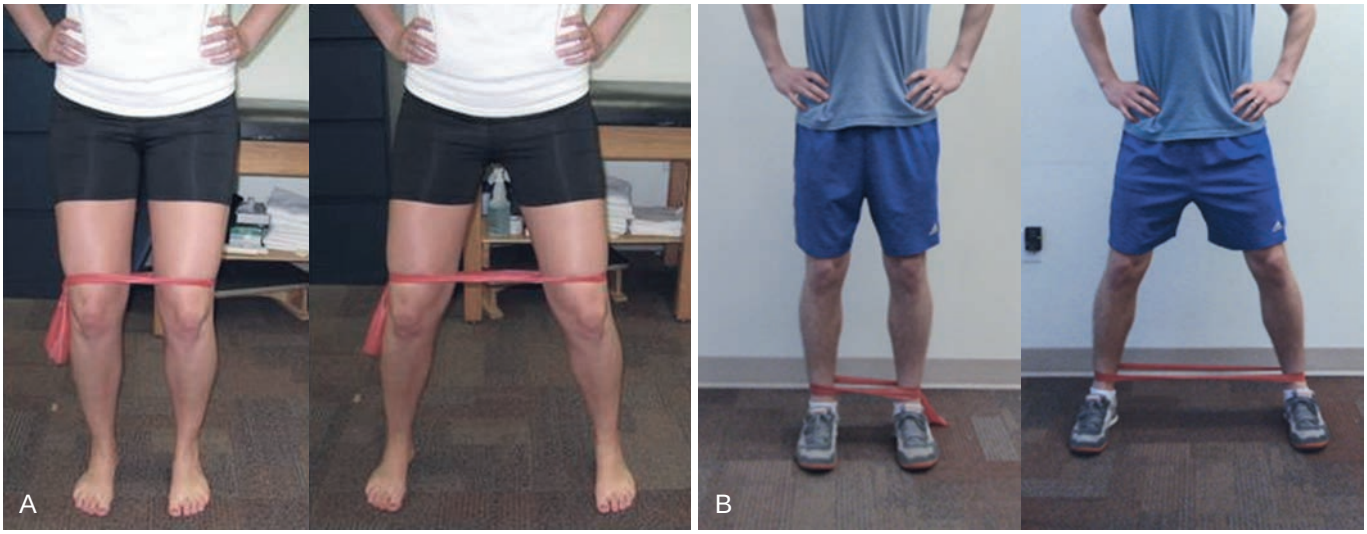

FIGURE 26-34 Standing side stepping with resistance (abduction). *A,* Side step with elastic band placed around distal femur (easier). *B,* Side step with elastic band placed just above the ankles (more difficult). Trunk should remain upright, pelvis level and knee over foot during side stepping.

  - For example, a person with femoral anteversion may be asked to perform hip LR from a position where the foot is turned to a position that is slightly past midline.
  - Clockwise and counterclockwise pelvic rotation against resistance from sport cord or elastic band through partial ROM (Figure 26-35).
- Prone with a pillow placed under the hips and knee flexed to 90°.
  - Active MR and LR
- Sitting upright:
  - Resisted ROM for LR with light to moderate elastic band. Cue to keep the thigh relaxed on the chair and to activate the buttock muscles (deep lateral rotators) to perform the motion. MR is typically not comfortable or necessary to perform in this position.
- Rotation control during sit to stand.
  - Place a circular elastic band around distal femurs. Perform sit to stand while pushing out against the elastic band. The goal for alignment during performance should be to keep the knee over foot (see Figure 26-27).

Exercises for Other Body Regions

- Standing: Hamstring stretch (Figure 26-36).
- Sitting upright: Active knee extension with ankle dorsiflexion for hamstring and gastrocnemius stretching (see Figure 26-28)
- Standing: Calf stretches

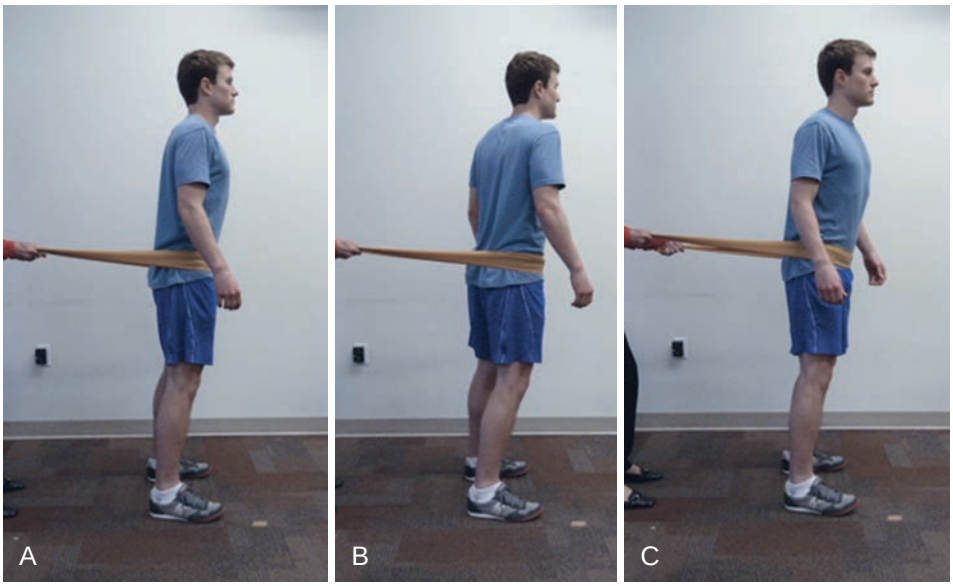

FIGURE 26-35 Pelvic/hip rotation with resistance. *A,* Starting position. *B,* Rotate pelvis counterclockwise (right hip lateral rotation and left hip medial rotation). *C,* Rotate pelvis clockwise (right hip medial rotation and left hip lateral rotation).

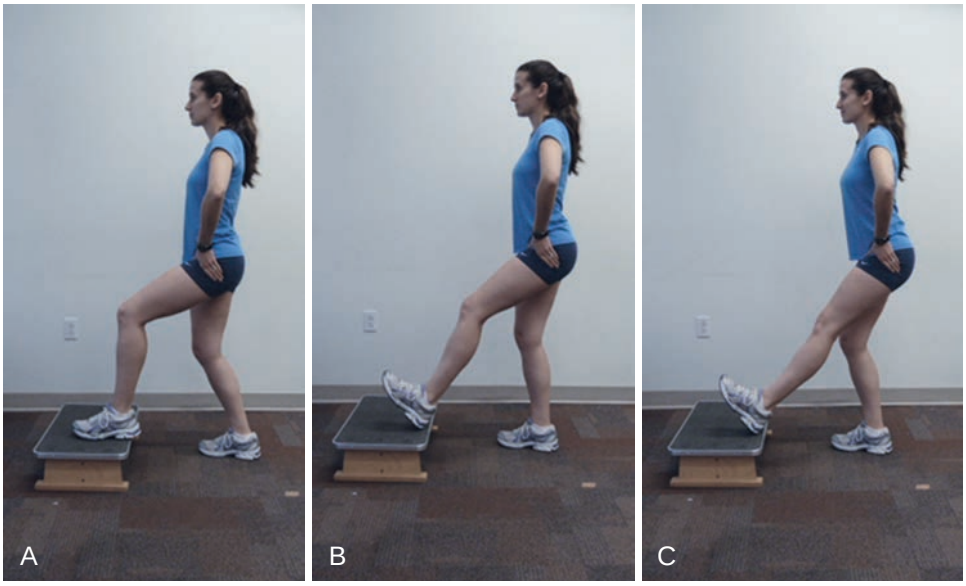

FIGURE 26-36 Standing hamstring stretch. The goal is to maintain an ideal hip joint position while stretching the hamstrings. *A,* Start by placing the foot on a step or short bench so that the hip is flexed. Place hand over proximal thigh. *B,* Apply a gentle posterior force over the proximal femur while extending the knee. *C,* Flexion of the stance knee may be necessary to achieve an appropriate stretch. The trunk may need to shift posteriorly to maintain balance while performing the stretch.

- Standing forward bending with hip flexion only (Figure 26-37)
- General lower extremity strengthening/multipurpose hip and knee
  - Hamstrings and quads (gluts)
    - Partial squat and partial lunge
    - Single leg small knee bend
    - Full lunge
  - Standing: Calf raises
  - General upper extremity strengthening
- General trunk strengthening. Focus on activation of the trunk musculature isometrically while maintaining the spine in a neutral position. Avoid single or double straight leg raises as a method for strengthening abdominals.
  - Resisted upper extremity motions
  - Planks with base of support at the feet.
  - Single leg bridge

Sports Readiness

- Exercises for impact sports, such as soccer, basketball, tennis, running/track, and baseball
- Emphasis is placed on achieving proper form, and then speed or duration may be increased.
  - Hopping: Within each level, begin with short bouts of hopping and longer rests between (15 seconds on: 30 seconds off), then increase on time and decrease off time (30 seconds on: 15 seconds off).
    - Hopping with both lower extremities
      - Emphasis should be placed on landing on both feet evenly and knees aligned over feet (avoid excessive hip adduction).
      - Use support of the upper extremities to decrease the amount of stress through the hip.
      - No upper extremity support
      - Different directions: side-to-side, back and forth, box

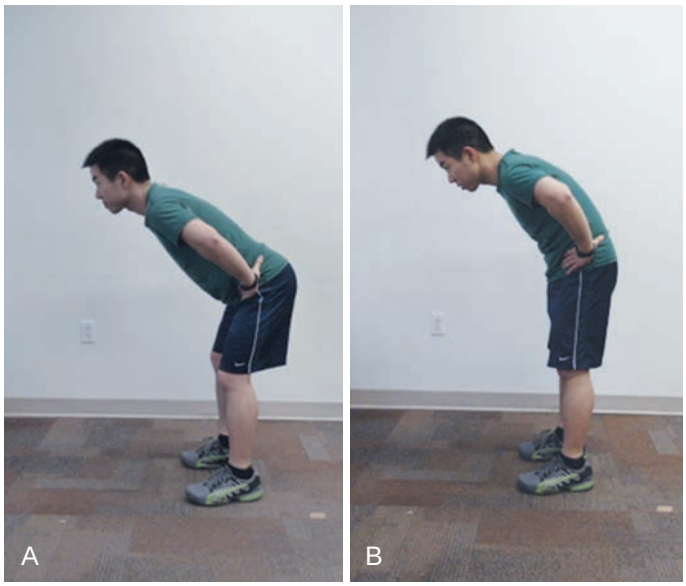

FIGURE 26-37 Standing forward bending and return moving in the hips only. *A,* Correct: Flexion of the trunk over the lower extremities while maintaining a constant position of the spine. Return to standing by contracting the gluteals and extending the hips. *B,* Incorrect: Flexion in the lumbar spine as a substitution for hip flexion.

FIGURE 26-38 Hopping: single lower extremity. *A,* Correct: Note knee is aligned over the foot during landing. *B,* Incorrect: Excessive hip adduction during landing. *C,* Patient attempting to correct alignment after instruction. If patient is unable to correct completely, a lower level activity should be used.

- Progress the same activities using a single lower extremity.
  - During the landing, knee should be aligned over foot (avoid excessive hip adduction) (Figure 26-38).
- Lateral agility (Figure 26-39)
  - Without resistance
  - With sport cord resistance
- Diagonal agility (Figure 26-40)
  - Without resistance
  - With sport cord resistance
- Box lunge (Figure 26-41)
  - Without resistance
  - With sport cord resistance
- Single knee bend
- Jumping down from short surface, 2 inches. Emphasis should be placed on landing on both feet evenly, knees flexed and with knees aligned over toes (avoid hip adduction).The patient should also think about landing softly to help absorb the landing.[6]
  - Jump forward, backward on both feet. Hold the landing with the same guidelines as in the preceding.
  - Jump forward and land on 1 lower extremity with same guidelines as in the preceding.
- Shuffle
  - Sideways in both directions
  - Forward and backward

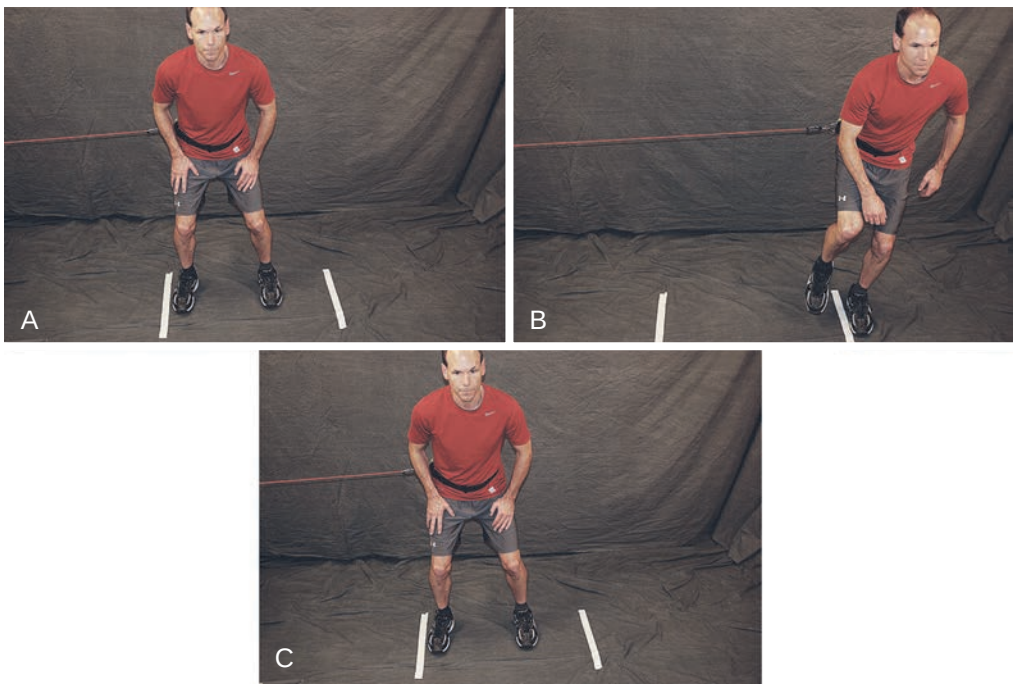

FIGURE 26-39 Lateral agility. *A,* Start position: Sport cord attached from the wall to the waist. First line placed on floor the distance away from wall where the cord remains taut. Second line is placed away from the first line by the distance of the patient's greater trochanter to the floor. *B,* Patient performs a lateral push-off from the leg nearest the wall with enough force to land with the opposite leg past the second line. *C,* The increase in cord tension will result in a force that pulls the patient back. The patient should land in front of the first line and absorb the landing with a controlled squat. *(From Wahoff M, Ryan M: Rehabilitation after hip femoroacetabular impingement arthroscopy.* Clin Sports Med *30(2):463–482, 2011.)*

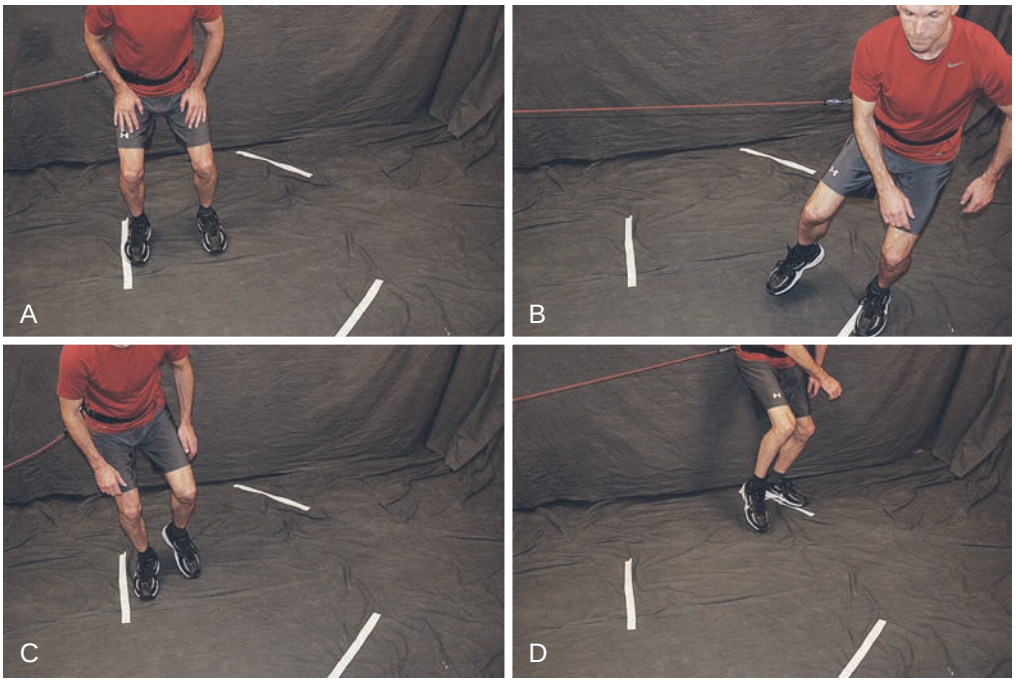

FIGURE 26-40 Diagonal agility. *A,* Start position: Same as lateral agility except two lines are placed at 45° angles forward and backward from the first. *B,* The patient performs the lateral push-off from the leg nearest the wall as before but lands first rep on forward line. *C,* The patient returns to the first line landing in a controlled squat. *D,* The patient performs the next rep landing on the back line and continues alternating forward and backward lines. *(From Wahoff M, Ryan, M: Rehabilitation after hip femoroacetabular impingement arthroscopy. Clin Sports Med 30(2):463–482, 2011.)*

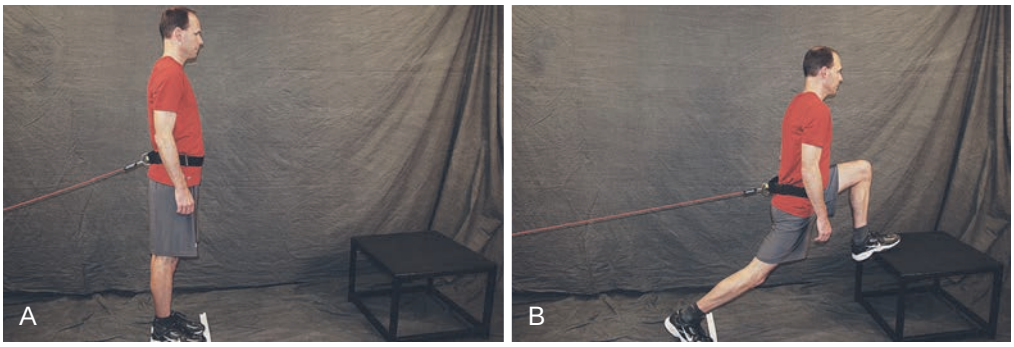

FIGURE 26-41 Forward lunge onto a box. *A,* Start position. Cord attached from wall to back of waist and taut. *B,* Perform a forward lunge onto a box then return and perform with the opposite leg. Height of box will need to be modified according to the patient to avoid excessive hip flexion. *(Modified from Wahoff M, Ryan, M: Rehabilitation after hip femoroacetabular impingement arthroscopy. Clin Sports Med 30(2):463–482, 2011.)*

Exercises for Low Impact Sports (e.g., golf, swimming, and cycling)

- Training activities for individual sports are highly variable. The clinician should consult with coach and athlete to design an appropriate sport-specific program. A few suggestions include:
  - Drills with sport-specific equipment, such as hitting golf balls at the driving range
    - Special considerations for drills require rotation in standing
      - When rotating away from the involved hip, shift weight to the uninvolved limb and be sure the foot of the involved limb pivots around. Do not turn on a fixed foot.
      - When turning toward the involved hip, modify the starting position to allow for optimal hip ROM.
      - For example, the golfer with femoral retroversion in the forward lower extremity should start with the lower extremity turned out slightly to avoid excessive MR during the follow through of the swing.
  - Practice activities specific to the sport at lower levels of intensity and short duration. Progress by gradually increasing either intensity level or duration.

Exercises for Balance and Neuromuscular Training

Activities to improve proprioception of the lower extremity should be incorporated as soon as possible.[4]

- Standing balance activities: The following activities are listed in the order of difficulty.
  - Stance with feet together
  - Tandem stance
  - Stance on unstable surfaces (pillows, foam, trampoline, BOSU ball)
  - Single leg stance
  - Single leg stance on unstable surfaces (pillows, foam, trampoline, BOSU ball)

Each activity can be made more difficult by asking the athlete to maintain balance:

1. For a longer period of time (up to 30 seconds)
2. With eyes closed
3. During perturbations applied by clinician[7]
4. While performing an additional activity, such as playing catch, upper extremity weightlifting, or kicking a ball. Select activity that is meaningful to the athlete's fitness or sport.

- Star balance excursion test[8] can be used as an exercise.

Cardiovascular Fitness

Progress to patient-preferred activities. Increase duration and intensity. Target heart rate is achieved.

- Swimming:
  - Freestyle, backstroke, butterfly
  - No breast stroke
- Upright biking
- Elliptical
- Treadmill
  - Caution to avoid excessive hip extension
- Running
  - When able to walk 30 minutes without increase in symptoms or swelling, may begin running. Alternate walking and running. Gradually increase time running and decrease time walking. For example, walk four minutes, run one minute. Repeat six times = 30 minutes.
  - Once able to run one mile without increasing pain or swelling, may begin other running drills, for example, figure-eight and soft cuts.

Milestones for Progression to the Next Phase

- Many people will achieve their functional and fitness goals after completion of Phase III and may not need to progress to Phase IV.
- If not progressed to Phase IV, the patient should:
  - Be independent in and perform correctly the exercises specific for the hip that are outlined in Phase IV.
  - No limitations or abnormal movement patterns during gait or stairs.
  - No abnormal movement patterns with patient-preferred fitness or sport activity
  - ROM necessary for function and preferred sport
- If progressing to Phase IV, the patient should achieve the milestones noted in the preceding plus:
  - Pass Sport test[9] (Table 26-2)

Table 26-2 Functional Hip Sport Test

Exercise Goal Points
Single knee bends 3 min 1 point earned for each 30 s completed
Lateral agility 100 s 1 point earned for each 20 s completed
Diagonal agility 100 s 1 point earned for each 20 s completed
Forward lunge on box 2 min 1 point earned for each 30 s completed

Passing score: 17 of 20. Emphasis on proper lower extremity alignment during performance of the test.

Modified from Wahoff M, Ryan M: Rehabilitation after hip femoroacetabular impingement arthroscopy. *Clin Sports Med* 30(2):463–482, 2011.

Phase IV (postoperative weeks 12 to 24): Return to Sport

Clinical Pearls

- Work closely with coach to determine appropriate transition back into sport.
- Continue to follow clinical pearls described in Phases II and III, regarding movement impairments, muscle performance, individual variations in bony structure, and joint mobility and relative flexibility.

Goals

- Maximize strength and endurance of lower extremity.
- Maximize agility, speed and power.
- Progress sport-specific activities to include rotational and diagonal movements.
- Promote symmetry with sport-specific drills.
- Education in maintenance program.
- Provide feedback to athlete on performance to help with motivation and reduce fear.

Techniques for Progressive Increase in Range of Motion, Muscle Activation, and Other Therapeutic Exercises

Advanced Exercises and Drills

- Jump-training program[6,10] (Box 26-1)
- Shuttle runs
- Cutting drills with soft cuts, hard cuts, cut and spin
  - Z cuts and W cuts
- Running program to increase speed and endurance

Sport-Specific Exercises and Drills

Training activities for individual sports are highly variable. The clinician should consult with coach and athlete to design an appropriate sport-specific program. A few suggestions include:

- Drills with sport-specific equipment, such as basketball, hockey stick, soccer
- Partner drills
- Sport cord: Sport-specific activities resisted with sport cord

Maintenance Exercises Primarily for the Hip

Recommend continued performance of these exercises a minimum of three per week in addition to the sport-specific workout.

- Strength/muscle activation
  - Iliopsoas:
    - Sitting: Resistance at end-range of hip flexion by using the hand. May need to allow slight LR as hip is flexed for comfort. If pain or popping is reported when lowering the thigh, cue to "relax the muscles [iliopsoas] and let the thigh drop down."
  - Gluteus maximus:
    - Quadruped: Active hip extension (knee flexed to 90°): Lift the lower extremity from starting position toward 0°. Cue to use lower abdominals to

BOX 26-1 Jump-Training Program for Prevention of Anterior Cruciate Ligament Injuries in Female Athletes

Exercise	Duration or Repetitions by Week	
PHASE I: TECHNIQUE	**WEEK 1**	**WEEK 2**
1. Wall jumps	20 seconds	25 seconds
2. Tuck jumps*	20 seconds	25 seconds
3. Broad jump stick (hold) landing	5 repetitions	10 repetitions
4. Squat jumps*	10 seconds	15 seconds
5. Double-legged cone jumps*	30 seconds/30 seconds	30 seconds/30 seconds (side-to-side and back-to-front)
6. 180-degree jumps	20 seconds	25 seconds
7. Bounding in place	20 seconds	25 seconds
PHASE II: FUNDAMENTALS	**WEEK 3**	**WEEK 4**
1. Wall jumps	30 seconds	30 seconds
2. Tuck jumps*	30 seconds	30 seconds
3. Jump, jump, jump, vertical jump	5 repetitions	8 repetitions
4. Squat jumps*	20 seconds	20 seconds
5. Bounding for distance	1 run	2 runs
6. Double-legged cone jumps*	30 seconds/30 seconds	30 seconds/30 seconds (side-to-side and back-to-front)
7. Scissors jump	30 seconds	30 seconds
8. Hop, hop, stick landing*	5 repetitions/leg	5 repetitions/leg
PHASE III: PERFORMANCE	**WEEK 5**	**WEEK 6**
1. Wall jumps	30 seconds	30 seconds
2. Step, jump up, down, vertical	5 repetitions	20 repetitions
3. Mattress jumps	30 seconds/30 seconds	30 seconds/30 seconds (side-to-side and back-to-front)
4. Single-legged jumps, distance*	5 repetitions/leg	5 repetitions/leg
5. Squat jumps*	25 seconds	25 seconds
6. Jump into bounding*	3 runs	4 runs
7. Hop, hop, stick landing	5 repetitions/leg	5 repetitions/leg

GLOSSARY OF JUMP-TRAINING EXERCISES

- 180-degree jump: two-footed jump. Rotate 180 degrees midair, hold landing for 2 seconds, repeat in reverse direction.
- Bounding for distance: start bounding in place, slowly increase distance with each step, keeping knees high.
- Bounding in place: jump from one leg to the other, straight up and down, progressively increasing rhythm and height.
- Broad jump stick (hold) landing: two-footed jump as far as possible, hold landing for 5 seconds.
- Cone jump: double-legged jump with feet together, quickly jump side-to-side over cones, repeat forward and backward.
- Hop, hop, stick landing: single-legged hop, stick second landing for 5 seconds, increase distance of hop as technique improves.
- Jump into bounding: two-footed broad jump, land on single leg, then progress into bounding for distance.
- Jump, jump, jump, vertical jump: three broad jumps with vertical jump immediately after landing the third broad jump.
- Mattress jump: two-footed jump on mattress, trampoline, or other easily compressed device, perform side-to-side and back-to-front.
- Scissors jump: start in stride position with one foot well in front of other.
- Single-legged jump, distance: single-legged hop for distance, hold landing (knees bent) for 5 seconds.
- Squat jump: standing jump raising both arms overhead, land in squatting position, touching both hands to floor.
- Step, jump up, down, vertical: two-footed jump onto 6- to 8-inch step, jump off step with two feet, and then vertical jump.
- Tuck jump: from standing position, jump and bring both knees up to chest as high as possible, repeat quickly
- Wall jump (ankle bounces): with knees slightly bent and arms raised overhead, bounce up and down off toes.

Stretching and Weight-Training Program

STRETCHES†	WEIGHT-TRAINING EXERCISES‡
1. Calf stretch with bent knee	1. Abdominal curl
2. Calf stretch with straight knee	2. Back hyperextension
3. Quadriceps	3. Leg press
4. Hamstring	4. Calf raise
5. Hip flexors	5. Pullover
6. Iliotibial band/lower back	6. Bench press
7. Posterior deltoids	7. Latissimus dorsi pull-down
8. Latissimus dorsi	8. Forearm curl
9. Pectorals/biceps	9. Warm-down short stretch

Note: Before jumping exercises: stretching (15–20 minutes), skipping (2 laps), side shuffle (2 laps).
During training: Each jump exercise is followed by a 30-second rest period.
Post-training: cool-down walk (2 minutes), stretching (5 minutes), weight training (after 15-minutes rest).
*These jumps performed on mats.
†Stretching consists of three sets of 30 seconds each.
‡Weight training consists of one set of each exercise, generally 12 repetitions for upper body exercises and 15 repetitions for the trunk and lower body exercise.
From Hewett TE, Lindenfeld TN, Riccobene JV, Noyes FR: The effect of neuromuscular training on the incidence of knee injury in female athletes. *Am J Sports Med* 27:699–706, 1999.

stabilize pelvis while moving the lower extremity. Because many tend to extend the knee during hip extension, cue to keep the knee flexed throughout the movement. Increase repetitions and sets as appropriate.
  - Posterior gluteus medius:
    - Side lying: Hips and knees slightly flexed
      - Active abduction, extension, and LR by lifting the top lower extremity. Slowly lower the lower extremity to neutral abduction/adduction and lift again. Increase repetitions and sets as appropriate. Knee should be relaxed (unlocked). Cue to keep the pelvis stable and avoid lateral pelvic tilt.
  - Deep hip lateral rotators:
    - Sitting upright resisted ROM for LR with light to moderate elastic band. MR is typically not comfortable or necessary to perform in this position.
  - Medial rotators: (pivoting) something in standing
    - Standing on uninvolved side with involved foot resting on heel, forefoot lifted
      - Resisted MR with elastic band. (Cue to move knee and foot together, not just the foot.)
- ROM/flexibility
  - Hip flexion ROM: Do not force hip flexion ROM. Focus on isolating hip flexion and avoiding lumbar flexion. A safe exercise is rocking backward in quadruped position.
  - Hip extension ROM: Focus on isolating hip extension and avoiding lumbar extension. A safe exercise is prone hip extension with the knee extended. Cues should be given to contract the abdominals to stabilize the pelvis and avoid pelvic anterior tilt or rotation during hip extension.
  - Hip rotation: Focus on isolating hip rotation and avoiding lumbopelvic rotation or tibiofemoral motion.[11] A safe exercise is prone hip rotation with the knee flexed to 90°. Hip should be in neutral abduction/adduction, but if faulty motion cannot be avoided, the hip may be placed in abduction or a pillow placed under the hips.
  - TFL-ITB and rectus femoris: A safe exercise is prone knee flexion with the hip should be in neutral abduction/adduction and rotation. If faulty motion cannot be avoided (anterior pelvic tilt or rotation or lateral tibial rotation), the hip may be placed in abduction or a pillow placed under the hips. To control lateral tibial rotation, may perform bilateral knee flexion with the heels and toes together. A more aggressive stretch can be achieved with the two joint hip flexor stretch (see Figure 26-22). Avoid this stretch if the athlete has excessive femoral anterior glide during extension.
  - Hamstrings: Hamstring stretches should start with the hips flexed and focus on movement of the knee. Avoid lumbar flexion. A safe exercise is sitting knee extension. Another suggestion is the standing hamstring stretch (see Figure 26-36).

Cardiovascular Fitness

Activities to target cardiovascular fitness should be progressed as tolerated.

Criteria for Return to Sport

The following criteria should be met before performing functional testing.
- Pain-free ROM (varies across individuals)
- Pain-free hopping
- Safe and proper performance of hops, broad jumps, lateral step, and direction changes.

Functional Testing

General lower extremity testing to determine if asymmetries exist between the uninvolved and involved extremity. Tests are to be performed on the involved and uninvolved side. The following equations are then used to quantify lower extremity asymmetry.
- Limb symmetry index (LSI)[12]
  - Distance measures = involved side/uninvolved side × 100
  - Timed measures = uninvolved side/involved side × 100

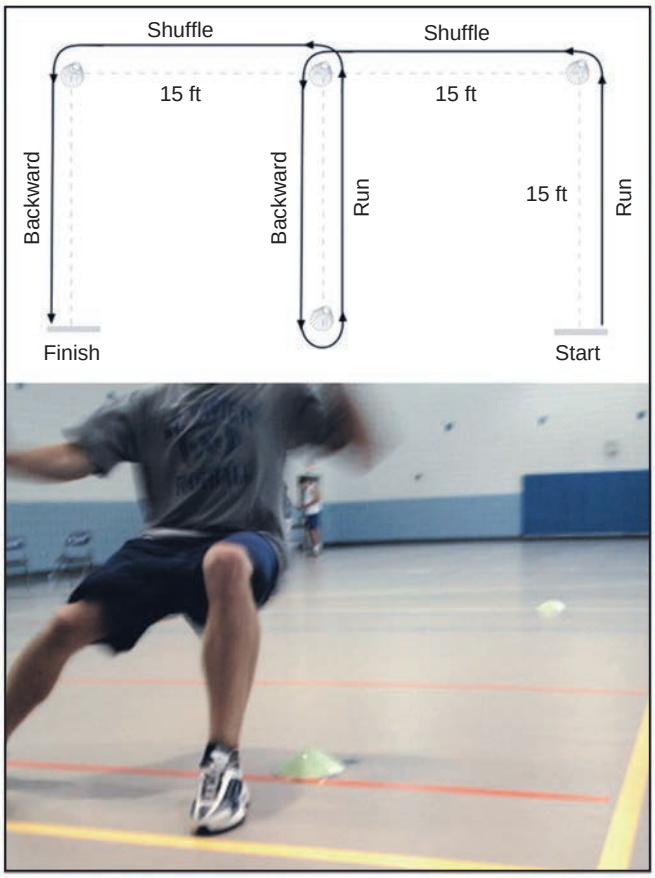

FIGURE 26-42 Modified agility T-test. Test is performed in both directions to assess both lower extremities. The time to complete the test with the involved limb is compared to the time on the uninvolved limb. The limb being tested is the limb pushing off during the shuffle. For example, the direction indicated in the figure would test the right lower extremity. The direction would be reversed to assess the left lower extremity. *(From Myer GD et al: Utilization of modified NFL combine testing to Identify functional deficits in athletes following ACL reconstruction.* J Orthop Sports Phys Ther *41(6);377–388, 2011.)*

Recommend that the athlete participate in one round of testing for practice before scoring.[13]

Performance of Functional Testing

- Double limb performance tests[12]
  Recommend LSI > 85-90%[14]
  - Modified agility T-test (Figure 26-42)
  - Modified ProShuttle (Figure 26-43)
  - Modified long shuttle (Figure 26-44)
- Single limb performance tests

These tests have been shown to be more sensitive to limb asymmetries.[12]

Recommend LSI greater than 85% to 90%[14–17]

- Hop tests[13,18,19] (Figure 26-45)
  - Single hop for distance
  - Crossover hop for distance
  - Triple hop for distance
  - Six-meter timed hop
- Lateral step[20]

The following values are based on a small sample of young, uninjured subjects (14 males and four females); however, the values may be useful to gauge the performance of the athlete.

- Number of repetitions completed in 15 seconds.
  - 0.15 m step = 25.5 ± 3.8 repetitions
  - 0.20 m step = 22.9 ± 3.1 repetitions
- Time needed to complete 50 repetitions
  - 0.15 m step = 29.5 ± 4.6 seconds
  - 0.20 m step = 34.4 ± 6.6 seconds
- Sport/position-specific functional testing
- Sport specific activities may be used to assess the athlete's ability to safely perform activities required in the sport.

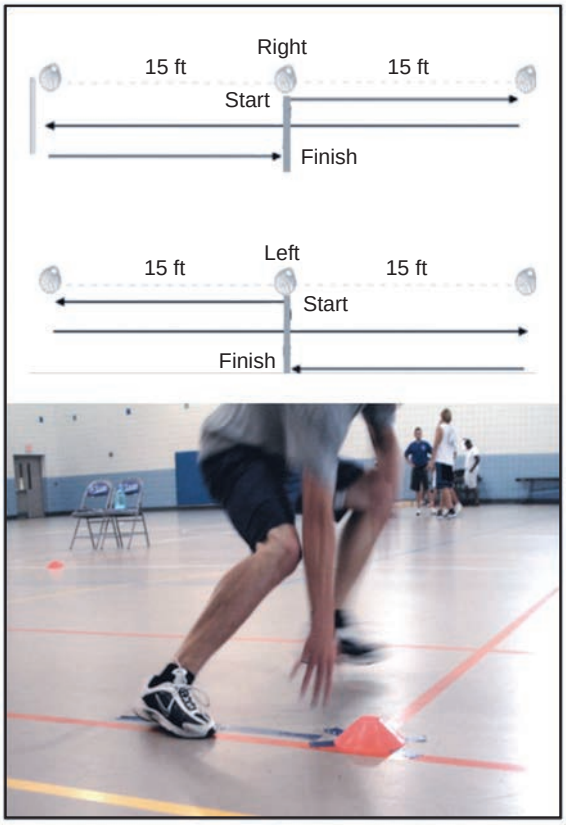

FIGURE 26-43 Modified ProShuttle test. Test is performed in both directions to assess both lower extremities. The time to complete the test with the involved limb is compared with the time on the uninvolved limb. The limb being tested is the limb initiating the first push off. Athlete starts in a three-point stance at the middle cone. The athletes sprints 15 feet, touches the cone with the outside hand, turns, and sprints in the opposite direction (30 feet), touches the cone with the outside hand, turns, and sprints to finish. *(From Myer GD et al: Utilization of modified NFL combine testing to Identify functional deficits in athletes following ACL reconstruction.* J Orthop Sports Phys Ther *41(6);377–388, 2011.)*

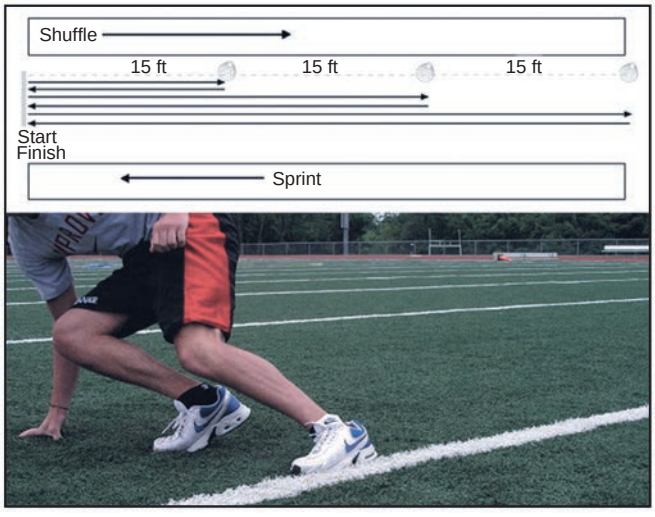

FIGURE 26-44 Modified long shuttle test. Test is performed in both directions to assess both lower extremities. The time to complete the test with the involved limb is compared to the time on the uninvolved limb. The limb being tested is the limb pushing off during the shuffle. The athlete shuffles to the first marker, touching the marker and sprinting to the starting line, turns and shuffles to the second marker and sprints. This is repeated for each of the longer distances. *(From Myer GD et al: Utilization of modified NFL combine testing to Identify functional deficits in athletes following ACL reconstruction.* J Orthop Sports Phys Ther *41(6);377–388, 2011.)*

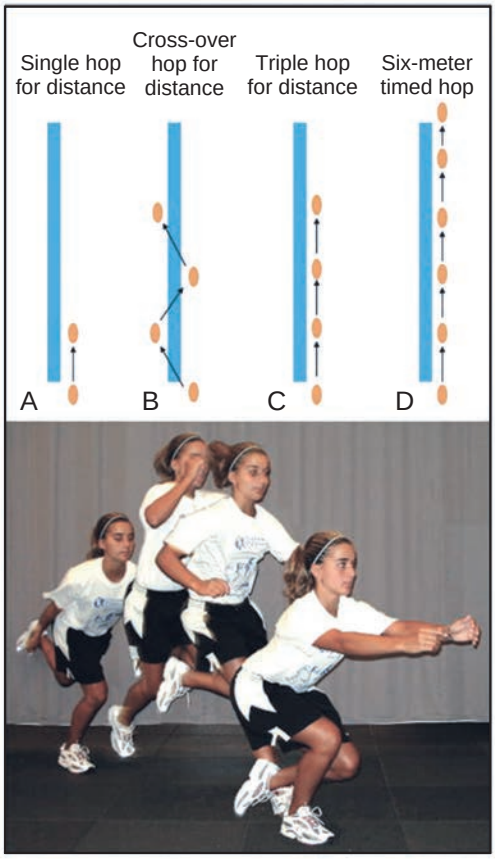

FIGURE 26-45 Hop tests. Tests are performed bilaterally and time or distance compared. *(From Myer GD et al: Utilization of modified NFL combine testing to Identify functional deficits in athletes following ACL reconstruction.* J Orthop Sports Phys Ther *41(6);377–388, 2011.)*

Evidence

Evidence specific to the postoperative rehabilitation after femoroacetabular impingement treatment is limited. Most literature available on rehabilitation is clinical commentary and no treatment trials are available. We have annotated studies that support treatment suggestions provided.

Byrd JW, Jones KS: Arthroscopic management of femoroacetabular impingement in athletes. *Am J Sports Med* 39:7S–13S, 2011.

This is a prospective case series of 200 athletes with femoroacetabular impingement treated with hip arthroscopy. All patients participated in a patient-specific postoperative program that included initial protected gait, ROM, strengthening, then functional return to sporting activities. At 19 months, patients reported a median improvement of 20 points on the modified Harris hip score. Ninety-five percent of the professional athletes and 85% of the collegiate athletes returned to sport. (Level IV evidence)

Clohisy JC, Zebala LP, Nepple JJ, et al: Combined hip arthroscopy and limited open osteochondroplasty for anterior femoroacetabular impingement. *J Bone Joint Surg Am* 92:1697–1706, 2010.

This is a retrospective study of 35 patients with cam femoroacetabular impingement that were treated with hip arthroscopy and limited open osteochondroplasty. At two years, the patients reported reduced symptoms, an improvement in function as demonstrated by a 24-point increase on the Modified Harris Hip score and enhanced activity. (Level IV evidence)

Clohisy JC, St John LC, Schutz AL: Surgical treatment of femoroacetabular impingement. A systematic review. *Clin Orthop Relat Res* 468:555–564, 2010.

The systematic review was performed to determine the level of evidence available related to surgical management of femoroacetabular impingement. Eleven studies that reported a minimum of 2-year follow-up were included in review. The studies reported reduced symptoms and improved hip-specific function in 68% to 96% of patients over a mean of 3.2 years. (Level IV evidence)

Hewett TE, Lindenfeld TN, Riccobene JV, et al: The effect of neuromuscular training on the incidence of knee injury in female athletes, a prospective study. *Amer J Sport Med* 27:699–706, 1999.

This prospective cohort study of 1263 athletes compared the ACL injury rate between 2 groups, 1 group completing a training program before sports participation, and the other group not trained. The training program included jump training emphasis the pattern and technique of the movements. Female athletes who participated in the training program demonstrated a decreased incidence of knee injury. (Level I evidence)

Lewis CL, Sahrmann SA, Moran DW: Effect of position and alteration in synergist muscle force contribution on hip forces when performing hip strengthening exercises. *Clin Biomech* 24:35–42, 2009.

The authors use a musculoskeletal model to estimate the hip joint forces during common lower extremity strengthening exercises. The authors concluded that hip joint forces are increased when the hip moves into extension while performing prone hip extension. Forces are increased further if the gluteus maximus is not performing optimally. (Measurement study)

Klingenstein GG, Martin R, Kivlan B, et al: Hip injuries in the overhead athlete. *Clin Orthop Relat Res* 470(6):1579–1585, 2012.

This retrospective study assessed the outcomes of 34 high-level baseball and lacrosse players after arthroscopic treatment of FAI. Surgical procedures varied according to patient pathology to include acetabuloplasty, femoroplasty, and labral repair or debridement. All patients participated in a standard postoperative rehabilitation program that included initial protected weightbearing, ROM, and isometrics that was then progressed to active and resistive activities. Modified Harris Hip score improved from 70 to 92. At 12 months, 33 of 34 returned to their previous level of sport. (Level IV evidence)

Myer GD, Schmitt LC, Brent JL, et al: Utilization of modified NFL combine testing of identify functional deficits in athletes following ACL reconstruction. *J Orthop Sport Phys Ther* 41:377–387, 2011.

This case control study used a modified NFL Combine testing technique to assess performance in athletes following ACL reconstruction. The testing included double- and single-limb activities. The authors found that unilateral tests, such as single leg hopping, are needed to identify unilateral deficits. (Level III evidence)

Nepple JJ, Zebala LP, Clohisy JC: Labral disease associated with femoroacetabular impingement. Do we need to correct the structural deformity? *J Arthroplasty* 24(6 Suppl):114–119, 2009.

This prospective cohort study compared the outcomes of 23 patients with labral disease and FAI undergoing arthroscopic labral resection to 25 patients undergoing arthroscopic labral resection with a limited open osteochondroplasty. The Modified Harris hip score tended to be higher and fewer subjects required subsequent surgery among patients undergoing the combined arthroscopy and osteochondroplasty, compared to those undergoing arthroscopy alone. (Level III evidence)

Philippon MJ, Weiss DR, Kuppersmith DA, et al: Arthroscopic labral repair and treatment of femoroacetabular impingement in professional hockey players. *Am J Sports Med* 38(1):99–104, 2010.

Twenty-eight professional hockey players unable to participate in their sport because of painful FAI underwent arthroscopic acetabular rim trimming, femoral neck osteoplasty, and labral tear. Postoperative physical therapy started with restoring passive hip ROM, followed by active ROM and strengthening. Average time to return to hockey drills was 3.8 months. Modified Harris Hip score improved from 70 to 95 at two years. Two players required additional surgery. (Level IV evidence)

Multiple-Choice Questions

QUESTION 1. A variety of surgical procedures may be performed when correcting FAI. Across all procedures, which ROM precaution is key and for what time frame?

A. Minimal medial and lateral rotation for 2 weeks
B. Hip abduction to 20° for 2 weeks
C. Hip flexion no greater than 90° for 4 weeks
D. Hip extension to 10° for 4 weeks

QUESTION 2. Why are active and resistive abduction exercises delayed with patients treated by surgical dislocation?

A. Acetabular labral repair protection
B. Need for joint healing from the dislocation
C. To prevent femoral head osteonecrosis
D. Protect the trochanteric osteotomy site for bony healing

QUESTION 3. As weightbearing is increased in Phase II, which of the following gait deviations is the most common and should be corrected before removal of an assistive device?

A. Hip adduction or pelvic drop during stance
B. Prolonged hip extension during midstance to push off
C. Excessive hip medial rotation
D. Sidebending of the trunk during stance
E. All of the above

QUESTION 4. When should sports readiness drills and neuromuscular retraining be introduced in the rehabilitative process?

A. Weeks 4 to 8
B. Weeks 8 to 16
C. Weeks 12 to 24
D. Weeks 24 to 30

QUESTION 5. Proper muscle activation and performance of the primary hip muscles is a focus of rehabilitation throughout all phases. In addition, exercises to maintain optimal performance of these muscles is important. Identify these primary hip muscles.

A. Iliopsoas, gluteus maximus, gluteus medius, deep LRs, MRs
B. Rectus femoris, hamstrings, posterior gluteus medius, gluteus maximus
C. Tensor fascia lata-iliotibial band, hamstrings, adductors, rectus femoris
D. Iliopsoas, adductors, hamstrings, tensor fascia lata-iliotibial band

Answer Key

QUESTION 1. Correct answer: **C** (see Table 26-1).

QUESTION 2. Correct answer: **D** (see Timeline 26-2).

QUESTION 3. Correct answer: **E** (see Gait section, Phase II).

QUESTION 4. Correct answer: **B** (see Phase III).

QUESTION 5. Correct answer: **A** (see Clinical Pearl box, Phase II, and Exercises for Primary Hip Muscles in all phases, especially Phase IV).

BEYOND BASIC REHABILITATION: RETURN TO BASEBALL AFTER OPERATIVE TREATMENT OF FEMOROACETABULAR IMPINGEMENT

Trevor Ryan Gaskill, MD, Mark Andrew Ryan, MS, ATC, CSCS, and Marc J. Philippon, MD

ASPECTS OF BASEBALL THAT REQUIRE SPECIAL ATTENTION IN REHABILITATION

- Sport-specific activities of baseball players require a unique coordination between the upper and lower extremity.
- These are unique to the player's position (pitcher vs. position player) and rehabilitation must be individualized based on these specific requirements.
- It is critical to "train" the athlete throughout all rehabilitation phases.
- It is our experience that this approach improves athlete motivation and ensures physical conditioning of the unoperated extremities for safe return to sport.
- Maintenance of upper and nonoperative lower extremity strength as well as cardiovascular conditioning are emphasized.
- Although training is incorporated into all rehabilitation phases, it should be progressively emphasized in successive phases when more advanced activities can be safely tolerated.
- The return to sport timeline should be individualized based on the specific needs of the athlete.
- Return to sport, however, should not exceed the body's physiological ability to heal the surgical repair.
- Therefore return to sport should occur no faster than indicated in protocol timelines; however, additional rehabilitation time may optimize the ability to return to sport in some circumstances.
- All athletes should successfully complete a "sports test" prior to returning to sport.
- This test is designed to help ensure adequate physiological hip conditioning prior to returning to high demand activities.

Introduction

- Femoroacetabular impingement (FAI) is increasingly being identified as an etiology of hip pain in young, athletic populations.
- The movements used to play baseball require cooperation between the upper and lower extremities that functionally places the "at-risk hip" in a position of abnormal bony conflict.
- For this reason, symptomatic femoroacetabular impingement is not uncommon in this population.
- The functional demands placed on the hip, however, are varied and position specific.
- For example, pitchers experience deep hip flexion of the leading leg and extension and external rotation of the push-off leg during the pitching motion.
- Position players by contrast experience explosive axial rotation of the hips during hitting and fielding activities.
- This variability makes the treatment and rehabilitation of these athletes more complex.
- It requires surgical intervention and postoperative rehabilitation to be individualized to the activities that result in hip impingement.
- For this reason, no one rehabilitation protocol can be ubiquitously applied. Therefore position specific rehabilitation protocols will be discussed.

Literature

- It is established that femoroacetabular impingement is a common cause of hip dysfunction in athletes and is responsible for mechanical damage to labral and cartilaginous tissue.
- Though hip impingement is no longer a novel concept, our understanding of, ability to treat, and rehabilitation experience has grown exponentially over the past few years.

- To date, very little published literature is available to guide rehabilitation of athletes undergoing decompression of abnormal bony conflict within the hip.
- To our knowledge no published scientific literature describes rehabilitation specific to baseball players.
- Under these circumstances both an understanding of the stresses experienced by the hip when competing in baseball and experience treating these particular athletes become critical to optimizing return to sport for these athletes.

Phase III: Sport-Specific Training

Periodization

- The return to sporting activity after hip arthroscopy for femoroacetabular impingement and labral repair has several important physiological considerations.
  - Healing of a surgical repair occurs over a relatively defined and predictable timeframe. Introduction of certain activities prior to sufficient healing may jeopardize surgical outcomes. This fact alone makes linear periodization a primary consideration in the design of postsurgical rehabilitation protocols.
  - After sufficient healing of the surgical repair, more advanced strength and endurance activities are introduced. Because training for these modalities has been limited in the acute postsurgical period, a gradual progression into these activities is also necessary, as discussed in previous chapters.
  - Once a foundation of conditioning is established and healing has occurred, functional sport-specific activities are introduced. Because many of these activities have not been performed vigorously for months, a linear progression is also necessary.
- It is our goal to incorporate as many sport-specific activities as is safe beginning in the immediate postoperative period and progress these activities as healing allows. The postoperative program therefore consists of multiple microcycles and mesocycles within a linear progression, within physiological healing parameters. Athletes are progressed through basic to complex skill sets while increasing performance speed and duration.

Program Design/Performance Training Program

Sport-Specific Concepts of Integrated Training

- Most return to sport programs begin approximately 2 weeks after normal gait has been established. This typically occurs around 6 to 8 weeks postsurgically. Prior to this time frame, flexibility and joint mobility are emphasized to minimize the risk of postsurgical adhesions within the hip. Core strengthening, gait, and balance training are also part of the early training process prior to introduction of conditioning exercises. When appropriate, upper extremity and nonoperative cardiovascular conditioning are incorporated into the program.
- Subsequent to this initial healing phase, it is safe to incorporate training to optimize balance, strength, endurance, and power. For example, a squat type progression might include basic double leg body weight squats, progress to body weight squats on uneven surfaces such as a BOSU, weight-resisted squats, single leg squats, and finally squat jumps. Additional progressions for core, hamstrings, deep hip rotators, and lateral hip stabilizers (gluteus medius) would also be concurrently completed.
- Concurrently, sport-specific progressions are initiated, including a throwing, running, fielding, and hitting progression. These progressions are included at the end of the chapter. Once these progressions are successfully completed, the athlete may return to their preinjury training regimen.

Olympic Lifts Used in the Training Program

- No Olympic lifts are routinely used in our return to baseball progression after arthroscopic treatment of femoroacetabular impingement. Alternatively, it is our preference to incorporate functional, sport-specific activities throughout the rehabilitation period to introduce these complex motor activities at a gradual pace; for example, exercises such as multiplanar lunges and resisted cable chops. Prior to actual hitting, athletes will swing a lighter weight fungo bat or broomstick for dry swinging and a slower speed, progressing to higher speeds, and finally a game bat. They will then progress to hitting in the cage.
- Additionally, it is our experience that athletes experience greater satisfaction and motivation as these activities are progressively instituted into the rehabilitation/training progression. Olympic lifts may be added back into the athlete's strength and conditioning program upon full return to game activity if the athlete has had previous experience performing the lifts.

Training Principles Used in the Design of the Program

- Progression and specific adaptation to imposed demand are used in the design of the return to sport program. As the athlete is able to perform the prescribed sport specific activities with the appropriate technique and without undue fatigue or pain, the prescribed activities can be advanced. Progression occurs through activity complexity, speed, intensity, and duration. Moreover, the frequency the athlete participates in the prescribed activity may also be increased.

Application of Acute Training Variables

- During each aspect of the return to baseball progression, several acute training variables are applied. Initial movements are performed in a controlled environment with planned movement patterns such as dry swinging in the clinic with a lighter weight bat at slow speeds, throwing short distances (30 ft), and fielding hand-fed ground balls to a known location to the athlete. These movements are progressed from basic to complex while speed and duration of activities are also increased gradually.
- To this end, sets and repetitions are gradually increased. In later phases, the frequency of training within each week also increases. As throwing distances increase for

pitchers and activities become more unpredictable for position players, intensity similarly increases. Tempo of the activities is also gradually increased over the training to simulate game conditions prior to return to unrestricted sporting activity.

Application of Chronic Training Variables

- The goal of return to sport training is to safely return an athlete to sport-specific activities while minimizing the risk of recurrent injury while the body is deconditioned. Therefore after successfully returning the athlete safely to sport, the athlete's typical training program can be restarted. It is important for the athlete, however, to continue a hip-specific strengthening program to maintain strength, endurance, and stability of the hip musculature This may include double and single leg squats, glute bridging, single leg RDLs, multidirectional core movements such as resisted wood chops or med ball throws, and core stabilization exercises such as planks and side planks

Sports Performance Testing

General Information

- A general history is obtained that includes the athlete's activity level, playing position, injury mechanism, inciting activities, and surgical procedure performed.
- Any other medical history, chronic injuries, or medications that may affect rehabilitation are also elicited.
- Subjective patient outcome questionnaires are also routinely obtained prior to surgery and intermittently throughout the rehabilitation process.

TIMELINE 26-3: **Beyond Basic Rehabilitation: Return to Baseball after Surgical Treatment of Femoroacetabular Impingement**

Weeks 1 to 6	Weeks 7 to 16
	All positions—running progression (3×/week)

• Follow general FAI rehabilitation protocol.
• Athlete may include cardiovascular activities beginning at 2 weeks postop.
  • General recommendations include: swimming with pull buoy, one-leg rowing, UBE and upper body exercise
• Athlete may include light upper body conditioning at 2 weeks postop.
  • General recommendations include: TRX suspension trainer
• Athlete may initiate rotator cuff maintenance program at 2 weeks.
All athletes should prepare to pass sport test between weeks 10 and 12 postoperatively.
	Weeks 1–6: Continue general FAI rehabilitation protocol in entirety.
	Begin Week 8 after 2 weeks of waist-deep water running if normalized gait, good abductor control, and the ability to perform 1 minute of single leg squats is present.
	Week 8: Walk 4 min, jog 1 min × 4 = 20 min
	Week 9: Walk 3 min, jog 2 min × 4 = 20 min
	Week 10: Walk 2 min, jog 3 min × 4 = 20 min
	Week 11: Run 8 × 180 yds (Poles) w/180-yd walking recovery
	Week 12: Run 10 × 180 yds (Poles) w/180-yd walking recovery (faster pace)
	Week 13: Run 10 × 180 yds (Poles) w/180-yd walking recovery (faster pace)
	Week 14: Base running (home to first × 4, first to third × 2, second to home × 2)
	Week 15: Base running (see above) Game Speed
	Week 16: Base running (see above) Game Speed + sliding

Specific Tests

- The Hip Sports Test is performed approximately 10 to 16 weeks postoperatively. It is intended to ensure adequate hip musculature conditioning necessary to protect the hip during sporting activities. No formal research has been completed to validate its effectiveness in predicting reinjury or readiness for return to sport. The authors have found it to be an effective clinical tool to test muscular endurance and stability of the hip musculature and also demonstrate what movement patterns may be painful to the athlete. We have found clinically that athletes who go through the process of training for the sport test have high compliance with the overall rehabilitation process and have proved to have high levels of endurance and stability. How this relates specifically to their ability to play baseball has yet to be determined.
- If the athlete is not able to pass the testing, it also serves as a guide to the type of rehabilitation necessary to optimize the athlete's recovery.

Objective Tests

- Single leg squat (3-minute max): 6 pts
  - **Description:** The athlete will perform single knee bends with cord resistance to 60° at a cadence of 1 second up and 1 second down for a goal of 3 minutes. The movement is between 30° to 60° of flexion with the knee never fully straightening past 30° throughout the 3 minutes. To cue the athlete to the depth of 60°, the buttocks can lightly touch the seat of a chair

TIMELINE 26-3 Beyond Basic Rehabilitation: Return to Baseball after Surgical Treatment of Femoroacetabular Impingement (Continued)

Weeks 7 to 16

Pitchers—throwing program	Position players—fielding progression
Weeks 1–6: Continue general FAI rehabilitation protocol in entirety. Week 7: • Monday: 10 @ 30', 20 @ 45' • Wednesday: 10 @ 30', 20 @ 45' • Friday: 20 @ 30', 20 @ 45' Week 8: • Monday: 20 @ 30', 20 @ 45' • Wednesday: 20 @ 30', 20 @ 45', 10 @ 60' • Friday: 20 @ 30', 20 @ 45', 10 @ 60' Week 9: • Monday: 10 @ 30', 20 @ 45', 20 @ 60' • Wednesday: 10 @ 30', 20 @ 45', 20 @ 60' • Friday: 10 @ 30', 10 @ 45', 20 @ 60', 10 @ 75' *Beginning week 10 add light toss on Tuesday, Thursday, and Saturday* Week 10: • Monday: 10 @ 30', 10 @ 45', 20 @ 60', 10 @ 75' • Wednesday: 10 @ 30', 10 @ 45', 20 @ 60', 20 @ 75' • Friday: 10 @ 30', 10 @ 45', 20 @ 60', 20 @ 75' Week 11: • Monday: 10 @ 45', 10 @ 60', 20 @ 75', 10 @ 90', 10 @ 60' • Wednesday: 10 @ 45', 10 @ 60', 20 @ 75', 10 @ 90', 10 @ 60' • Friday: 10 @ 45', 10 @ 60', 10 @ 75', 20 @ 90', 10 @ 60' Week 12: • Monday: 10 @ 45', 10 @ 60', 10 @ 75', 10 @ 90', 10 @ 105', 10 @ 60' • Wednesday: 10 @ 45', 10 @ 60', 10 @ 75', 10 @ 90', 10 @ 105', 10 @ 60' • Friday: 10 @ 45', 10 @ 60', 10 @ 75', 10 @ 90', 20 @ 105', 10 @ 60' Week 13: • Monday: 10 @ 45', 10 @ 60', 10 @ 75', 10 @ 90', 20 @ 105', 10 @ 60' • Wednesday: 10 @ 45', 10 @ 60', 10 @ 75', 10 @ 90', 10 @ 105', 10 @ 120', 10 @ 60' • Friday: 10 @ 45', 10 @ 60', 10 @ 75', 10 @ 90', 10 @ 120', 10 @ 60' Week 14: • Monday: 10 @ 45', 10 @ 60', 10 @ 75', 10 @ 90', 10 @ 105', 20 @ 120' • Wednesday: Side mound 55', 20-25 pitches • Friday: Side mound 60', 30-35 pitches, Week 15: • Monday: Side mound, 35-40 pitches, • Wednesday: Side mound 40-45 pitches • Friday: Side mound 45-50 pitches Week 16: • Monday: Sim game 40-45 pitches (2-3 innings) • Wednesday: Long toss • Friday: Sim game 50 pitches (3-4 innings) Week 17: Game activity	Weeks 1–7: Continue general FAI rehabilitation protocol in entirety. *Position dependent. Athletes should be progressed from basic sport-specific movement patterns to predictable reactive movements, to faster predictable movements, and finally unpredictable game simulation movements over a 6-week period.* Week 8: • Infielder: Lateral shuffles, crossovers (backhand) • Outfielder: Lateral shuffles, drop-step, backward jogging Week 9: • Infielder: Hand thrown grounders (easy reach and direction known by athlete) • Outfielder: Hand-thrown pop-ups & grounders Week 10: Infielder & Outfielder: Predictable fungo at position (add range) Week 11: • Infielder & Outfielder: Predictable fungo at position (add range) • Catcher: Bullpens Week 12: • Infielder & Outfielder: Reactive fungo at position • Catcher: Bullpens, blocking Week 13: • Infielder & Outfielder: Reactive fungo at position (add range) • Catcher: Bullpens, blocking, foul balls • Pitcher: Predictable fungo at position Week 14: • Infielder & Outfielder: Field bullpen • Catcher: Bullpens, blocking, foul balls • Pitcher: Predictable fungo at position, situational fielding Week 15: All: Simulated game Week 16: All: Simulated game activities (add range) Week 17: All: Game activity

or object. Two fingers are allowed for balance on a chair back.
  - **Setup:**
    - With a goniometer, measure a 60° knee bend and place a chair in a position to allow the athlete's buttocks to lightly touch at that depth.
    - The athlete places the heel of the foot on the cord at a position so the D-ring of the handle is aligned with the knee joint line to remove slack from the cord.
    - Tension is set by pulling the cord handle to the waist line and holding. Having the athlete hook her or his thumb around the pant line is helpful in maintaining tension on the cord.
    - Two fingers of the opposite hand are allowed to lightly touch another chair back for balance.
  - **Technique:** The athlete must perform each repetition of a single knee bend *without* the following:
    - Trendelenburg sign (pelvis must remain level)
    - The knee locking in full extension
    - The knee "collapsing" into medial rotation/adduction
    - The patella extending past the toe

    Cuing should be provided when one of the following compensations are noted. **If unable to correct, STOP THE TEST.**
  - **Scoring:** One point is earned for each 30-second increment completed with proper form for a total of 6 possible points.
  - **Testing is stopped if and when:**
    Form: once the subject is unable to complete single knee bends without compensation even with cuing
    - Pain: the patient has pain greater than 3/10 OR reproduces his/her pain
    - Endurance: the athlete fatigues
- Lateral agility test (100 seconds max): 5 pts
  - **Purpose:** To test the ability of the leg to accept load (absorb) and push off in a lateral direction
  - **Supplies:** Sport cord (Topper Sports Medicine, black cord), stopwatch, and tape
  - **Description:** The athlete will hop laterally with cord resistance from the surgical leg, land momentarily on the nonsurgical leg, only to return onto the surgical leg with the cord pulling the athlete back to the starting position for a total test time of 100 seconds. Each repetition of 1 second includes exploding laterally off the surgical side, landing momentarily on the opposite leg, and then returning to the starting position with emphasis on absorbing by bending at the hip and knee with 30° of knee excursion. Excursion is defined as the amount of absorption from knee flexion at landing to max knee flexion.
  - Setup:
    - Place the belt through the sport cord handles and then attach around the waist.
    - Attach the other end of the sport cord to the door jam or secure post.
    - Stand sideways with the involved leg toward the cord attachment.
    - Step away laterally until tension is reached where the athlete slightly compensates with leaning and place a line with tape on the lateral aspect of the involved foot.
    - Measure the distance from the greater trochanter to the floor.
    - Use this measured distance to place a second tape line parallel to the first.
  - **Technique:** The athlete must perform each lateral hop by landing on or inside the first tape line with the *involved* foot and on or outside the second tape line with the *uninvolved* foot. Only one foot should be on the ground at the same time and the athlete must absorb onto the involved leg without the following:
    - Trendelenburg sign (pelvis must remain level)
    - The knee "collapsing" into medial rotation/adduction
    - The patella extending past the toe
    - Losing control or stability

    Cuing should be provided when one of the following compensations are noted. **If unable to correct, STOP THE TEST.**
  - Scoring: One point is earned for each 20 second increment completed with proper form for a total of 5 possible points.
  - Testing is stopped if and when:
    - Form: once the subject is unable to complete single knee bends without compensation even with cuing
    - Pain: the patient has pain greater than 3/10 OR reproduces her/his pain
    - Endurance: the athlete fatigues
- Diagonal agility test (100 seconds max): 5 pts
  - **Purpose:** To test the ability of the leg to accept load (absorb) and push off in a diagonal direction.
  - **Supplies:** Sport cord (Topper Sports Medicine, black cord), stopwatch, and tape
  - **Description:** The athlete will hop diagonally forward at a 45° angle with cord resistance from the surgical leg, land momentarily on the nonsurgical leg, only to return onto the surgical leg with the cord pulling the athlete back to the starting position. The following repetition the athlete will hop diagonally backward at a 45° angle. The goal is 100 seconds total. Each repetition of 1 second includes exploding diagonally forward or backward at 45° angles off the surgical side, landing momentarily on the opposite leg, and then returning to the starting position with emphasis on absorbing by bending at the hip and knee with 30° of knee excursion. Excursion is defined as the amount of absorption from knee flexion at landing to max knee flexion.
  - Setup:
    - Place the belt through the sport cord handles and then attach around the waist.
    - Attach the other end of the sport cord to the door jam or secure post.
    - Stand sideways with the involved leg toward the cord attachment.
    - Step away laterally until tension is reached where the athlete slightly compensates with leaning and place a line with tape on the lateral aspect of the involved foot.
    - Measure the distance from the greater trochanter to the floor.
    - Use this measured distance to place a second tape line at a 45° angle forward and a third tape line at a 45° backward to form a V if connecting the lines.

- **Technique:** The athlete must perform each diagonal lateral hop by landing on or inside the first tape line with the *involved* foot and on or outside the second or third tape line with the *uninvolved* foot. (Each foot should land parallel with each tape line). Only one foot should be on the ground at the same time and the athlete must absorb onto the involved leg *without* the following:
  - Trendelenburg sign (pelvis must remain level)
  - The knee "collapsing" into medial rotation/adduction
  - The patella extending past the toe
  - Losing control or stability

    Cuing should be provided when one of the following compensations are noted. **If unable to correct, STOP THE TEST.**
- Scoring: One point is earned for each 20-second increment completed with proper form for a total of 5 possible points.
- Testing is stopped if and when:
  - Form: once the subject is unable to complete single knee bends without compensation even with cuing
  - Pain: the patient has pain greater than 3/10 OR reproduces his/her pain
  - Endurance: the athlete fatigues

- Forward single leg lunges (2-minute max): 4 pts
  - **Purpose:** To test the lower extremity strength and endurance into extension.
  - **Supplies:** Sport cord (Topper Sports Medicine, black cord), stopwatch, and tape
  - **Description:** The athlete will perform alternating forward lunges onto a box with cord resistance at a cadence of 2 seconds per lunge for a goal of 2 minutes. The movement is a forward lunge with maximum hip extension without compensation at the pelvis or spine throughout the 2 minutes.
  - **Setup:**
    - Place the belt through the sport cord handles and then attach around the waist.
    - Attach the other end of the sport cord to the door jam or secure post.
    - Stand facing away from the cord attachment.
    - Step forward until tension is reached where the athlete slightly compensates by leaning and tape a line in front of the feet.
    - Measure the distance from the greater trochanter to the floor.
    - Place a stable box or chair the height of the athlete's knees in front of them at a distance equal to the measure of the greater trochanter to the floor.
  - **Technique:** The athlete must perform *alternating* forward lunges onto the box keeping their planted leg behind the line and extending the hip *without* the following:
    - Trendelenburg sign (pelvis must remain level)
    - Excessive lumbar hyperextension
    - Pelvic rotation

      Correct performance of this activity is through proper extension of the hip.
  - **Scoring:** One point is earned for each 30-second increment completed with proper form for a total of 4 possible points.
  - **Testing is stopped if and when:**
    - Form: once the subject is unable to complete single knee bends without compensation even with cuing
    - Pain: the patient has pain greater than 3/10 OR reproduces her/his pain
    - Endurance: the athlete fatigues
- A score of greater than 16 is required prior to return to advanced sporting activities. Points are deducted based on inadequate form (i.e., Trendelenburg, collapse of the leg into internal rotation of adduction, or the use of a chair for support rather than balance) or the lack of endurance (i.e., failure to maintain rhythm or trembling).[1]

Specific Criteria for Progression to the Next Stage to Determine Readiness for Baseball

- Progression to any subsequent phase of rehabilitation should not occur until the goals of the previous phase can be completed appropriately and without undue discomfort. These goals include pain-free completion of each step of the throwing, hitting, running, and fielding progressions listed at the end of the chapter.
- Sport specific rehabilitation (apart from general rehabilitation after arthroscopic hip surgery) should not be started until the surgeon and therapist are satisfied sufficient biological healing has occurred and that the hip musculature has been conditioned to a point the functional sporting activity is not likely to be detrimental to the overall recovery process. This typically occurs 6 to 8 weeks postsurgically at the postop followup with the surgeon, though some basic components can be incorporated earlier if cleared verbally by the surgeon.
- Each phase of the sports specific training should be able to be completed without discomfort. If discomfort occurs, the athlete should return to the prior satisfactorily completed phase.

Specific Criteria for Release to Unsupervised Complete Participation in Baseball

- Prior to returning to complete participation without further supervision, several criteria must be present.
  - First, each phase of the general femoroacetabular impingement rehabilitation protocol must be completed to ensure appropriate conditioning of the hip musculature. As part of this non–sport-specific rehabilitation program, the athlete should be required to pass the hip sports test.
  - Second, the athlete should be progressed through a sport-specific training program as detailed later. This progression ensures gradual return to functional sport specific activities to minimize injury risk.
  - Ultimately, as part of a return to sport program, the athlete should be able to perform in simulated game situations without limitation prior to full return to sport, including baseball practice, simulation games, and gradual return to play such as playing three innings, then six innings, and finally nine-inning games.

Recommended Ongoing Exercises

- Analogous to the shoulder's rotator cuff, it is important for all athletes to engage in a general hip conditioning program. This is even more important in the postsurgical patient.
- Exercises including single leg squats, stool rotations, and standing hip abduction exercises are frequently recommended as maintenance exercises in postsurgical patients. They also serve as a good basic hip program for all athletes. Additionally, glute bridges (one and two legged), step-ups, and lateral band walks can be used.

Evidence

Enseki KR, Martin RL, Draovitch P, et al: The hip joint: arthroscopic procedures and postoperative rehabilitation. *J Orthop Sports Phys Ther* 36:516–525, 2006.

This report emphasizes the need for rehabilitation protocols to be individualized based on the principals of soft tissue healing and patient characteristics. These concepts remain critical in the postoperative rehabilitation of femoroacetabular impingement. (Level V evidence)

Philippon M, Schenker M, Briggs K, et al: Femoroacetabular impingement in 45 professional athletes: associated pathologies and return to sport following arthroscopic decompression. *Knee Surg Sports Traumatol Arthrosc* 15:908–914, 2007.

This retrospective review of professional athletes treated arthroscopically for femoroacetabular impingement indicates 93% of athletes were able to return to sport and 78% remained active in professional sport an average of 1.6 years later. Athletes unable to return to professional sport all demonstrated diffuse osteoarthritis at the time of arthroscopy. This suggests that arthroscopic treatment of hip impingement, coupled with rehabilitation and return to sport training, allow athletes to return to a high level of functioning when osteoarthritis is not present. (Level IV evidence)

Stalzer S, Wahoff M, Scanlan M: Rehabilitation following hip arthroscopy. *Clin Sports Med* 25:337–357, 2006.

This report describes an early rehabilitation protocol that stresses several important theoretic considerations. These principles include consideration of soft tissue healing constraints, edema control, early passive motion, early neuromuscular control, strengthening and proprioception, and sport-specific rehabilitation. While rehabilitation after hip arthroscopy continues to evolve, these considerations remain important. (Level V evidence)

Wahoff M, Ryan M: Rehabilitation after hip femoroacetabular impingement arthroscopy. *Clin Sports Med* 30:463–482, 2011.

The phases of a current rehabilitation protocol and their rationale are discussed. Because few evidence-based rehabilitation studies have been reported, current protocols are frequently based on expert opinion. To this end, it is thought that the introduction of early passive circumduction and functional sport progressions will better enable patients to effectively return to sport. (Level V evidence)

Multiple-Choice Questions

QUESTION 1. Maintenance of cardiovascular conditioning should be incorporated into the rehabilitation protocol:

A. As soon as feasible.
B. Six-weeks postoperatively.
C. Three months postoperatively.
D. Not until sport-specific training is completed.

QUESTION 2. Return to baseball after arthroscopic treatment of femoroacetabular impingement is different from other sports because:

A. There is no difference
B. Athletes do not suffer from FAI.
C. Position played affects rehabilitation timing and drills.
D. Impingement is typically in the upper extremity.

QUESTION 3. Sport-specific training should begin:

A. In the immediate postoperative period where appropriate.
B. Six weeks postoperatively.
C. 12 weeks postoperatively.
D. After basic hip rehabilitation is completed.

QUESTION 4. A hip sport test should be completed 10 to 12 weeks postoperatively and is intended to:

A. Judge hip range of motion.
B. Evaluate for residual impingement.
C. Slow return to sport.
D. Ensure adequate hip musculature conditioning to protect the hip during sport activity.

QUESTION 5. Return to sport principals include which of the following?

A. Soft tissue healing rate
B. Individual athlete goals
C. Gradual return to sport-specific activities/situations
D. All of the above

Answer Key

QUESTION 1. Correct answer: **A** (see Introduction)

QUESTION 2. Correct answer: **C** (see Introduction)

QUESTION 3. Correct answer: **A** (see Introduction)

QUESTION 4. Correct answer: **D** (see Objective Tests)

QUESTION 5. Correct answer: **D** (see Evidence)

BEYOND BASIC REHABILITATION: RETURN TO GOLF AFTER OPERATIVE TREATMENT OF FEMOROACETABULAR IMPINGEMENT

Trevor Ryan Gaskill, MD, Mark Andrew Ryan, MS, ATC, CSCS, and Marc J. Philippon, MD

ASPECTS OF GOLF THAT REQUIRE SPECIAL ATTENTION IN REHABILITATION

- Competitive golfers place considerable torsional loads on the hip joint. These activities are unique to golfers and therefore require an individualized approach to rehabilitation after hip arthroscopy.
- It is critical to "train" the athlete throughout all rehabilitation phases. It is our experience this approach improves athlete motivation and ensures physical conditioning of the unoperated extremities for safe return to sport.
- Maintenance of upper and nonoperative lower extremity strength as well as cardiovascular conditioning is emphasized.
- Although training is incorporated into all rehabilitation phases, it is progressively emphasized in successive phases when more advanced activities can be safely tolerated.
- The return to sport timeline should be individualized based on the specific needs of the athlete. Return to sport, however, should not exceed the body's physiological ability to heal the surgical repair.
- Therefore return to sport should occur no faster than indicated in protocol timelines; however, additional rehabilitation time may optimize the ability to return to sport in some circumstances.
- All athletes should successfully complete a "sports test" before returning to sport. This test is designed to help ensure adequate physiologic hip conditioning prior to returning to high-demand activities. Femoroacetabular impingement is a common cause of hip pain in young active athletes.
- Although symptoms may be produced by any activity sufficient to result in bony conflict, the torsional load that occurs repetitively to a golfer's hip places the "at-risk hip" in a position capable of impingement and is unique to these athletes.
- To this end, an individualized return to golf program is imperative to the successful return to sport after arthroscopic management of femoroacetabular impingement.

Introduction

Literature

- It is established that femoroacetabular impingement is a common cause of hip dysfunction in athletes and is responsible for mechanical damage to labral and cartilaginous tissue.
- Although hip impingement is no longer a novel concept, our understanding of, ability to treat, and rehabilitation experience continues to evolve.
- To date, little literature is available to guide rehabilitation of athletes undergoing decompression of abnormal bony conflict within the hip. To our knowledge, no published scientific literature describes rehabilitation specific to golfers.
- Under these circumstances, both an understanding of the stresses experienced by the hip when competing in this sport and experience treating these particular athletes become critical to optimizing return to sport for these athletes.

Advanced Strength and Conditioning Programs

Periodization

- The return to sporting activity after hip arthroscopy for femoroacetabular impingement and labral repair has several important physiological considerations.
- First, healing of a surgical repair occurs over a relatively defined and predictable time frame.
- Introduction of certain activities before sufficient healing may jeopardize surgical outcomes. This fact alone makes linear periodization a primary consideration in the design of postsurgical rehabilitation protocols.
- After sufficient healing of the surgical repair, more advanced strength and endurance activities are introduced. Because training for these modalities has been limited in the acute postsurgical period, a gradual progression into these activities is also necessary, as discussed in previous chapters.
- Once a foundation of conditioning is established and healing has occurred, functional sport-specific activities are introduced.
- Because many of these activities have not been performed vigorously for months, a linear progression is also necessary.
- It is the authors' goal to incorporate as many sport-specific activities as is safe beginning in the immediate postoperative period and progress these activities as healing allows.
- The postoperative program therefore consists of multiple microcycles and mesocycles within a linear progression within physiological healing parameters.
- Athletes are progressed through basic to complex skill sets while increasing performance speed and duration.

Program Design/Performance Training Program

Sport-Specific Concepts of Integrated Training

- Most return to sport programs begin approximately 2 weeks after normal gait has been established. This typically occurs around 6 to 8 weeks postsurgically.
- Before this time frame flexibility and joint mobility are emphasized to minimize the risk of postsurgical adhesions within the hip.
- Core strengthening, gait, and balance training are also part of the early training process before introduction of conditioning exercises.
- When appropriate, upper extremity and nonoperative cardiovascular conditioning are incorporated into the program.
- Subsequent to this initial healing phase, it is safe to incorporate training to optimize balance, strength, endurance, and power. For example, a squat type progression might include basic double leg body weight squats, progress to body weight squats on uneven surfaces such as a BOSU, weight-resisted squats, single leg squats, and finally squat jumps. Additional progressions for core, hamstrings, deep hip rotators, and lateral hip stabilizers (gluteus medius) would also be concurrently completed.
- Sport-specific activities are incorporated gradually beginning with putting, chipping, and pitching. The athlete can begin incorporating a progression of full swinging with irons at approximately 50% intensity with increased intensity of 10% to 20% a week until full power swinging is achieved provided there is no increase in hip pain. Drivers can then be added to the practice program in Week 5. (The full progression is described in the chart at the end of the chapter.)
- Olympic lifts used in the training program
  - Olympic lifts are not routinely used in our return to sport progression for golfers after arthroscopic treatment of femoroacetabular impingement.
  - Alternatively, it is our preference to incorporate functional, sport-specific activities throughout the rehabilitation period to introduce these complex motor activities at a gradual pace. For golfers, these include performing simulated golf swings in the pool, slow-speed simulated golf swings with resistant

TIMELINE 26-4: **Beyond Basic Rehabilitation: Return to Golf after Surgical Treatment of Femoroacetabular Impingement**

Weeks 0 to 2	Weeks 4 to 12	
	All golfers swing progression (3×/week)	**Concurrent walking progression if needed (tournament players not allowed to use carts) (3×/week)**

• Follow general FAI rehabilitation protocol
• Athlete may include cardiovascular activities beginning at 2 weeks postop
  • General recommendations include: swimming with pull buoy, one-leg rowing, upper body exercise
• Athlete may include light upper body conditioning at 2 weeks postop
  • General recommendations include: TRX suspension trainer
• Athlete may initiate rotator cuff maintenance program at 2 weeks
	Begin 3x/week, minimum 2 weeks after weaning off crutches. Add additional day Weeks 4 and 6 if needed.
	Weeks 1–6: Continue general FAI rehabilitation protocol in entirety.
	Week 1: Putting, chipping at 20% (approx. 30 minutes)
	Week 2: Continue putting, chipping, pitching at 40% (approx. 30 minutes)
	Week 3:
	• Continue putting, chipping and pitching
	• Add: Mid irons starting at 50%
	Week 4:
	• Continue putting, chipping and pitching
	• Add: Swing intensity up to 70%
	Week 5:
	• Continue putting, chipping and pitching
	• Add: Woods/driver starting at 50%, irons at 90%
	Week 6:
	• Continue putting, chipping and pitching
	• Add: Woods/driver up to 70%, irons up to 95%
	• Can play holes within intensity levels outlined
	Week 7: Play 9 holes using cart, swinging woods at up to70%, irons up to 95%
	Weeks 8–9: Play 9 holes, walk if there is a need to, swinging woods at 80%, irons at 100%
	Weeks 9–10: Play 18 holes, with cart, swinging woods at 90%, irons at 100%
	Weeks 11–12: Play 18 holes, walk if there is a need to, swinging 100%
	All athletes should prepare to pass sport test between weeks 10 and 12 postoperatively.
		Begin 3x/week, minimum 2 weeks after weaning off crutches. Add additional day Weeks 4 and 6 if needed
		Weeks 1–6: Continue general FAI rehabilitation protocol in entirety.
		Week 1: 0.25-mile walk
		Week 2: 0.33-mile walk
		Week 3: 0.5-mile walk
		Week 4: 1-mile walk
		Week 5: 1.5-mile walk
		Week 6: 2-mile walk
		Week 7: 2.5-mile walk
		Week 8: 3-mile walk or walk nine-hole course
		Week 9: 3.5-mile walk or walk nine-hole course
		Week 10: 4-mile walk
		Week 11: 4.5-mile walk
		Week 12: 5-mile walk
		Week 13: 6-mile walk or walk 18-hole course
		All athletes should prepare to pass sport test between weeks 10 and 12 weeks postoperatively.

cord, and finally live swinging progressions as described in the preceding.
- Additionally, it is our experience that athletes experience greater satisfaction and motivation as these activities are progressively instituted into the rehabilitation/training progression.
- Olympic lifts may be added back into the athlete's strength and conditioning program upon full return to sport activity if the athlete has had previous experience performing the lifts.

Training Principles Used in the Design of the Program

- Progression and specific adaptation to imposed demand are used in the design of the return to sport program.
- As the athlete is able to perform the prescribed sport-specific activities with the appropriate technique and without undue fatigue or increased pain, golf progression can be advanced.
- Progression occurs through activity complexity, speed and intensity of the activity, and the duration the activity is performed. Moreover, the frequency the athlete participates in the prescribed activity may also be increased.

Application of Acute Training Variables

- During each aspect of the return to golf progression several acute training variables are applied.
- Initial movements are performed in a controlled environment with planned movement patterns. Initial golf swings are done in the clinic or pool. As adaptation and acceptance of these movements are made, activities can be moved outdoors to a driving range, and finally to a course where playing surfaces vary such as uneven lies and bunkers are encountered.
- These movements are progressed from basic to complex, while speed and duration of activities are also increased gradually. To this end, club length, repetitions, and intensity are gradually increased. Skills and activities will progress from easy putting, chipping and pitching using submaximal efforts, to the use of irons at gradually increasing swing power, and finally adding drivers and full power.
- In later phases the frequency of training within each week also increases.
- The tempo of the activities is also gradually increased over the training to simulate match conditions before return to unrestricted sporting activity.

Application of Chronic Training Variables

- The goal of return to sport training is to safely return an athlete to sport-specific activities while minimizing the risk of recurrent injury while the body is deconditioned.
- Therefore after successfully returning the athlete safely to sport, their typical training program can be restarted.
- It is important for the athlete, however, to continue a hip specific strengthening program to maintain strength, endurance, and stability of the hip musculature. These may include double and single leg squats, gluteal bridging, single leg RDLs, multidirectional core movements such as resisted wood chops or med ball throws, and core stabilization exercises such as planks and side planks.

Sports Performance Testing

General Information

- The Hip Sports Test is performed around 10 to 12 weeks postoperatively.
- It is intended to ensure adequate hip musculature conditioning necessary to protect the hip during sporting activities. No formal research has been completed to validate its effectiveness in predicting reinjury or readiness for return to sport, but the authors are unaware of any such test. The authors have found it to be an effective clinical tool to test muscular endurance and stability of the hip musculature and also demonstrate what movement patterns may be painful to the athlete. We have found clinically that athletes who go through the process of training for the sport test have high compliance with the overall rehabilitation process and have proved to have high levels of endurance and stability. How this relates specifically to their ability to play golf has yet to be determined.
- If the athlete is not able to pass the test, it also serves as a guide to the type of rehabilitation necessary to optimize the athlete's recovery.

Objective Tests

- Single leg squat (3 min max): 6 pts
  - **Description:** The athlete will perform single knee bends with cord resistance to 60° at a cadence of 1 second up and 1 second down for a goal of 3 minutes. The movement is between 30° to 60° of flexion with the knee never fully straightening past 30° throughout the 3 minutes. To cue the athlete the depth of 60°, the buttocks can lightly touch the seat of a chair or object. Two fingers are allowed for balance on a chair back.
  - **Setup:**
    - With a goniometer, measure a 60° knee bend and place a chair in a position to allow the athlete's buttocks to lightly touch at that depth.
    - The athlete places the heel of the foot on the cord at a position so the D-ring of the handle is aligned with the knee joint line to remove slack from the cord.
    - Tension is set by pulling the cord handle to the waist line and holding. Having the athlete hook his or her thumb around the pant line is helpful in maintaining tension on the cord.
    - Two fingers of the opposite hand are allowed to lightly touch another chair back for balance
  - Technique: The athlete must perform each repetition of a single knee bend without the following:
    - Trendelenburg sign (pelvis must remain level)
    - The knee locking in full extension
    - The knee "collapsing" into medial rotation/adduction
    - The patella extending past the toe.

      Cuing should be provided when one of the following compensations are noted. **If unable to correct, STOP THE TEST.**
  - Scoring: One point is earned for each 30-second increment completed with proper form for a total of 6 possible points.

- Testing is stopped if and when:
  - Form: Once the subject is unable to complete single knee bends without compensation even with cuing.
  - Pain: The patient has pain greater than 3/10 OR reproduces the pain.
  - Endurance: The athlete becomes fatigued.
- Lateral agility test (100s max): 5 pts
  - Purpose: To test the ability of the leg to accept load (absorb) and push off in a lateral direction.
  - Supplies: Sport cord (Topper Sports Medicine, black cord), stopwatch, and tape
  - Description: The athlete will hop laterally with cord resistance from the surgical leg, land momentarily on the nonsurgical leg, only to return onto the surgical leg with the cord pulling him or her back to the starting position for a total test time of 100 seconds. Each repetition of 1 second includes exploding laterally off the surgical side, landing momentarily on the opposite leg, and then returning to the starting position with emphasis on absorbing by bending at the hip and knee with 30° of knee excursion. Excursion is defined as the amount of absorption from knee flexion at landing to max knee flexion.
  - Setup:
    - Place the belt through the sport cord handles and then attach around the waist.
    - Attach the other end of the sport cord to the door jam or secure post.
    - Stand sideways with the involved leg toward the cord attachment.
    - Step away laterally until tension is reached where the athlete slightly compensates with leaning and place a line with tape on the lateral aspect of the involved foot.
    - Measure the distance from the greater trochanter to the floor.
    - Use this measured distance to place a second tape line parallel to the first.
  - Technique: The athlete must perform each lateral hop by landing on or inside the first tape line with the involved foot and on or outside the second tape line with the uninvolved foot. Only one foot should be on the ground at the same time and the athlete must absorb onto the involved leg without the following:
    - Trendelenburg sign (pelvis must remain level)
    - The knee "collapsing" into medial rotation/adduction
    - The patella extending past the toe
    - Losing control or stability

      Cuing should be provided when one of the following compensations are noted. **If unable to correct, STOP THE TEST.**
  - Scoring: One point is earned for each 20 second increment completed with proper form for a total of 5 possible points.
  - Testing is stopped if and when:
    - Form: Once the subject is unable to complete single knee bends without compensation even with cuing.
    - Pain: The patient has pain greater than 3/10 OR reproduces the pain.
    - Endurance: The athlete becomes fatigued.
- Diagonal agility test (100s max): 5 pts
  - Purpose: To test the ability of the leg to accept load (absorb) and push off in a diagonal direction
  - Supplies: Sport cord (Topper Sports Medicine, black cord), stopwatch, and tape
  - Description: The athlete will hop diagonally forward at a 45° angle with cord resistance from the surgical leg, land momentarily on the nonsurgical leg, only to return onto the surgical leg with the cord pulling him or her back to the starting position. The following repetition the athlete will hop diagonally backward at a 45° angle. The goal is 100 seconds total. Each repetition of 1 second includes exploding diagonally forward or backward at 45° angles off the surgical side, landing momentarily on the opposite leg, and then returning to the starting position with emphasis on absorbing by bending at the hip and knee with 30 degrees of knee excursion. Excursion is defined as the amount of absorption from knee flexion at landing to max knee flexion.
  - Setup:
    - Place the belt through the sport cord handles and then attach around the waist.
    - Attach the other end of the sport cord to the door jam or secure post.
    - Stand sideways with the involved leg toward the cord attachment.
    - Step away laterally until tension is reached where the athlete slightly compensates with leaning and place a line with tape on the lateral aspect of the involved foot.
    - Measure the distance from the greater trochanter to the floor.
    - Use this measured distance to place a second tape line at a 45° angle forward and a third tape line at a 45° backward to form a V if connecting the lines.
  - Technique: The athlete must perform each diagonal lateral hop by landing on or inside the first tape line with the involved foot and on or outside the second or third tape line with the uninvolved foot. (Each foot should land parallel with each tape line.) Only one foot should be on the ground at the same time and the athlete must absorb onto the involved leg without the following:
    - Trendelenburg sign (pelvis must remain level)
    - The knee "collapsing" into medial rotation/adduction
    - The patella extending past the toe
    - Losing control or stability

      Cuing should be provided when one of the following compensations are noted. **If unable to correct, STOP THE TEST.**
  - Scoring: One point is earned for each 20-second increment completed with proper form for a total of 5 possible points.
  - Testing is stopped if and when:
    - Form: Once the subject is unable to complete single knee bends without compensation even with cuing.

    - Pain: the patient has pain greater than 3/10 OR reproduces the pain.
    - Endurance: The athlete becomes fatigued.
- Forward single leg lunges (2 min max): 4 pts
  - Purpose: To test the lower extremity strength and endurance into extension.
  - Supplies: Sport cord (Topper Sports Medicine, black cord), stopwatch, and tape
  - Description: The athlete will perform alternating forward lunges onto a box with cord resistance at a cadence of 2 seconds per lunge for a goal of 2 minutes. The movement is a forward lunge with maximum hip extension without compensation at the pelvis or spine throughout the 2 minutes.
  - Setup:
    - Place the belt through the sport cord handles and then attach around the waist.
    - Attach the other end of the sport cord to the door jam or secure post.
    - Stand facing away from the cord attachment.
    - Step forward until tension is reached where the athlete slightly compensates by leaning and tape a line in front of the feet.
    - Measure the distance from the greater trochanter to the floor.
    - Place a stable box or chair the height of the athlete's knees in front of him or her at a distance equal to the measure of the greater trochanter to the floor.
  - Technique: The athlete must perform *alternating* forward lunges onto the box keeping their planted leg behind the line and extending the hip without the following:
    - Trendelenburg sign (pelvis must remain level)
    - Excessive lumbar hyperextension
    - Pelvic rotation

      Correct performance of this activity is through proper extension of the hip.
  - Scoring: One point is earned for each 30-second increment completed with proper form for a total of 4 possible points.
  - Testing is stopped if and when:
    - Form: Once the subject is unable to complete single knee bends without compensation even with cuing.
    - Pain: The patient has pain greater than 3/10 OR reproduces the pain.
    - Endurance: The athlete becomes fatigued.
- A score of greater than 16 is required before return to advanced sporting activities. Points are deducted based on inadequate form (i.e., Trendelenburg, collapse of the leg into internal rotation of adduction, or the use of a chair for support rather than balance) or the lack of endurance (i.e., failure to maintain rhythm or trembling).[1]

Specific Criteria for Progression to the Next Stage to Determine Readiness for Golf

- Progression to any subsequent phase of rehabilitation should not occur until the goals of the previous phase can be completed appropriately and without undue discomfort.
- Golf progression is described in the preceding.
- Sport-specific rehabilitation (apart from general rehabilitation after arthroscopic hip surgery) should not be started until the surgeon and therapist are satisfied that sufficient biological healing has occurred and that the hip musculature has been conditioned to a point the functional sporting activity is not likely to be detrimental to the overall recovery process. This decision is made at the 8 week physician follow-up.
- This typically occurs 6 to 8 weeks postsurgically, although some basic components can be incorporated earlier.
- Each phase of the sport-specific training should be able to be completed without discomfort. If discomfort occurs, the athlete should return to the prior satisfactorily completed phase.

Specific Criteria for Release to Unsupervised Complete Participation in Golf

- Before returning to complete participation without further supervision, several criteria must be present.
- First, each phase of the general femoroacetabular impingement rehabilitation protocol must be completed to ensure appropriate conditioning of the hip musculature.
- As part of this non–sport-specific rehabilitation program, the athlete should be required to pass the hip sports test.
- Second, the athlete should be progressed through a sport-specific training program as detailed below.
- This progression ensures gradual return to functional sport-specific activities to minimize injury risk.
- Ultimately, as part of a return to sport program, the athlete should be able to perform in simulated game situations (driving range and practice rounds) without limitation before full return to sport.

Recommended Ongoing Exercises

- Analogous to the shoulder's rotator cuff, it is important for all athletes to engage in a general hip-conditioning program.
- This is even more important in the postsurgical patient.
- Exercises including single leg squats, stool rotations, standing hip abduction exercises are frequently recommended as maintenance exercises in postsurgical patients. They also serve as a good basic hip program for all athletes. Additionally, gluteal bridges (one- and two-legged), step ups and lateral band walks can be used.

Evidence

Enseki KR, Martin RL, Draovitch P, et al: The hip joint: arthroscopic procedures and postoperative rehabilitation. *J Orthop Sports Phys Ther* 36:516–525, 2006.

This report emphasizes the need for rehabilitation protocols to be individualized based on the principals of soft tissue healing and patient characteristics. These concepts remain

critical in the postoperative rehabilitation of femoroacetabular impingement. (Level V evidence)

Philippon M, Schenker M, Briggs K, et al: Femoroacetabular impingement in 45 professional athletes: associated pathologies and return to sport following arthroscopic decompression. *Knee Surg Sports Traumatol Arthrosc* 15:908–914, 2007.

This retrospective review of professional athletes treated arthroscopically for femoroacetabular impingement indicates 93% of athletes were able to return to sport and 78% remained active in professional sport an average of 1.6 years later. Athletes unable to return to professional sport all demonstrated diffuse osteoarthritis at the time of arthroscopy. This suggests that arthroscopic treatment of hip impingement, coupled with rehabilitation and return to sport training allow athletes to return to a high level of functioning when osteoarthritis is not present (Level IV evidence).

Stalzer S, Wahoff M, Scanlan M: Rehabilitation following hip arthroscopy. *Clin Sports Med* 25:337–357, 2006.

This report describes an early rehabilitation protocol that stresses several important theoretic considerations. These principles include consideration of soft tissue healing constraints, edema control, early passive motion, early neuromuscular control, strengthening and proprioception, and sport-specific rehabilitation. Although rehabilitation after hip arthroscopy continue to evolve, these considerations remain important. (Level V evidence)

Wahoff M, Ryan M: Rehabilitation after hip femoroacetabular impingement arthroscopy. *Clin Sports Med* 30:463–482, 2011.

The phases of a current rehabilitation protocol and their rationale are discussed. Because few evidence-based rehabilitation studies have been reported, current protocols are frequently based on expert opinion. To this end, it is thought that the introduction of early passive circumduction and functional sport progressions will better enable patients to effectively return to sport. (Level V evidence)

Multiple Choice Questions

QUESTION 1. Maintenance of cardiovascular conditioning should be incorporated into the rehabilitation protocol:

A. As soon as feasible.
B. Six weeks postoperatively.
C. Three months postoperatively.
D. Not until sport-specific training is completed.

QUESTION 2. Sport-specific training should begin:

A. In the immediate postoperative period where appropriate.
B. Six weeks postoperatively.
C. 12 weeks postoperatively.
D. After basic hip rehabilitation is completed.

QUESTION 3. Return to sport principals includes which of the following?

A. Soft-tissue healing rate
B. Individual athlete goals
C. Gradual return to sport-specific activities/situations
D. All of the above

QUESTION 4. The major physiological event of concern to the hip with return to golf progressions is:

A. The deep hip flexion required.
B. Upper body endurance.
C. The repetitive torsional strain placed on the healing hip.
D. Early weightbearing.

QUESTION 5. A hip sport test should be completed 10 to 12 weeks postoperatively and is intended to:

A. Judge hip range of motion.
B. Evaluate for residual impingement.
C. Slow return to sport.
D. Ensure adequate hip musculature conditioning to protect the hip during sport activity.

Answer Key

QUESTION 1: Correct answer: **A** (see Introduction)

QUESTION 2: Correct answer: **A** (see Introduction)

QUESTION 3: Correct answer: **D** (see Introduction)

QUESTION 4: Correct answer: **C** (see Evidence)

QUESTION 5: Correct answer: **D** (see Sports Performance Testing: General Information)

Chapter 27

Stress Fractures of the Femoral Neck and Shaft

INTRODUCTION

Bryan C. Heiderscheit, PT, PhD, and Geoffrey S. Baer, MD, PhD

Epidemiology

- Femoral neck stress fractures account for approximately 11% of stress fractures in athletes; the incidence of stress fractures in the femoral shaft has been reported as approximately 3.5%, but is suspected to be as high as 20% in athletes.
- They are most commonly associated with vigorous weight-bearing activities, such as running, gymnastics, dancing, and marching.
- Females appear to be more prone to this injury.
- The role of age as an independent risk factor is inconclusive, as secondary factors such as training volume and intensity are typically not controlled.
- In athletes, femoral shaft stress fractures are more common in the mid-medial or posteromedial cortex

Pathophysiology

Intrinsic Factors

- Previous stress fracture or family history of stress fracture
- Low bone mineral density
- In women, low aerobic fitness, menstrual dysfunction during the prior year and small calf girth
- Bisphosphonate use in older athletes, most often female
- Poor nutritional status, including low vitamin D status
- Lower extremity alignment, such as rigid medial longitudinal arch of the foot, leg length inequality, and excessive forefoot varus
- Acetabular retroversion

Extrinsic Factors

- A rapid or substantial increase in training volume (i.e., frequency, duration, intensity) with inadequate rest days
- Greater vertical ground reaction force loading rate during running

Classic Pathological Findings

- Periosteal resorption occurs at a faster rate than bone formation, resulting in the cortex becoming weakened and fractured.
- The balance between resorption and bone formation is influenced by the extrinsic and intrinsic risk factors.

Clinical Presentation

History

- Pain is typically nonspecific, insidious, and related to activity.
- Anterior hip, inguinal, and groin pain is common for femoral neck involvement, with diffuse thigh or possibly knee pain if the femoral shaft is involved.
- Pain often persists during rest, particularly with more severe injuries.
- Increased pain with impact type activity
- Increased pain with continued activity
- Patient frequently reports a recent increase in activity level.

Physical Examination

Abnormal Findings

- Antalgic gait may be present
- Fulcrum test can be used to identify femoral shaft stress fractures, which involves the patient being seated with examiner's arm under the involved distal thigh and applying gentle pressure over the knee directed toward the floor. The arm under the thigh is progressively

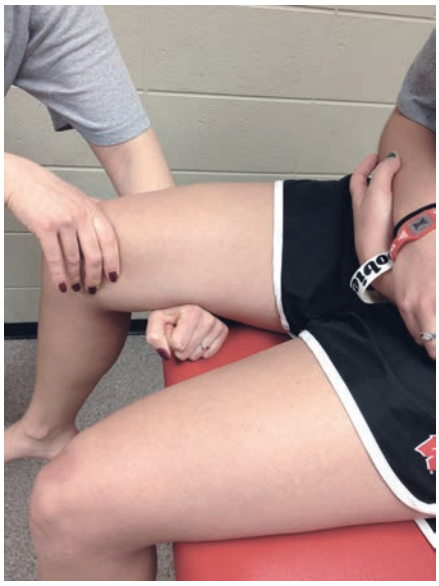

FIGURE 27-1. Fulcrum test.

moved from distal to proximal, with pressure applied at each position, until deep pain is felt by the patient indicating a positive test (Figure 27-1).
- Patrick's test (hip flexion, abduction, and external rotation) or extremes of passive range of motion may provoke pain with involvement of the femoral neck or proximal shaft.
- Hopping on the involved side may elicit pain, although not specific for a femoral stress fracture.

Pertinent Normal Findings

- Bone tenderness may be absent because of the depth of the involved bones.
- Joint range of motion is usually normal, except if the femoral neck is involved.
- Strength is generally normal unless pain is provoked.
- Normal reflexes
- No referred symptoms during testing of lumbar spine

Imaging

- Plain radiographs have poor sensitivity but high specificity. Abnormalities are unlikely unless symptoms have been present for at least 2 to 3 weeks.
- If radiographs show new periosteal bone formation, a visible area of sclerosis, the presence of a callus, or a visible fracture line, the diagnosis of stress fracture is confirmed.
- If radiographs are negative but suspicion of a femoral stress fracture remains, a bone scan or magnetic resonance imaging (MRI) is indicated, with magnetic resonance imaging being the better modality to diagnose femoral neck stress fractures (Figure 27-2).

Differential Diagnosis

- Groin pain: likely to provoke pain with strength testing and palpation
- Hip flexor strain: likely to provoke pain with strength testing and palpation
- Hip osteoarthritis: more gradual onset
- Hip labral tear or femoroacetabular impingement (FAI): MRI demonstrates labral tear or FAI without evidence of femoral neck involvement
- Sports hernia: MRI findings are often normal
- Avascular necrosis: gradual onset with pain in groin, thigh or buttock
- Greater trochanteric pain syndrome: superficial pain with palpation
- Osteosarcoma: swelling and tenderness; unexpected weight loss
- Osteoid osteoma: presence of night pain that can be initially relieved with over-the-counter pain medication; well-demarcated lytic lesion on imaging
- Lumbar spine involvement (i.e., radiculopathy, spinal stenosis, herniated disc, facet syndrome, spondylosis): positive lumbar spine physical exam
- Sacroiliac joint dysfunction: positive sacroiliac joint exam

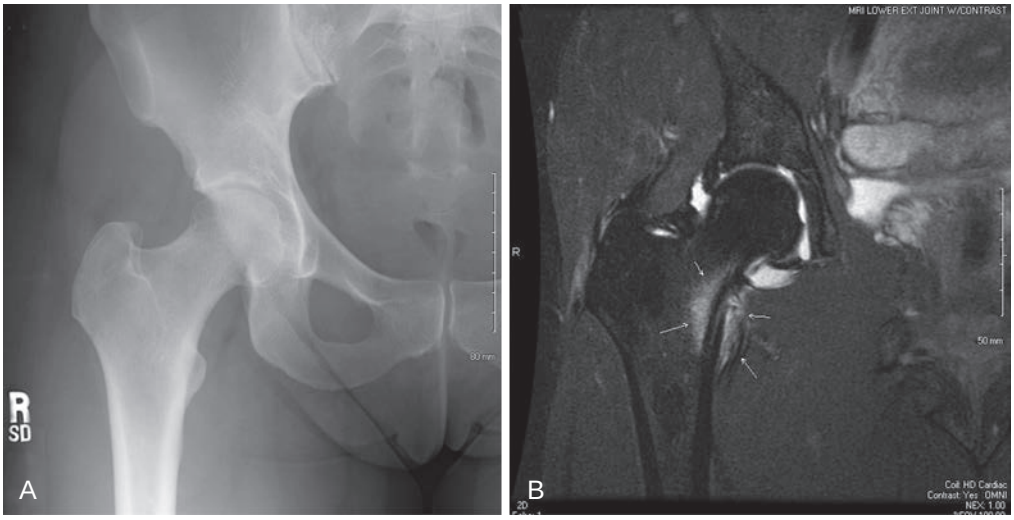

FIGURE 27-2. Femoral neck stress fracture negative on (**A**) radiograph but positive on (**B**) magnetic resonance imaging.

Treatment

Nonoperative Management

- For nondisplaced compression stress reactions involving the femoral shaft, a 1- to 4-week period of limited weight bearing followed by a gradual, progressive return to activity is sufficient for recovery.
- For nondisplaced compression stress fractures involving the femoral shaft, a 4- to 6-week period of limited weight bearing followed by a gradual, progressive return to activity is sufficient for recovery.
- For nondisplaced stress fractures involving the inferior aspect of the femoral neck, a 4- to 6-week period of non–weight bearing is recommended. Radiographic evidence of healing should be evident before beginning a progressive return to weight bearing and activity.
- The gradual return to activity should include exercises to address strength, flexibility, and postural control deficits.
- An analysis of the individual's sports mechanics (i.e., running, gymnastics, dance) should be performed to identify and correct any pathomechanics that may have contributed to the original injury or resulted from it.
- A nutritional assessment should be performed to ensure adequate caloric intake and appropriate vitamins and minerals to maintain adequate bone density.
- Calcium and vitamin D supplementation should be considered, especially for competitive athletes.
- If a metabolic disorder or hormonal imbalance is suspected to contribute to the stress fracture, a more detailed medical evaluation is required.
- Use of an electrical bone stimulator may be considered with stress fractures showing delayed healing or nonunion.

Guidelines for Choosing Among Nonoperative Treatments

- The location (shaft vs neck; compression-sided vs tension-sided) and severity (displaced vs nondisplaced) of the stress fracture determines the extent and duration of non–weight bearing.
- Prolonged non–weight bearing may be recommended if the individual has low bone mineral density.

FIGURE 27-3. Radiograph of right femoral neck stress fracture with displacement.

Surgical Indications

- Displaced fracture (Figures 27-3 and 27-4)
- Tension-sided stress fracture
- Subtrochanteric stress fracture
- Extension of fracture line of compression side femoral neck beyond 50%
- Failure of nonoperative management
- Malunion or nonunion
- Failure of prior fixation
- History of multiple stress fractures (relative)
- Low bone mineral density (relative)

Aspects of History, Demographics, or Exam Findings That Affect Choice of Treatment

- Location of fracture established through physical examination and imaging
- History of multiple stress fractures
- Vitamin D deficiency (serum 25[OH]D status less than 10 ng/ml severe; 10 to 29 ng/ml mild/moderate; 30 to 80 ng/ml optimum; greater than 80 ng/ml toxicity possible) with goal of 60 ng/ml in athletes with stress fractures
- Low bone mineral density
- Patient's relative activity level, more aggressive with more activity (e.g., competitive runner)

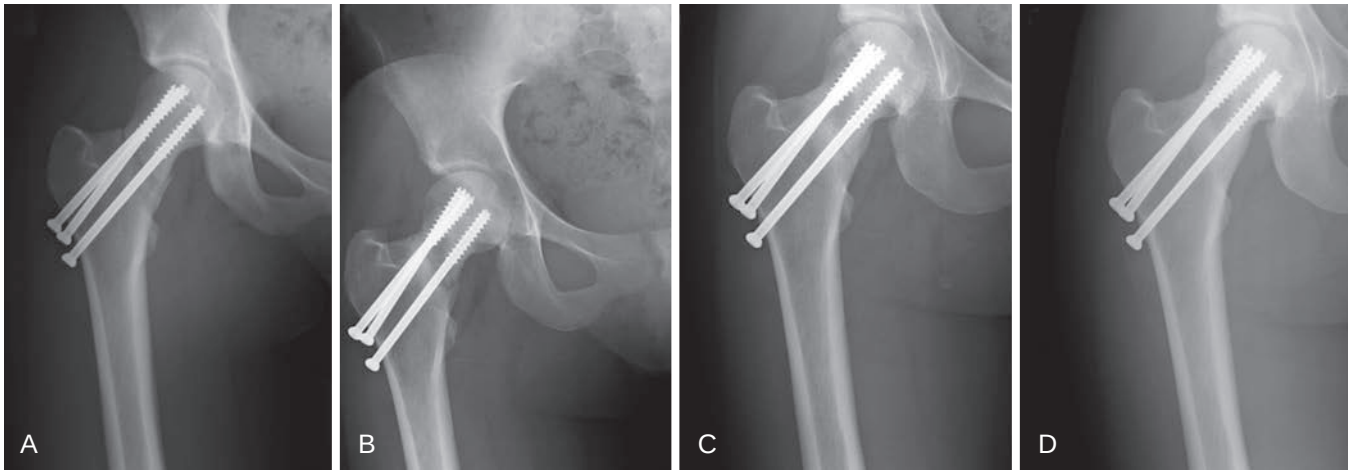

FIGURE 27-4. Postoperative radiographs following closed reduction and internal fixation of displaced right femoral neck fracture shown in Figure 27-3. Minimal healing was evident at (**A**) 1 month postsurgery, with progressive healing present at (**B**) 7 months, (**C**) 14 months, and (**D**) 19 months postsurgery.

Aspects of Clinical Decision Making When Surgery Is Indicated

- Displaced femoral neck fractures often require emergent anatomical open reduction and fixation.
  - Dynamic hip screw of fixed angle plate is often required for stable fixation.
- Osteotomy may be required for varus angulation in malunion or nonunion cases.
- Subtrochanteric fractures can often be treated with intermedullary nails or fixed angle plates.
- Nondisplaced tension-sided (superior) femoral neck stress fractures can be treated with percutaneous fixation.
- Compression-sided femoral neck stress fracture that extend beyond 50% can be treated with percutaneous fixation.

Evidence

Bennell KL, Malcolm SA, Thomas SA, et al: Risk factors for stress fractures in track and field athletes. A twelve-month prospective study. *Am J Sports Med* 24:810–818, 1996.

This prospective cohort study investigated risk factors for stress fractures in 111 track and field athletes. No risk factors were identified for men; however, lower bone density, a history of menstrual disturbance, less lean mass in the lower limb, a discrepancy in leg length, and a lower fat diet were significant risk factors for women. (Level IIb evidence)

Boden BP, Speer KP: Femoral stress fractures. *Clin Sports Med* 16:307–317, 1997.

This expert opinion article reviews common femoral stress fractures and includes a brief case report for each. A summary of presentation, examination, and treatment is provided for each stress fracture location. (Level V evidence)

Kiuru MJ, Pihlajamaki HK, Ahovuo JA: Fatigue stress injuries of the pelvic bones and proximal femur: Evaluation with MR imaging. *Eur Radiol* 13:605–611, 2003.

This retrospective review of 340 consecutive patients with stress-related hip, buttock, or groin pain sought to determine the injury prevalence and distribution based on MRI and radiographs. Bone stress injuries were present in 40% of patient with hip pain, with 60% located in the proximal femur, and 40% in the pelvic bones. The sensitivity of radiography was 37%, specificity 79%, accuracy 60%, positive predictive value 59%, and negative predictive value 61%. The kappa value for agreement between radiography and MRI was poor (0.17, p = .0008). (Level IV evidence)

Kuhn KM, Riccio AI, Saldua NS, et al: Acetabular retroversion in military recruits with femoral neck stress fractures. *Clin Orthop Relat Res* 468:846–851, 2010.

This case-control study compared the anteroposterior radiographs of 54 patients treated for femoral neck stress fractures. The prevalence of a positive cross-over sign was greater in patients with stress fractures than in the control subjects (31 of 54 [57%] vs 17 of 54 [31%], respectively). A greater incidence of acetabular retroversion was present in patients with femoral neck stress fractures. (Level IV evidence)

Pihlajamaki HK, Ruohola JP, Kiuru MJ, et al: Displaced femoral neck fatigue fractures in military recruits. *J Bone Joint Surg Am* 88:1989–1997, 2006.

This descriptive study reported on 21 military recruits that sustained displaced femoral neck stress fracture, with 19 recruits followed for an average of 18 years. Following treatment, six patients had delayed union or nonunion of the fracture; six patients developed osteonecrosis of the femoral head; and eight patients developed severe osteoarthritis. (Level IV evidence)

Multiple Choice Questions

QUESTION 1. Which of the following athletes is at the greatest risk for a femoral shaft stress fracture?

A. Female softball player
B. Female cross country runner
C. Male cross country runner
D. Female basketball player

QUESTION 2. Which of the following is not an intrinsic risk factor for a femoral stress fracture?

A. Poor nutritional status
B. High medial longitudinal arch of the foot
C. Prior stress fracture
D. Rapid or substantial increase in training volume

QUESTION 3. Which clinical test may be useful in detecting a stress fracture of the femoral shaft?

A. Ober's test
B. Fulcrum test
C. Straight leg raise test
D. Scour test

QUESTION 4. To confirm the diagnosis of stress fracture from radiographs, which of the following should be observed?

A. New periosteal bone formation
B. Visible area of sclerosis
C. Visible fracture line
D. Any of the above

QUESTION 5. Which of the following is recommended as part of the recovery process for a nondisplaced, compression-sided femoral shaft stress fracture?

A. Limited weight bearing for 1 to 4 weeks
B. Exercises to address strength, flexibility, and postural control deficits
C. Nutritional assessment
D. All of the above

Answer Key

QUESTION 1. Correct answer: **B** (see Epidemiology)

QUESTION 2. Correct answer: **D** (see Pathophysiology)

QUESTION 3. Correct answer: **B** (see Clinical Presentation—Abnormal Findings)

QUESTION 4. Correct answer: **D** (see Clinical Presentation—Imaging)

QUESTION 5. Correct answer: **D** (see Treatment)

NONOPERATIVE REHABILITATION OF STRESS FRACTURES OF THE FEMORAL NECK AND SHAFT

Bryan C. Heiderscheit, PT, PhD, and Geoffrey S. Baer, MD, PhD

GUIDING PRINCIPLES OF NONOPERATIVE REHABILITATION

- Protection to site of injury to prevent fracture propagation
- Progressive loading to promote bone regeneration
- Maintenance of muscle strength
- This rehabilitation program is designed for nonoperative management of nondisplaced femoral neck and shaft stress fractures.
- Because of risk for significant complications, most tension-sided femoral neck stress fractures are managed surgically. This rehabilitation program is not appropriate for postoperative management because additional restrictions may apply.

Phase I (weeks 1 to 4–6): Limited Weight Bearing

Protection

- Crutches
  - Femoral shaft
    - Toe-touch weight bearing with progression to weight bearing as tolerated over a 1- to 4-week period
  - Femoral neck
    - Non–weight bearing until pain free with radiographic evidence of healing, often 4 to 6 weeks

Techniques for Progressive Increase in Range of Motion

- Femoral neck stress fracture may display limited hip range of motion primarily owing to muscle guarding. Soft tissue mobilization may prove useful in resolving the muscle guarding; however non–weight bearing and activity restriction often produce the same effect.
- Joint mobilization techniques should not be performed with femoral neck stress fractures as they are typically unnecessary and could compromise the fracture healing. Hip range of motion is rarely affected as a result of femoral shaft stress fractures.

Soft Tissue Techniques

- Deep tissue massage, trigger point release and augmented soft tissue mobilization may be considered to resolve associated muscle guarding (gluteals, adductors, quadriceps, hamstrings)

Stretching and Flexibility Techniques for the Musculotendinous Unit

- Gentle to moderate intensity stretching to hamstrings, quadriceps, hip flexors, adductors, and plantar flexors.

Other Therapeutic Exercises

- Easy freestyle swimming
- Deep water running with a flotation belt
- Seated cycling with low to moderate resistance
- Total arm strengthening
- Core stability, as appropriate given limited weight-bearing status

Activation of Primary Muscles Involved

- Vastus medialis and adductor brevis attach at a common site for femoral shaft stress fractures (junction of proximal and middle thirds). Therefore selected exercises should minimize the force production required of these muscles.

TIMELINE 27-1: **Nonoperative Rehabilitation of Femoral Neck and Shaft Stress Fractures**

PHASE I (weeks 1 to 4 to 6)	PHASE II (weeks 4 to 6 to 8)	PHASE III (weeks 8 to 12)
• Crutches • Soft tissue mobilization as needed • Stretching • Cross-training (swimming, cycling) • TAS activities • Core exercises as recommended and tolerated	• Soft tissue mobilization as needed • Stretching • Elliptical • TAS/TLS activities • Core exercises as recommended and tolerated • Balance/proprioception • Weight-bearing lower extremity PREs • Neuromuscular stability exercises • Plyometric exercises as recommended • Begin walk-run program	• Soft tissue mobilization as needed • Stretching • Elliptical • TAS/TLS activities • Core exercises as recommended and tolerated • Balance/proprioception • Weight-bearing lower extremity PREs • Neuromuscular stability exercises • Plyometric exercises as recommended • Complete walk-run program

FIGURE 27-5. Bent knee hip extension in quadruped.

Techniques to Increase Muscle Strength, Power, and Endurance

- For femoral shaft stress fractures:
  - Side-lying hip abduction, 2 × 15
  - Bent knee hip extension in quadruped, 2 × 15 each side (Figure 27-5)
  - One-leg standing (uninvolved side) hip extension with tubing, 2 × 15 with tubing on involved side only, low resistance (Figure 27-6)
  - One-leg standing (uninvolved side) hip abduction with tubing, 2 × 15 with tubing on involved side only, low resistance (Figure 27-7)

Neuromuscular Dynamic Stability Exercises

- For femoral shaft stress fractures:
  - Alternate straight leg and arm raise in quadruped, 2 × 15 each side (Figure 27-8)

Milestones for Progression to the Next Phase

- Pain-free in weightbearing with no antalgic gait
- Radiographic evidence of healing of femoral neck stress fractures

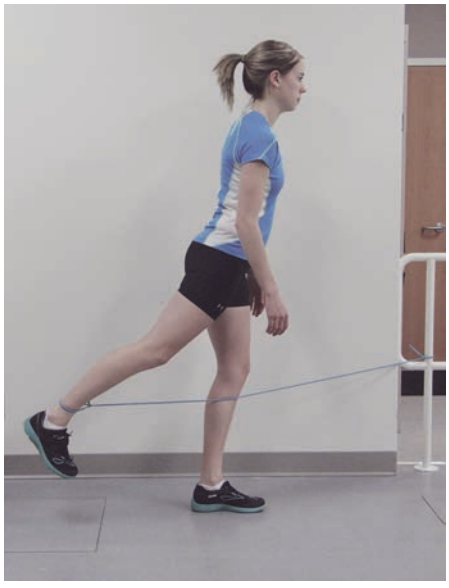

FIGURE 27-6. One-leg standing (uninvolved side) hip extension with tubing on involved side.

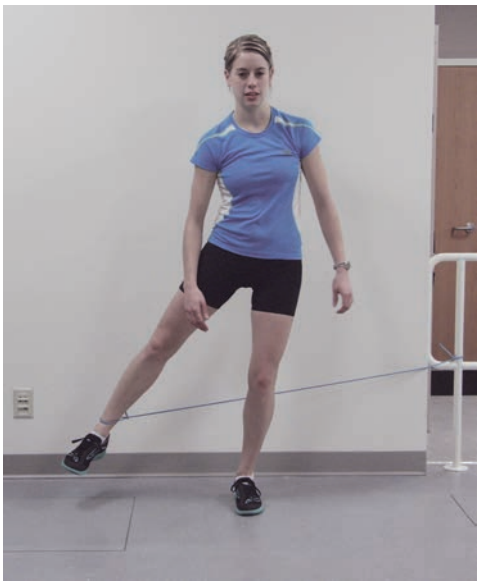

FIGURE 27-7. One-leg standing (uninvolved side) hip abduction with tubing on involved side.

- Full range of motion at hip based on goniometric assessment

Phase II (weeks 4–6 to 8): Low- to Moderate-Impact Activities

- The amount of impact associated with the activities and exercises in this phase is progressively increased. The initial 1 to 2 weeks are typically spent doing low impact activities to determine the bone's tolerance to loading.
- Once the low impact exercises are fully tolerated without any symptom provocation, the moderate impact exercises can be initiated.

Techniques for Progressive Increase in Range of Motion

Soft Tissue Techniques

- Stretching of anterior hip capsule with joint mobilization techniques (posterior to anterior) once femoral neck stress fracture has healed

FIGURE 27-8. Alternate straight leg and arm raise in quadruped.

Stretching and Flexibility Techniques for the Musculotendinous Unit

- Moderate to aggressive intensity stretching to hamstrings, quadriceps, hip flexors, and adductors, intensity based on patient's perceived level of stretch; should avoid any symptom provocation

Other Therapeutic Exercises

- Core stability (e.g., planks, side planks, bridging), low (20%) to moderate (50%) intensity relative to estimated maximum effort
- Total arm and leg strengthening
- Elliptical trainer

Sensorimotor Exercises

- One-leg standing on foam with eyes closed, 3 × 30 seconds
- One-leg standing with ball toss, 3 × 30 seconds

Techniques to Increase Muscle Strength, Power, and Endurance

- Wall squats, 3 × 12
- Heel raises, 3 × 12
- Step ups, 3 × 12
- Side stepping with resistance band at ankles, 3 × 30 seconds
- Diagonal forward lunges, 3 × 12
- Dead lifts, 3 × 12

Neuromuscular Dynamic Stability Exercises

- Supine bridging, 2 × 15
- Supine bridging on Physioball, 2 × 15
- Supine bridge on Physioball with leg curl, 2 × 15

Plyometrics

- Two-leg rapid heel raises, 3 × 30 seconds
- Lateral shuffle with ladder, each direction, 2 × 4 ladder lengths
- Two-leg standing hops, 3 × 30 seconds

Sport-Specific Exercises

- Walk-Run program (avoid down hills because of increased impact forces): Self-selected preferred pace for all levels unless indicated. Repeat each level two to three times with a rest day between each and advance only if no pain.
  - Walk 30 minutes
  - Walk 30 minutes at 15% faster pace
  - Walk 4 minutes, Run 1 minutes; repeat six times (30 minutes total)
  - Walk 3 minutes, Run 2 minutes; repeat six times (30 minutes total)

Milestones for Progression to the Next Phase

- Pain-free and able to tolerate moderate-impact activities in Phase II
- Walking 30 minutes moderate pace without pain

phase III (weeks 8 to 12): Moderate-to-High Impact Activities

- As in Phase II, the amount of impact associated with the activities and should continue to increase to a level that is typical of the athlete's sport.
- The duration of this phase should be adjusted for each athlete based upon the specific sport, with the goal of safely increasing impact and training volume.

Techniques for Progressive Increase in Range of Motion

Soft Tissue Techniques

- Same as for Phase II.

Stretching and Flexibility Techniques for the Musculotendinous Unit

- Same as for Phase II.

Other Therapeutic Exercises

- Core stability (e.g., planks, side planks, bridging), moderate to high intensity
- Total arm and leg strengthening

Techniques to Increase Muscle Strength, Power, and Endurance

- Diagonal forward lunges with external weight, 3 × 12
- Dead lifts with external weight, 3 × 12 (Figure 27-9)

Neuromuscular Dynamic Stability Exercises

- Two-leg squat-jump-toss with 10 lb medicine ball, 2 × 15

Plyometrics

- Lateral jumps with ladder, each direction, 2 × 4 ladder lengths
- Line jumping
  - Forward-backward, 2 × 30 seconds
  - Side-to-side, 2 × 30 seconds
- Jump on to box (12")
  - Forward, 2 feet jump and 2 feet land, 1 × 10
  - Side, 2 feet jump and 2 feet land, 1 × 5 each side
- Bounding (progress as tolerated)
  - Two-leg, 2 × 6
  - One-leg alternate, 2 × 6 each leg

Sport-Specific Exercises

- Walk-Run program (avoid down hills): Self-selected preferred pace for all levels unless indicated. Repeat

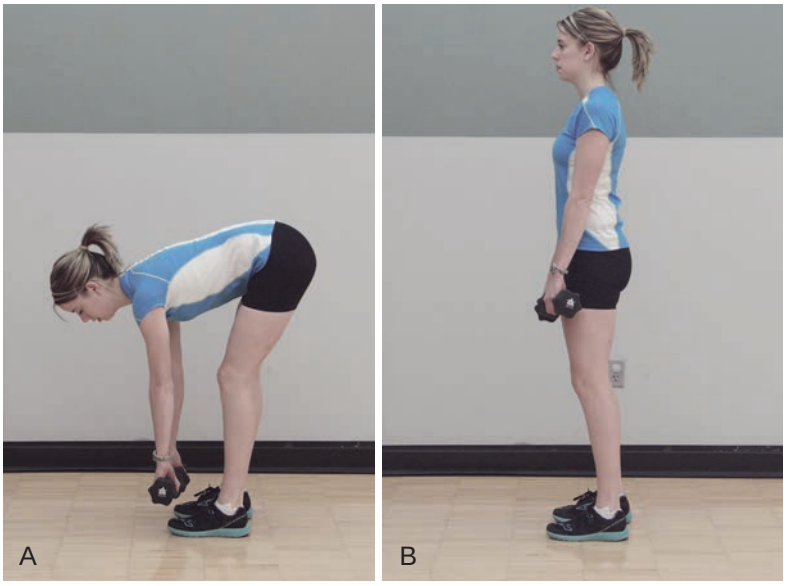

FIGURE 27-9. Dead lifts with external weight.

each level two to three times with a rest day between each and advance only if no pain.
- Walk 2 minutes, Run 3 minutes; repeat six times (30 minutes total)
- Walk 1 minute, Run 4 minutes; repeat six times (30 minutes total)
- Run 30 minutes

Milestones for Progression to Advanced Sport-Specific Training and Conditioning

- No palpable tenderness over involved area
- Pain free and able to tolerate high-impact activities involved in Phase III
- Completion of return to running program without symptom provocation

Criteria for Abandoning Nonoperative Treatment and Proceeding to Surgery or More Intensive Intervention

- Radiographic evidence of delayed union or nonunion
- Propagation of fracture to complete or displaced

Tips and Guidelines for Transitioning to Performance Enhancement

- At this point, the athlete should be completely symptom free and able to tolerate high-impact activities.
- As this type of injury is common in sports involving running, a progressive return to full running volume (approximately 10% per week) is essential to prevent re-injury, as well as re-acclimate tissues to the demands of the sport.
- For those involved in jumping sports, plyometric training needs to be continued and advanced to include box jumps

Performance Enhancement and Beyond Rehabilitation: Training/Trainer and Optimization of Athletic Performance

- Given the time away from sport and limited endurance training during recovery, adequate time should be devoted to cardiovascular training.
- If the athlete is returning to a sport involving running, an assessment of the running gait should be performed to identify pathomechanics that may have contributed to the injury.

Specific Criteria for Return to Sports Participation: Tests and Measurements

- No palpable tenderness over involved area
- Pain free and able to tolerate impact activities reflective of the sport
- Completion of return to running program without symptom provocation

Evidence

Boden BP, Speer KP: Femoral stress fractures. *Clin Sports Med* 16:307–317, 1997.

This expert opinion article reviews common femoral stress fractures and includes a brief case report for each. A summary of rehabilitation treatment is provided for each stress fracture location. (Level V evidence)

Diehl JJ, Best TM, Kaeding CC: Classification and return-to-play considerations for stress fractures. *Clin Sports Med* 25:17–28, 2006.

This expert opinion article reviews the classification and return-to-play criteria of a variety of stress fractures common to athletes. Stress fractures are classified as low or high risk with treatment goals and return-to-play timelines described. (Level V evidence)

Ivkovic A, Bojanic I, Pecina M: Stress fractures of the femoral shaft in athletes: A new treatment algorithm. *Br J Sports Med* 40:518–520; discussion 20, 2006.

This case series of seven athletes with a femoral shaft stress fracture describes nonoperative management using a progressive rehabilitation program. Following a four-phase program with specific testing criteria for advancement, all athletes returned to competition without re-injury over a long-term follow-up period. (Level IV evidence)

Talbot JC, Cox G, Townend M, et al: Femoral neck stress fractures in military personnel: A case series. *J R Army Med Corps* 154(1):47–50, 2008.

This retrospective case series of 20 military recruits with a femoral neck stress fracture describes their injury epidemiology and clinical outcome. Most injuries were nondisplaced (85%) and treated conservatively. (Level IV evidence)

Weishaar MD, McMillian DM, Moore JH: Identification and management of two femoral shaft stress injuries. *J Orthop Sports Phys Ther* 35:665–673, 2005.

This case series of two military cadets with a femoral shaft stress fracture describes the nonoperative management using a progressive rehabilitation program. Both cadets returned to full training and athletic activity without re-injury at approximately 12 weeks. (Level IV evidence)

Multiple Choice Questions

QUESTION 1. Which location of a stress fracture is not appropriate for conservative management?

A. Proximal medial femoral shaft
B. Distal medial femoral shaft
C. Superior femoral neck
D. Inferior femoral neck

QUESTION 2. Progression of a patient with a femoral neck stress fracture from non–weight bearing to weight bearing most often requires

A. radiographic evidence of healing.
B. full range of motion.
C. full strength.
D. pain score of 2 out of 10.

QUESTION 3. To help maintain cardiovascular endurance, which of the following activities is considered safe during Phase I?

A. Elliptical trainer
B. Deep water running with a flotation belt
C. Treadmill walking
D. Step aerobics

QUESTION 4. During Phase II, progression to moderate-impact activities can occur

A. immediately for all types of femoral stress fractures.
B. when low-impact activities are fully tolerated without symptom provocation.
C. if full range of motion is demonstrated at the involved hip.
D. once normal walking mechanics are observed.

QUESTION 5. To promote a safe transition back to running, which of the following return to running programs is recommended?

A. Immediate return to full mileage
B. Progressive return over a period of 1 week
C. Walk-run combination program with progressive increase in running duration over several weeks
D. Individuals with a recent femoral stress fracture should not run for at least 6 months.

Answer Key

QUESTION 1. Correct answer: **C** (see Overview)

QUESTION 2. Correct answer: **A** (see Phase I)

QUESTION 3. Correct answer: **B** (see Phase I)

QUESTION 4. Correct answer: **B** (see Phase II)

QUESTION 5. Correct answer: **C** (see Phase III)

BEYOND BASIC REHABILITATION: RETURN TO RUNNING AFTER OPERATIVE TREATMENT OF A STRESS FRACTURE OF THE FEMORAL NECK

Bryan C. Heiderscheit, PT, PhD, and Geoffrey S. Baer, MD, PhD

Aspects of Running that Require Special Attention in Rehabilitation

- Because of the magnitude and repetition of loading, return to running following surgical treatment of a femoral neck stress fracture should be done so in a progressive yet cautious manner.
- A thorough analysis of running technique should be conducted to identify and correct mechanics that may produce increased loading to the hip region.
- Femoral neck stress fractures most commonly occur with running.
- Although rather uncommon, tension-sided femoral neck stress fractures are particularly concerning as surgical management is often required.
- The likelihood of a full and complete return to running following surgical treatment of a femoral neck stress fracture is fair, with elite runners typically unable to achieve their prior level of performance.
- With radiographic evidence of fracture healing and resolution of hip pain with unassisted walking, consideration should be given to removal of the fixation. A prolonged period (minimum of 3 months) of restricted activity should follow with a gradual return to athletic activity once there is evidence the pin tracks have filled.

Literature

- Johansson and colleagues compiled a case series of 23 athletes (15 of which were runners) who experienced a femoral neck stress fracture. Sixteen of the athletes were initially treated surgically with internal fixation, with the remaining seven treated conservatively.
- Thirty percent of the athletes experienced a complication requiring major surgery, including pseudoarthrosis, avascular necrosis, and refracture. Complications most often occurred in athletes with a displaced fracture.
- At an average follow-up of 6.5 years after injury, none of the elite athletes were able to return to their prior level of performance.

Phase I (weeks 1 to 6)

Goals

- To ensure stability of fracture site and surgical fixation
- To promote healing
- To maintain core and upper body strength

Weight-Bearing Status

- For nondisplaced fractures, weight bearing can be progressive during weeks 1 to 6.
- Displaced fractures after ORIF often require non–weight bearing with crutches for 8 to 10 weeks.

Manual Therapy

- Soft tissue mobilization as needed to hamstring, quadriceps, and gluteal muscles
- Incision scar mobilization as needed

Therapeutic Exercise

- Stretching to knee and ankle of involved and entire noninvolved limb, 2 × 30 seconds each stretch
  - Use stretching positions that minimize compression forces acting on the hip
- AROM initiated at 1 week postop, 2 × 10 reps through pain-free range of motion
  - Flexion, extension, abduction, adduction, internal/external rotation

TIMELINE 27-2: **Return to Running After Surgical Treatment of a Stress Fracture of the Femoral Neck**

PHASE I (postop weeks 1 to 6)	PHASE II (postop weeks 6 to 8)
• Crutches for displaced; progressive weight bearing if nondisplaced • Soft tissue mobilization as needed • Stretching • Aquatic therapy when appropriate • TAS activities • Core exercises as recommended and tolerated	• Soft tissue mobilization as needed • Stretching • Cross-training (swimming, cycling) • TAS activities • Core exercises as recommended and tolerated • Balance/proprioception • Weight-bearing lower extremity PREs • Neuromuscular stability exercises

- Aquatic therapy can be initiated at 2 to 4 weeks postop (with a sealed incision)
  - Same movements as AROM but using resistance of water to increase intensity
- Total arm strengthening
- Core exercises
  - Use positions that minimize hip joint loading

Criteria for Progression to Phase II

- Fully healed incision
- Stable and well-healed fracture site

Phase II (weeks 6 to 8)

Goals

- Promote full weight bearing and normal walking gait
- Full AROM
- Initiate resistance training

Weight Bearing Status

- Full weight bearing, except displaced fractures after ORIF often require non–weight bearing with crutches for 8 to 10 weeks

Joint Mobility

- Joint and soft tissue mobilizations as needed to restore full hip joint ROM.
- Use of self-directed soft tissue mobilization (e.g., foam roller) may be initiated.
- If restricted spinal mobility is present, such as thoracic spine hypomobility or sacroiliac joint restriction, the appropriate manual therapy technique should be employed.

Therapeutic Exercise

- Cross-training (cycling, swimming)
- Gait training—focus on restoration of normal walking mechanics and speed
- Total arm strengthening—unrestricted
- Balance/proprioception
  - Low to moderate intensity steps forward and backward over a tape line while moving sideways, 2 × 1 minutes

FIGURE 27-10. Double leg stand on foam.

  - Double leg stand, progressing from eyes open to eyes closed and with foam, 4 × 20 seconds (Figure 27-10)
  - Partial body weight single leg stand, 3 × 20 seconds
- Progressive resistance exercise
  - Leg press, 3 × 10 repetitions, light to moderate intensity
  - Knee extensions, 3 × 10 repetitions, light to moderate intensity
  - Knee curls, 3 × 10 repetitions, light to moderate intensity
  - Calf raises, 3 ×10 repetitions, light to moderate intensity
  - Hip abduction, 3 × 10 repetitions, light intensity
  - Wall slides, 3 × 15 repetitions
- Core exercises
  - Prone abdominal body bridge (performed by using abdominal and hip muscles to hold the body in a face down straight plank position with the elbows and feet being the only point of contact), 4 × 20 seconds (Figure 27-11)
  - Supine extension bridge (performed by using abdominal and hip muscles to hold the body in a supine hook lying position with the head, upper back, arms and feet being the points of contact), 4 × 20 seconds (Figure 27-12)

TIMELINE 27-2: **Return to Running After Surgical Treatment of a Stress Fracture of the Femoral Neck** (Continued)

PHASE III (postop weeks 8 to 12)	PHASE IV (postop weeks 12 to 16)
• Soft tissue mobilization as needed • Stretching • Cross-training (swimming, cycling) • Elliptical • TAS/TLS activities • Core exercises as recommended and tolerated • Balance/proprioception • Weight-bearing lower extremity PREs • Neuromuscular stability exercises • Mild plyometric exercises as recommended • Begin walk-run program; delayed 2–4 weeks for displaced fractures	• Soft tissue mobilization as needed • Stretching • Cross-training (swimming, cycling) • TAS/TLS activities • Core exercises as recommended and tolerated • Balance/proprioception • Weight-bearing lower extremity PREs • Neuromuscular stability exercises • Moderate plyometric exercises as recommended • Continue walk-run program

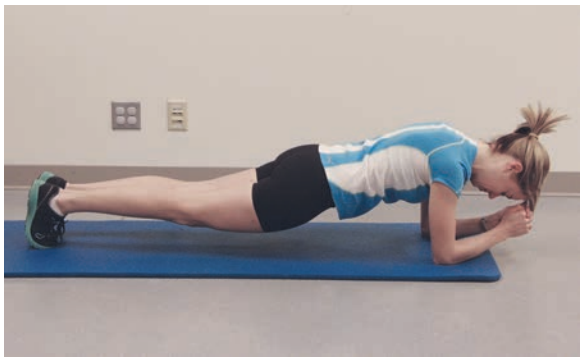

FIGURE 27-11. Prone abdominal body bridge.

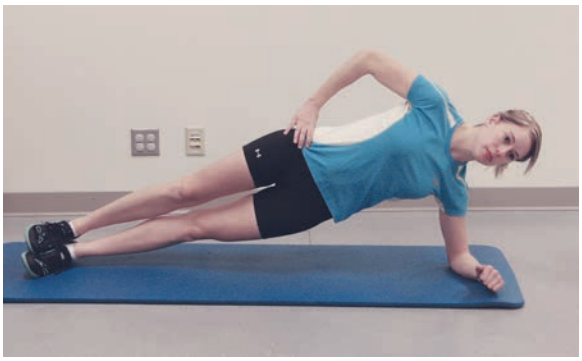

FIGURE 27-13. Side bridge.

- Side bridge (performed by using abdominal and hip muscles to hold the body in a side lying plank position with the lower elbow and feet being the only point of contact), 4 × 20 seconds on each side (Figure 27-13)

Criteria for Progression to Phase III

- Full AROM
- Normal walking mechanics without pain per visual assessment
- Single leg standing for 20 seconds on involved side without pain

Phase III (weeks 8 to 12)

Goals

- Progress resistance training to at least moderate intensity (at least 50% of estimated maximum effort)
- Unrestricted exercise in single leg postures
- Begin walk-run program

Joint Mobility

- Joint and soft tissue mobilizations as needed to maintain full hip joint ROM
- Self-directed soft tissue mobilization (e.g., foam roller) may be used.
- If restricted spinal mobility is present, such as thoracic spine hypomobility or sacroiliac joint restriction, the appropriate manual therapy technique should be employed.

FIGURE 27-12. Supine extension bridge.

Therapeutic Exercise

- Cross-training (cycling, swimming, elliptical)
- Gait training—focus on restoration of normal slow running mechanics
- Total arm/leg strengthening—unrestricted
- Balance/proprioception
  - Moderate to high intensity steps forward and backward over a tape line while moving sideways, 3 × 1 minute, intensity reflective of stepping speed and qualitatively determined
  - Moderate to high intensity grapevine stepping, 3 × 1 minute, intensity reflective of stepping speed and qualitatively determined
  - Single leg stand, progressing from eyes open to eyes closed and with foam, 4 × 20 seconds
- Progressive resistance exercise (moderate [50%] to high [90%] intensity, relative to estimated maximum effort)
  - Leg press, 3 × 6 to 8 repetitions, moderate to high intensity
  - Knee extensions, 3 × 6 to 8 repetitions, moderate to high intensity
  - Knee curls, 3 × 6 to 8 repetitions, moderate to high intensity
  - Calf raises, 3 × 6 to 8 repetitions, moderate to high intensity
  - Hip abduction, 3 × 6 to 8 repetitions, moderate intensity
- Core exercises—continue as in the preceding
- Neuromuscular stabilization
  - Fast feet in place, 3 × 20 seconds
  - Mini hopping on both feet, 3 × 20 seconds
  - Side stepping with moderate elastic resistance around toes, 3 × 30 seconds (Figure 27-14)
  - Supine knee curls on Physioball, 3 × 30 seconds, start with two legs and progress to single leg (Figure 27-15)
  - Single leg windmill touches, 4 × 20 seconds with alternate hand touches (Figure 27-16)
  - Lateral pelvic tilts, 2 × 30 seconds each side (Performed by standing on one leg replicating knee and hip posture during early stance phase of running; keeping trunk erect, raise and lower pelvis in frontal plane through full range) (Figure 27-17)
- Walk-run progression (avoid down hills because of increased impact forces): Self-selected preferred pace

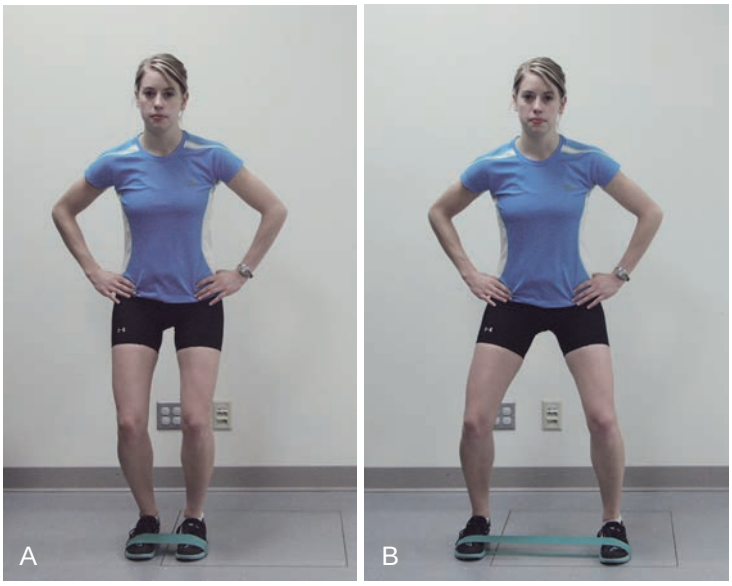

FIGURE 27-14. A,B, Side stepping with elastic resistance around toes.

for all levels unless indicated. Repeat each level two to three times and advance only if no pain.

- Walk 30 minutes
- Walk 30 minutes at 15% faster pace
- Walk 4 minutes, run 1 minute; repeat six times (30 minutes total)
- Walk 3 min, run 2 minutes; repeat six times (30 minutes total)

Criteria for Progression to Phase IV

- No pain in single leg activities
- Normal slow jogging mechanics without pain

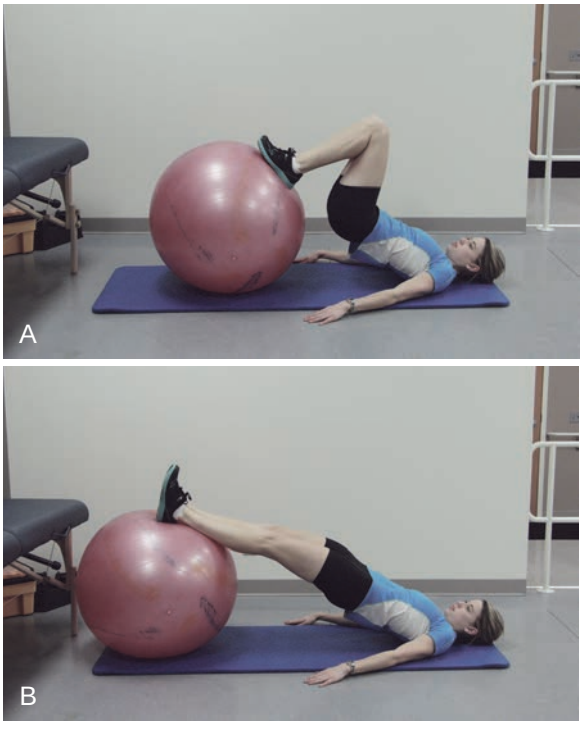

FIGURE 27-15. A,B, Supine knee curls on Physioball.

- 5/5 isometric strength for hip abductors, external rotators and extensors, assessed via manual muscle testing or with handheld dynamometer

Phase IV (weeks 12 to 16)

Goals

- Tolerate low to moderate intensity plyometrics.
- Initiate sports-specific training.
- Complete walk-run program.

Joint Mobility

- Employ joint and soft tissue mobilizations as needed to maintain full hip joint ROM.
- Use of self-directed soft tissue mobilization (e.g., foam roller) may be used.
- If restricted spinal mobility is present, such as thoracic spine hypomobility or sacroiliac joint restriction, the appropriate manual therapy technique should be employed.

Therapeutic Exercise

- Cross-training (cycling, swimming, elliptical)
- Total arm/leg strengthening—unrestricted
- Balance/proprioception
  - Moderate to high intensity steps forward and backward over a tape line while moving sideways, 3 × 1 minute, intensity reflective of stepping speed and qualitatively determined
  - Moderate to high intensity grapevine stepping, 3 × 1 minute, intensity reflective of stepping speed and qualitatively determined
  - One-leg standing with ball toss, 3 × 30 seconds
- Core exercises—continue as in the preceding
- Neuromuscular stabilization
  - Two-leg squat-jump-toss with 10 lb medicine ball, 2 × 15 (Figure 27-18)

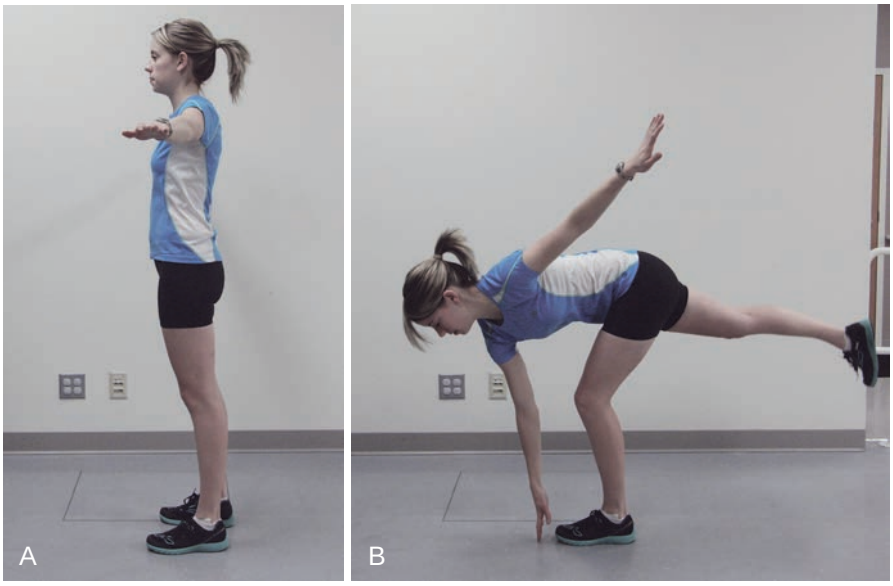

FIGURE 27-16. A,B, Single leg windmill touches.

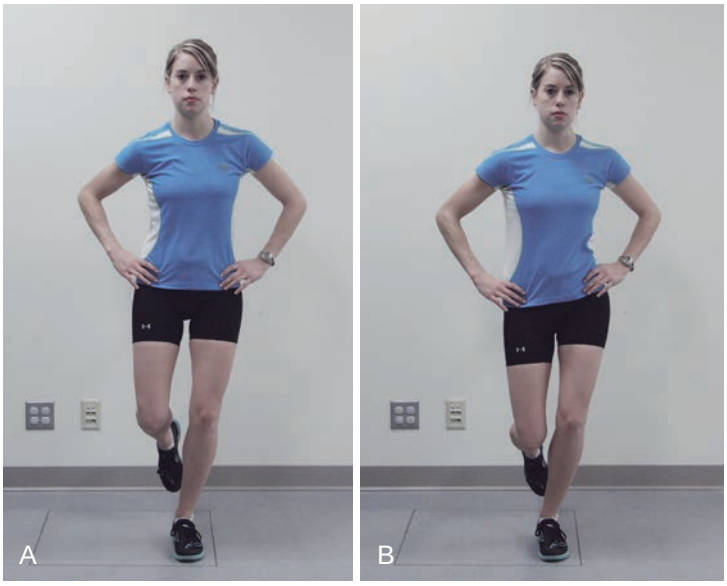

FIGURE 27-17. A,B, Lateral pelvic tilts.

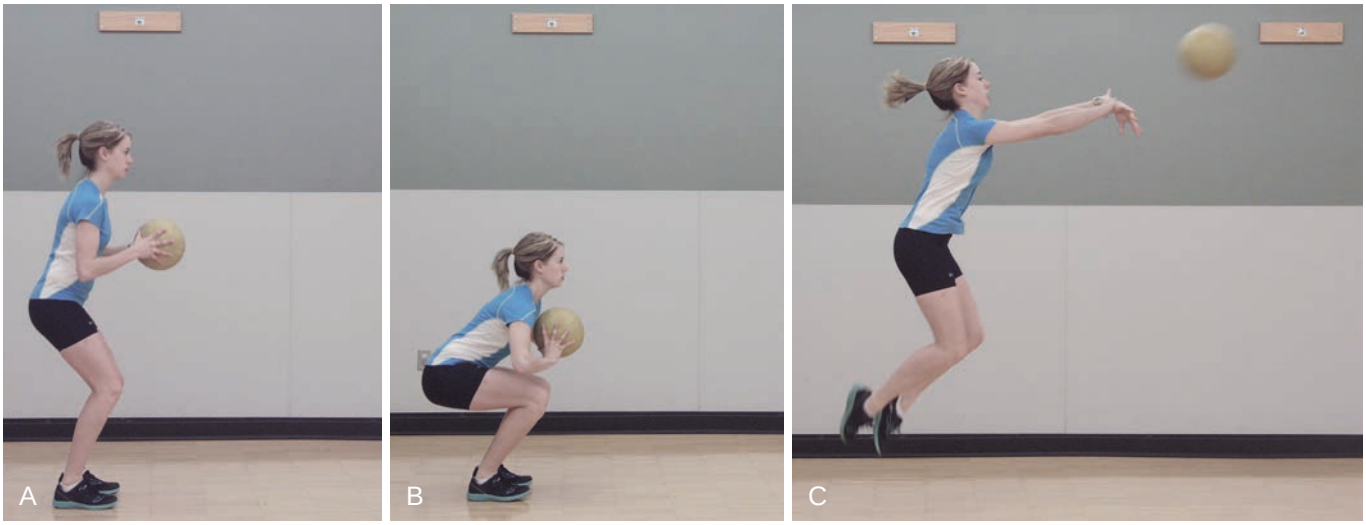

FIGURE 27-18. A–C, Two-leg squat-jump-toss with 10 lb medicine ball.

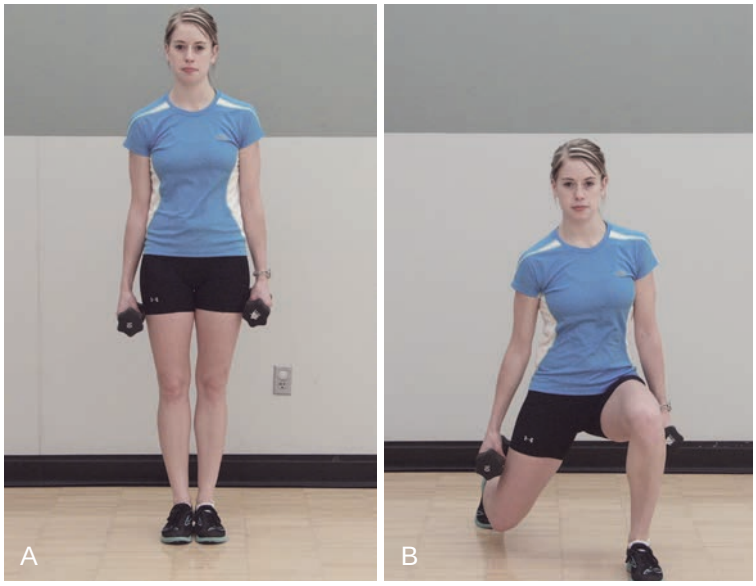

FIGURE 27-19. A,B, Diagonal forward lunge with external weight.

- Diagonal forward lunge with external weight, 3 × 12 (Figure 27-19)
- Dead lifts with external weight, 3 × 12
- Single leg windmill touches, 4 × 20 seconds with alternate hand touches and hand-held weight
- Lateral jumps with ladder, each direction, 2 × 4 ladder lengths (Figure 27-20)
- Jump on to box (12")
  - Forward, 2 feet jump and 2 feet land, 1 × 10 (Figure 27-21)

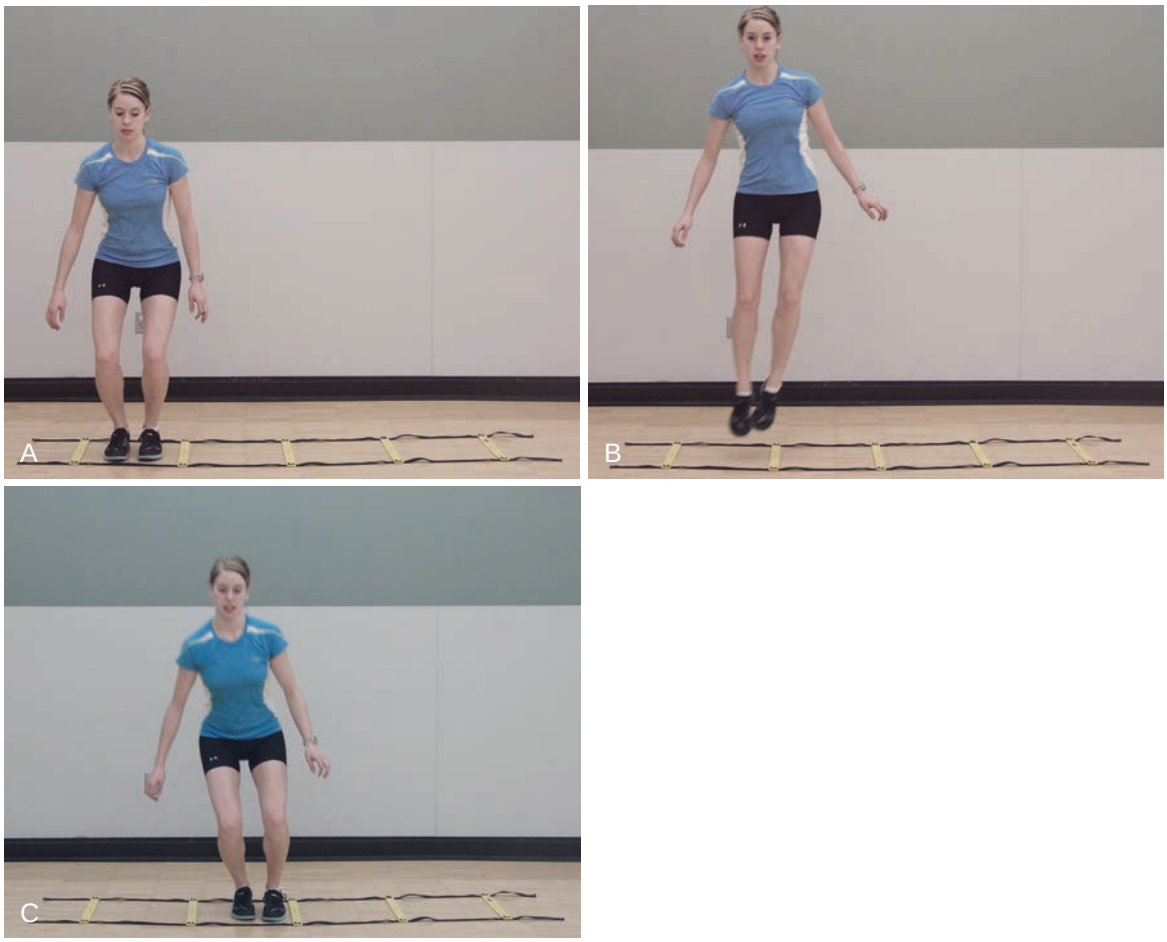

FIGURE 27-20. A–C, Lateral jumps with ladder.

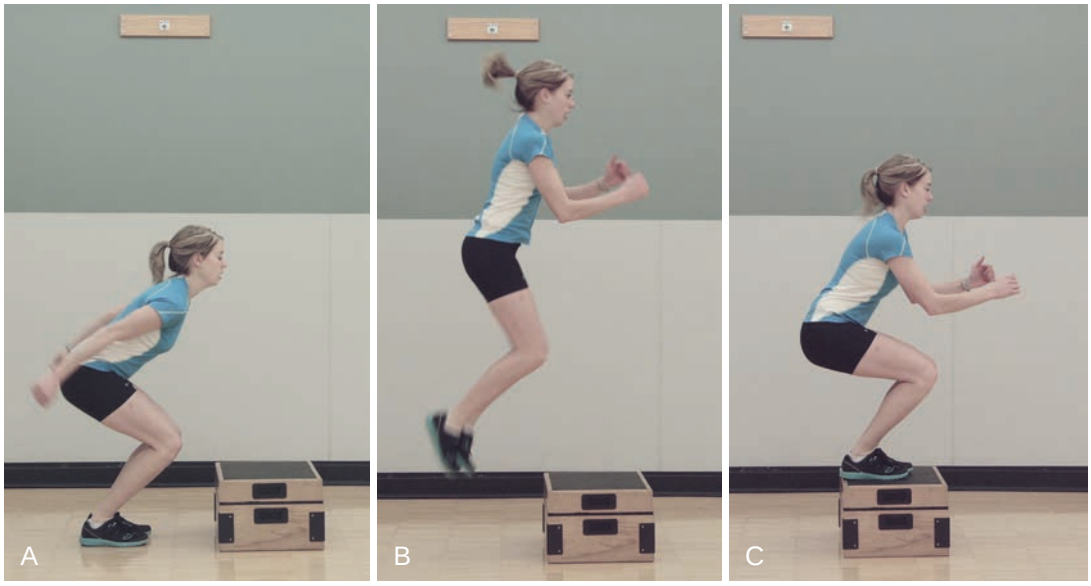

FIGURE 27-21. A–C, Forward box jump.

  - Side, 2 feet jump and 2 feet land, 1 × 5 each side (Figure 27-22)
- Bounding (progress as tolerated)
  - Two-leg, 2 × 6 (Figure 27-23)
  - One-leg alternate, 2 × 6 each leg (Figure 27-24)
- Walk-run progression (avoid down hills because of increased impact forces): Self-selected preferred pace for all levels unless indicated. Repeat each level two to three times and advance only if there is no pain.
  - Walk 2 minutes, run 3 minutes; repeat six times (30 minutes total)
  - Walk 1 minute, run 4 minutes; repeat six times (30 minutes total)
  - Run 30 minutes

Criteria for Progression

- Pain free and able to fully tolerate high-impact activities
- Completion of return to running program without symptom provocation

Advanced Strength and Conditioning Programs

Periodization

- The program is progressed in a linear manner over time.

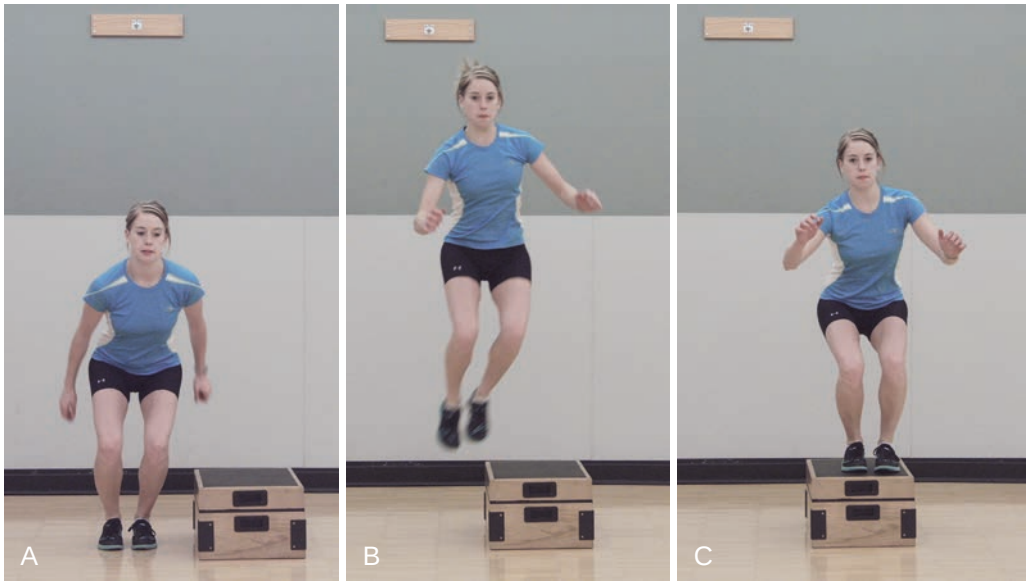

FIGURE 27-22. A–C, Side box jump.

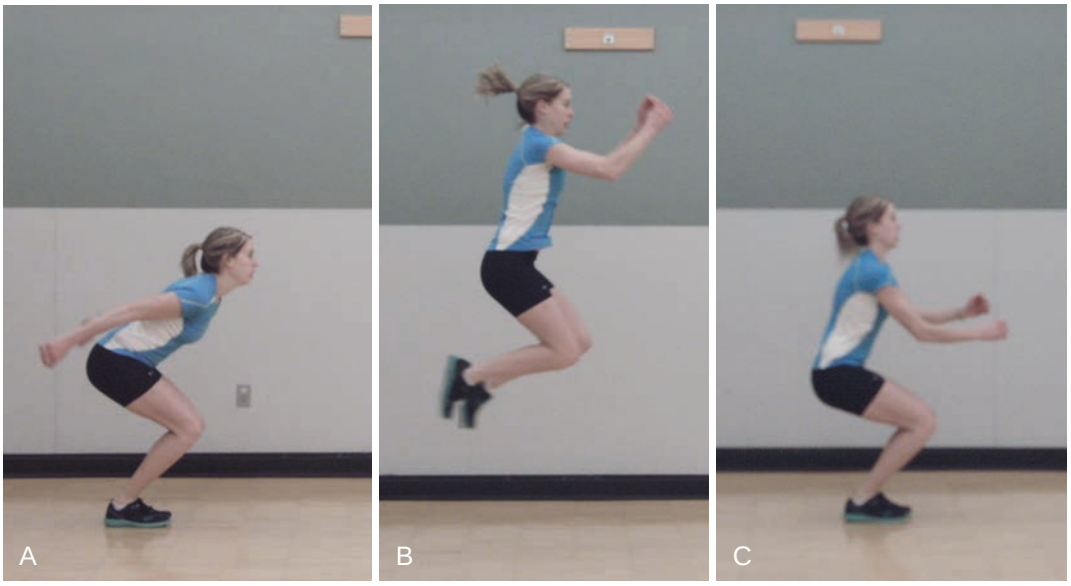

FIGURE 27-23. A–C, Two-leg bounding.

Program Design/Performance Training Program

Sport-Specific Concepts of Integrated Training

- Training continuum
- Flexibility/joint mobility for joint stability
- Training with optimum posture
- Sensorimotor and balance training
- Core training
- Cardiorespiratory training
- Multiplanar training activities
- Training for optimum muscle balance
- Training for optimum muscle functional strength
- Training for optimum muscle functional power
- Neuromuscular dynamic stability exercises
- Plyometric training
- Functional training
- Sport-specific training

Training Principles Used in the Design of the Program

- Principle of progression
- Principle of overload
- Principle of variation
- Principle of individualization
- Principles of specificity—specific adaptation to imposed demands (SAID)

Sports Performance Testing

General Information

Specific Criteria for Progression to the Next Stage to Determine Readiness for Running

- This is described in the preceding training program.

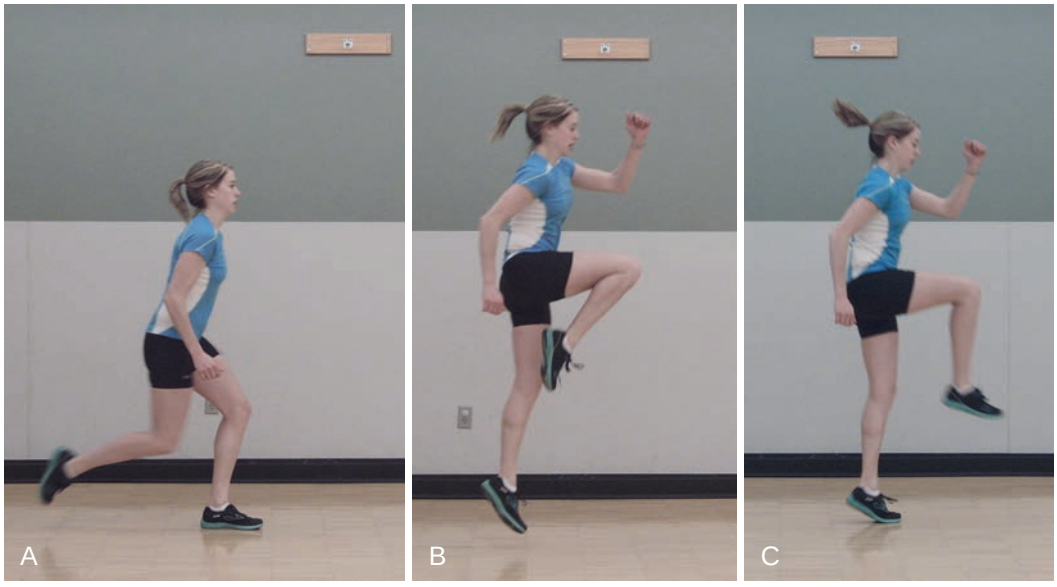

FIGURE 27-24. A–C, One-leg alternate bounding.

Specific Criteria for Release to Unsupervised Complete Participation in Running

- This is described in the preceding training program.

Recommended Ongoing Exercises

- Maintaining strong posterolateral pelvic musculature is important to enable normal hip loading during running.

Evidence

Johansson C, Ekenman I, Tornkvist H, et al: Stress fractures of the femoral neck in athletes. The consequence of a delay in diagnosis. *Am J Sports Med* 18:524–528, 1990.

This case series followed 23 athletes with femoral neck stress fractures for an average period of 6.5 years. Seven (30%) of the athletes experienced complications requiring major surgery, with none of the elite athletes able to return to their prior level of performance. The most important factor influencing complication rate seems to be the severity/type of fracture. (Level IV evidence)

Lee CH, Huang GS, Chao KH, et al: Surgical treatment of displaced stress fractures of the femoral neck in military recruits: A report of 42 cases. *Arch Orthop Trauma Surg* 123:527–533, 2003.

This single prospective cohort study followed 42 patients with displaced femoral neck stress fractures over an average period of 5.6 years. All patients required internal fixation. Ten of the patients developed avascular necrosis of the femoral head with eight treated with prosthetic replacement. Of the 42 patients, 30 (71.4%) had good functional results, four (9.5%) had acceptable, and eight (19%) had poor results. (Level IV evidence)

Niva MH, Kiuru MJ, Haataja R, et al: Fatigue injuries of the femur. *J Bone Joint Surg Br* 87:1385–1390, 2005.

This study described the anatomical location and incidence of femoral stress injuries in 1857 physically active young adults, based on MRI. Of these, 170 individuals had a total of 185 stress injuries, with 57% showing a stress reaction and 22% showing a fracture line. The three most common sites affected were the femoral neck (50%), the condylar area (24%) and the proximal shaft (18%), suggesting femoral neck involvement is more common than previously thought. (Level IV evidence)

Pihlajamaki HK, Ruohola JP, Kiuru MJ, et al: Displaced femoral neck fatigue fractures in military recruits. *J Bone Joint Surg Am* 88:1989–1997, 2006.

This descriptive study reported on 21 military recruits that sustained displaced femoral neck stress fracture, with 19 recruits followed for an average of 18 years. Following treatment, six patients had delayed union or nonunion of the fracture; six patients developed osteonecrosis of the femoral head; and eight patients developed severe osteoarthritis. (Level IV evidence)

Talbot JC, Cox G, Townend M, et al: Femoral neck stress fractures in military personnel: A case series. *J R Army Med Corps* 154(1):47–50, 2008.

This retrospective case series of 20 military recruits with a femoral neck stress fracture describes their injury epidemiology and clinical outcome. Most injuries were nondisplaced (85%) and treated conservatively. (Level IV evidence)

Multiple Choice Questions

QUESTION 1. Which location of a stress fracture is most often managed surgically?

A. Proximal medial femoral shaft
B. Distal medial femoral shaft
C. Superior femoral neck
D. Inferior femoral neck

QUESTION 2. For sub-elite and elite runners, the likelihood of returning to one's prior level of running performance following a surgically managed femoral neck stress fracture is

A. excellent.
B. good.
C. fair.
D. poor.

QUESTION 3. Complications related to a femoral neck stress fracture can include

A. severe osteoarthritis.
B. avascular necrosis.
C. refracture.
D. all of the above.

Answer Key

QUESTION 1. Correct answer: **C** (see Overview)

QUESTION 2. Correct answer: **C** (see Overview)

QUESTION 3. Correct answer: **D** (see Overview and Evidence)

Chapter 28

Patellar Instability

INTRODUCTION

Diego Herrera, MD, Najeeb Khan, MD, Donald C. Fithian, MD, and Christopher M. Powers, PhD, PT

Epidemiology

- The average annual incidence of primary patellar dislocation is 5.8 per 100,000. This incidence increases to 29 per 100,000 in the 10- to 17-year-old age group. The majority of these patients will experience no further instability with reported recurrence rates of 15% to 44% after conservative treatment.[1-3]
- Although recurrence is the exception and not the rule, many patients continue to be symptomatic following their dislocation episode. At 6 months postinjury, 58% of patients continue to have limitations with strenuous activity. Failure to return to sports has been reported in up to 55% of patients.[3]
- There is a slight female predilection.[3,4]

Pathophysiology

Intrinsic Factors

- The medial patellofemoral ligament (MPFL) is the primary ligamentous restraint against lateral patellar displacement.[5-7] In early flexion, the medial retinacular structures (particularly the MPFL) provide the primary restraint to lateral displacement of the patella. As the patella engages the trochlear groove with increasing flexion, trochlear geometry provides increasing constraint to mediolateral patellar motion.
- Deficiency of constraint by the MPFL can be exacerbated by patella alta, which causes the patella to engage late within the trochlea so that the patella spends a greater proportion of early flexion in a precarious state where only the ligaments constrain its mediolateral motion.[8,9]
- A lateralized tibial tubercle, as measured by tibial-tubercle-trochlear groove (TT-TG) distance on CT or MRI, is associated with patellar instability.[10]
- Systemic hypermobility can increase the risk of patellar instability, and articular injury is less likely in this cohort.[11,12]

Extrinsic Factors

- A history of contralateral patellar dislocation would increase the risk of recurrence sixfold, as much as a previous dislocation, even on the index knee.[1]

Traumatic Factors

- The most common mechanisms of patellar dislocation are sports (61%) and dance (9%) injuries.[1]
- The mechanism of injury is most often with the foot planted and internal rotation of the femur, with subsequent tibia external rotation relative to the femur.
- Direct trauma causing patellar translation and ultimately dislocation is also seen.

Classic Pathological Findings

- Injury to the MPFL is a lesion of necessity.[13] Residual laxity of the ligament is primarily responsible for

patellar instability after the initial dislocation event. Injury to the MPFL may occur at more than one location along its length during the dislocation.[14]
- Articular cartilage injuries have been reported in up to 95% of first-time patellar dislocations, although most do not require surgery.[15]
- Imaging studies may also show trochlear dysplasia, patella alta, increased TT-TG distance, and patellar tilt.[10]

Clinical Presentation

History

- For the acute first-time dislocation, knee swelling, and hemarthrosis are nearly always seen. Symptoms associated with the swelling and hemarthrosis, such as pain, decreased range of motion (ROM), and gait changes, can be seen.
- For recurrent dislocators, minimal pain and swelling is seen between episodes of patellar instability. These patients may complain of their knee giving way unexpectedly during activities of daily living and/or sports.
- It is crucial that the clinician distinguish the patient who has true episodic patellar instability from those who primarily complain of pain.

Physical Examination

Abnormal Findings

- For first-time dislocators, a large effusion with tenderness to palpation about the medial retinaculum is a typical finding. If the effusion is large and tense, aspiration can serve as a palliative measure and hasten normalization of ROM and gait.
- Apprehension to lateral patella translation, usually accompanied by pain with straight leg raise and active ROM.
- The Q-angle is rarely helpful, as it is imprecise and changes with patellar mobility. If a patella is subluxed laterally, the Q-angle measurement is falsely low. However, femoral and tibial torsion can play a role in patellar instability, with the largest lateral force placed on the patella when the tibia rotates externally in terminal knee extension. A distance between the tibial tuberosity and the trochlear groove (TT-TG as measured on axial imaging) that exceeds 20 mm is nearly always associated with patellar instability.[10]

Imaging

- Anteroposterior (AP), lateral, and merchant radiographs are used to confirm patellar location, presence of osteochondral fracture, and patellofemoral relationships.
- The lateral view with the knee flexed 30 degrees can help determine patella height. The Caton-Deschamps ratio is the distance between the lower edge of the patellar joint surface to the upper edge of the tibial plateau divided by the length of the patellar articular surface. A ratio greater than 1.2 signifies patella alta (Figure 28-1).
- The lateral view with the posterior condyles aligned can evaluate trochlear dysplasia. The "crossing" sign, where the curve of the trochlear floor crosses the anterior contour of the lateral femoral condyle, represents flattening of the trochlear groove and absence of trochlear constraint against patellar displacement. Trochlear prominence (also called a trochlear "boss," "bump," or "eminence") is represented by the distance between the most anterior point of the trochlear floor and a line drawn along the distal 10 cm of the anterior femoral cortex. The degree of trochlear prominence on a lateral radiograph correlates with the severity of dysplasia (Figure 28-2).
- MRI examination for first-time dislocators, particularly if a hemarthrosis is present, should be considered to assess for osteochondral or chondral injuries that are amenable to surgical intervention.
- Axial MRI images are also used to determine TT-TG offset (Figure 28-3).

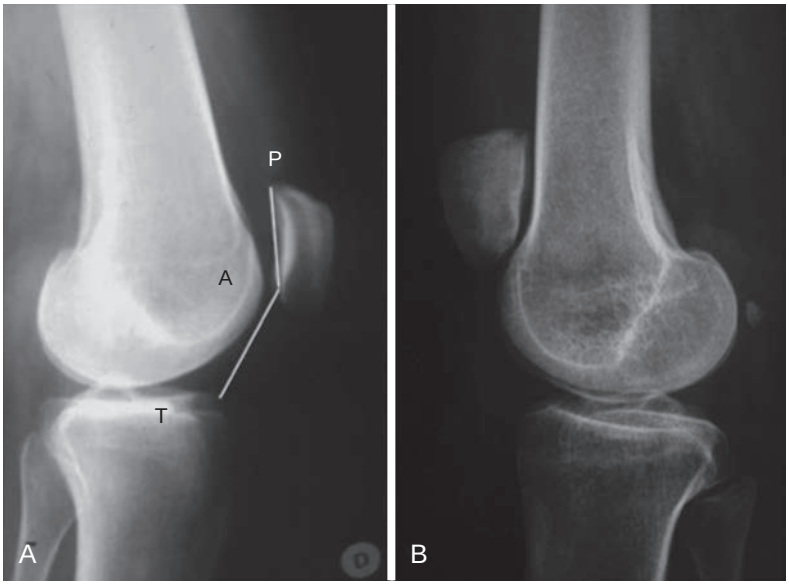

FIGURE 28-1. A, Patellar height. The height of the patella is surprisingly difficult to measure reliably. The Caton-Deschamps ratio is the distance between the lower edge of the patellar joint surface and the upper edge of the tibial plateau (AT) and the length of the patellar articular surface (AP). **B,** Severe patella alta.

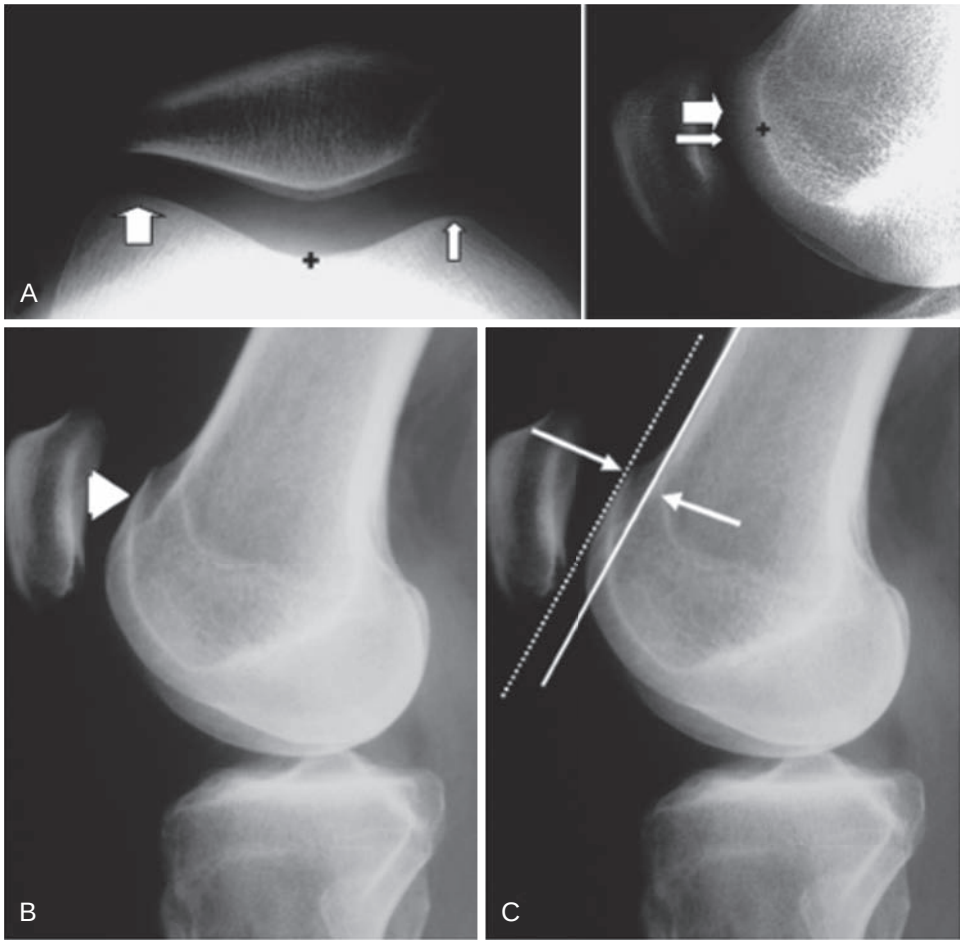

FIGURE 28-2. Crossing sign. **A,** Normal trochlea. On the lateral view, the profile shows a sclerotic curved white line that corresponds to the floor of the trochlea (+). The curves representing the trochlear ridges (*arrows*) do not cross the curve of the trochlear floor. Note that accurate interpretation of the lateral view requires that the posterior condyles be aligned. **B,** The crossing sign is a simple and characteristic image, a qualitative criterion of trochlear dysplasia. The arrowhead indicates the point where the curve of the trochlear floor crosses the anterior contour of the lateral femoral condyle. By definition, the trochlea is flat at this level. This sign is of fundamental importance in the diagnosis. **C,** The prominence (*bump*) is a quantitative characteristic that is particularly significant in trochlear dysplasia. The prominence represents the distance between the most anterior point of the trochlear floor (*dashed line*) and a line drawn along the distal 10 cm of the anterior femoral cortex (*solid line*). The greater the trochlear prominence, the greater the dysplasia.

Differential Diagnosis

- For a primary complaint of instability, it is important to evaluate the cruciates, collaterals, and menisci, as injuries to these structures can accompany patellar dislocations.
- Complaints of anterior knee pain carry a long differential diagnosis, including tumors, Hoffa disease, Osgood Schlatter disease, osteochondritis dessicans, stress fracture, patellofemoral osteoarthritis, bursitis, Sinding-Larson-Johanssen syndrome, symptomatic bipartite patella, meniscal pathology, loose bodies, and others.

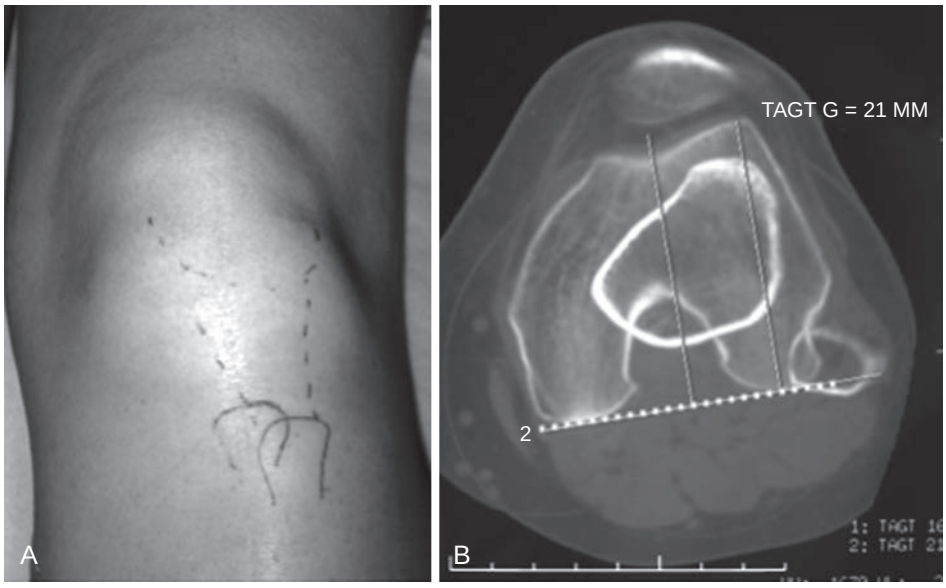

FIGURE 28-3. TT-TG offset. **A,** The lateral offset of the tibial tubercle is suspected clinically, but the analysis is qualitative. A CT scan (or an MRI) allows a reliable and reproducible measurement. **B,** Two axial cuts (*slices*) are superimposed: one through the apex of the tibial tubercle (TT) and the other through the femur at the level where the notch posteriorly resembles a curved "Roman arch" (*arrow*) (trochlear groove [TG]). The TT-TG offset is the distance between the most anterior point of the TT and the apex of the TG along a line parallel to the posterior condylar line (*dashed line*).

Treatment

Nonoperative Management

- Acute first-time patellar dislocations are treated with reduction and measures such as cryotherapy and NSAIDS to reduce pain and swelling. Tense hemarthrosis should be aspirated. Weight bearing as tolerated is encouraged, often with a knee immobilizer if symptoms do not allow sufficient quadriceps control. Physical therapy is started to address pain and swelling, ROM, normalization of gait, and ultimately quadriceps strengthening and proximal lower limb control.
- There is no established standard of care regarding immobilization after first-time dislocation. Whereas a simple knee sleeve was associated with relatively higher rates of recurrent dislocation,[16] strict immobilization can cause muscular atrophy, weakness, and stiffness.

Surgical Indications

- An osteochondral fracture that is visible on conventional radiographs is likely to be a significant lesion that should be followed by an MRI and possible surgical excision or fixation.
- MPFL reconstruction is best used to treat episodic lateral patellar instability due to excessive laxity of medial retinacular patellar stabilizers. The ideal candidate has minimal pain between episodes of patellar instability and seeks medical care primarily to address the occasional dislocation or subluxation. A tibial tubercle osteotomy in addition to MPFL reconstruction is considered in patients with TT-TG > 20 mm, patella alta, or both.

Evidence

Dejour H, Walch G, Nove-Josserand L, et al: Factors of patellar instability: An anatomic radiographic study. *Knee Surg Sports Traumatol Arthrosc* 2:19–26, 1994.

Case control study that identifies relevant radiographic and CT factors in knees with symptomatic patellar instability. The following factors were common findings in the symptomatic knees: Trochlear dysplasia (85%), patellar tilt (83%), tibial tuberosity-trochlear groove distance equal to or greater than 20 mm (56%), patella alta (24%), and very rare findings in nonsymptomatic knees (3% to 6.5%). The identification of these factors can lead to treatments that correct the aforementioned abnormalities. (Level IV evidence)

Desio SM, Burks RT, Bachus KN: Soft tissue restraints to lateral patellar translation in the human knee. *Am J Sports Med* 26:59–65, 1998.

In a biomechanical study that included nine cadaveric knees, it was found that the medial patella femoral ligament was the main restraint to lateral patellar translation at 20 degrees of flexion, contributing 60% of the total restraining force. (Level V evidence)

Fithian DC, Paxton EW, Stone ML, et al: Epidemiology and natural history of acute patellar dislocation. *Am J Sports Med* 32:1114–1121, 2004.

This is a prospective cohort study that identifies risk factors in 189 patients with acute patellar dislocations and a minimum follow up of 2 years (range of 2 to 5 years). Patellar dislocators with a previous history of patellar instability were more likely to be females. These patients also have a higher risk to have subsequent instability episodes than first-time dislocators. (Level I evidence)

Stefancin J, Parker R: First-time traumatic patellar dislocation: A systematic review. *Clin Orthop Relat Res* 455:93–101, 2007.

In a systematic review of 70 Level I to IV studies that included patients with first-time patella dislocation. The authors recommended initial nonoperative management except in specific circumstances, including the presence of an osteochondral fracture, substantial disruption of the medial patellar stabilizers, a laterally subluxated patella with normal alignment of the contralateral knee, a second dislocation, or in patients not improving with appropriate rehabilitation. (Level III evidence)

Multiple-Choice Questions

QUESTION 1. The primary ligamentous restraint against lateral patellar displacement is the:

A. Medial collateral ligament (MCL)
B. Medial patellomeniscal ligament (MPML)
C. Medial patellofemoral ligament (MPFL)
D. Trochlea

QUESTION 2. The most common mechanisms of patellar dislocation are:

A. Direct trauma
B. Motor vehicle collisions
C. Sports and dance
D. Ehlers-Danlos syndrome

QUESTION 3. How do you measure excessive lateralization of the tibial tubercle?

A. Merchant view
B. Lateral view with the knee flexed 30 degrees
C. Axial imaging; measure tibial tubercle to trochlear groove offset (TT-TG)
D. Q-angle

QUESTION 4. Articular cartilage injuries are seen in up to _____% of first-time patellar dislocators.

A. 0%
B. 20%
C. 95%
D. 100%

QUESTION 5. Choose the best indication for MPFL reconstruction:

A. Patellofemoral pain syndrome
B. First-time patellar dislocation with tense effusion
C. Episodic patellar instability with minimal pain between episodes
D. Patellofemoral osteoarthritis

Answer Key

QUESTION 1. Correct answer: **C** (see Pathophysiology: Intrinsic Factors)

QUESTION 2. Correct answer: **C** (see Pathophysiology: Traumatic Factors)

QUESTION 3. Correct answer: **C** (see Pathophysiology: Intrinsic Factors)

QUESTION 4. Correct answer: **C** (see Classic Pathologic: Intrinsic Factors)

QUESTION 5. Correct answer: **C** (see Surgical Indications)

NONOPERATIVE REHABILITATION OF PATELLAR INSTABILITY

Najeeb Khan, MD, Donald C. Fithian, MD, and Christopher M. Powers, PhD, PT

- Most patients who suffer a first-time patellar dislocation do not have a recurrence. More than half, however, have some limitations with strenuous activities and do not return to sports.[1] The treatment goals after a first-time dislocation are to reduce the patella, diminish pain and swelling, normalize gait patterns, avoid recurrence, return to activities of daily living, and, ultimately, return to sports.
- Patients who have failed nonoperative treatment are considered for surgical intervention. The results of operative treatment, namely, MPFL repair, after primary patellar dislocations generally are not different from nonoperative treatment, although some authors report decreased recurrence with MPFL repair.[2,3] Controversy persists regarding operative treatment of the first-time patellar dislocator. The standard of care at this time is a trial of nonoperative treatment.
- Younger patients and those with predisposing anatomic factors, such as patella alta, trochlear dysplasia, and a high TT-TG offset, may have a higher risk of recurrence and failure of nonoperative treatment.
- Patients with patellofemoral pain, particularly females, may have decreased hip muscular strength in abduction, external rotation, and extension.[4] Once pain and swelling are treated, the ultimate goal is to gain proximal limb control and avoid valgus collapse and dynamic hip internal rotation that comes with weak hip abductors and external rotators.
- Patellofemoral rehabilitation, both for nonoperative and operative treatment of patellar instability, should ultimately address dynamic lower extremity function (Figure 28-4).
- The rehabilitation protocol, following, is somewhat arbitrarily divided into phases. Patients with underlying patellofemoral pathoanatomy (e.g., trochlear dysplasia, patella alta) may achieve goals and progress slower than those without. Athletes who have sustained a patella dislocation caused by direct trauma are generally expected to progress well with therapy, as they may not necessarily have the degree of proximal weakness and imbalance as their counterparts who dislocated caused by indirect trauma. Progression to

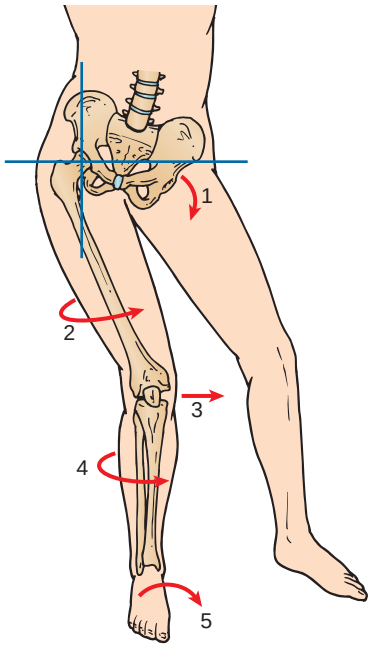

FIGURE 28-4. Schematic of the various potential contributions of limb malalignment and malrotation to increase the dynamic Q-angle: **A,** Hip adduction. **B,** Femoral internal rotation. **C,** Genu valgum. **D,** Tibial external rotation. **E,** Foot pronation.

the next stage is contingent upon achieving the goals of the prior stage.

GUIDING PRINCIPLES OF NONOPERATIVE REHABILITATION

- Reduce pain and swelling
- Normalize ROM
- Normalize gait pattern
- Quadriceps strengthening
- Proximal lower limb control training

Phase I (weeks 0 to 2)

Goals

- The goals of this phase are to reduce pain and swelling, initiate muscular strength and endurance training without pain, and introduce balance training.

Protection

- Encourage weight bearing as tolerated in a hinged knee brace, locked in extension for ambulation. The knee brace is unlocked once appropriate quad strength and control are achieved.
- Crutches may be provided initially, with encouragement to wean from supportive devices as soon as possible.

Management of Pain and Swelling

- Pain and swelling reduction techniques: rest, cryotherapy, NSAIDs.
- Modalities such as E-stim and biofeedback can be used as needed.

Therapeutic Exercises

- Gentle quadriceps strengthening should begin as soon as pain allows. Care should be taken to avoid active terminal knee extension, as this range of motion places high stress on the patellofemoral joint.[5,6] In this early phase, patients also should perform nonweightbearing exercises targeting the hip abductors, external rotators, and extensors. When performing strengthening exercises for the gluteus medius, the patient must take care to minimize the contribution of the tensor fascia lata, as contraction of this muscle contributes to medial rotation of the lower extremity.
- Balance training is introduced as symptoms allow including wobble board, BOSU ball, single-leg squat and reach, and other methods.

Open and Closed Kinetic Chain Exercises

- Care must be taken to avoid open chain active terminal knee extension (15° to full extension), as the stress on the patellofemoral is quite high in this range.[6]

Phase II (weeks 3 to 6)

Goals

- The goals of this phase are to fully treat pain and swelling, enhance leg strength and proximal limb control, normalize gait, and prepare for return to functional activities.

Protection

- Knee brace should be unlocked by Phase II and then exchanged for a neoprene sleeve.[7]

Management of Pain and Swelling

- Treatment of pain and swelling continues with cryotherapy and NSAIDs as needed.

Therapeutic Exercises

- Facilitation of normal gait is an essential component of the overall treatment plan. This is particularly important for the returning athlete (especially runners) in whom even a slight gait deviation can be compounded by repetitive loading. The clinician should pay particular attention to the quadriceps avoidance gait pattern (walking with the knee extended or hyperextended). Because knee flexion during weight acceptance is critical for shock absorption,[8] this key function must be restored to prevent the deleterious effects of high-impact tibiofemoral joint loading.
- Strength training as in Phase I continues. Once the patient can isolate the proximal muscles of interest in nonweightbearing, progression to weightbearing activities can begin.

- The concept of neutral lower extremity alignment is introduced. This involves alignment of the lower extremity such that the anterior superior iliac spine (ASIS) and knee remain positioned over the second toe, with the hip positioned in neutral. Postural alignment and symmetrical strengthening should be emphasized during all exercises.
- If the patient has a difficult time maintaining proper lower extremity alignment during initial weightbearing exercises, femoral strapping can be used to provide kinesthetic feedback and to augment muscular control and proprioception. Also, taping or bracing of the patellofemoral joint may be used if pain is limiting the patient's ability to engage in a meaningful weightbearing exercise program. Partial squats, which may have started already in very controlled environment with supervision, can be advanced to incorporate a BOSU ball or similar device to facilitate proximal control. Close supervision is required to ensure proper execution, as most patients may exhibit abnormal postures or movements during these tasks. Once the patient understands the proper movement and goal of the task, continued performance in front of a mirror provides useful feedback.
- As strength, control, and balance progress, single-leg activities may be initiated. This is the final step before returning to full unrestricted activity.

Phase III (weeks 7 and beyond)

- Rehabilitation from this point onward requires careful assessment and progressive development of proximal lower limb control.
- Patients should be encouraged to return to their sport or activity gradually once they can achieve satisfactory single-limb dynamic control. With competitive or recreational athletes who will be returning to full participation, plyometric training (e.g., jump training) should be considered during this phase of the rehabilitation program. As patients, particularly athletes, return to sport activities, repetitive forces applied through the knee joint must be controlled adequately to allow continued healing of the injured or repaired tissues.

Criteria for Abandoning Nonoperative Treatment and Proceeding to Surgery or More Intensive Intervention

- Surgical management is considered if patellar instability becomes recurrent and interferes with sports and/or activities of daily living.

Specific Criteria for Return to Sports Participation

- Full and painless ROM
- Absence of effusion and swelling
- Satisfactory and symmetric proximal single-limb dynamic control during high-impact activities (e.g., landing from a jump, cutting, etc.)
- Quadriceps, hamstring, and hip strength in at least 90% of the uninjured leg
- Psychologically ready to return to sports

Multiple-Choice Questions

QUESTION 1. Which of the following is not a treatment goal after first-time patellar dislocation?

A. Reduce pain and swelling
B. Normalize gait pattern
C. Surgical repair of the medial patellofemoral ligament
D. Return to activities of daily living

QUESTION 2. When are crutches discontinued after primary patellar dislocation?

A. After Phase I
B. After normalization of ROM
C. As soon as possible
D. Never

QUESTION 3. Activation of which muscle groups should be avoided?

A. Hip abductors and external rotators
B. Quadriceps and hamstrings
C. Vastus medialis oblique (VMO) and tensor fascia lata
D. Hip extensors

QUESTION 4. Surgical management is considered for:

A. Pain and swelling
B. Damage to the MPFL
C. Recurrence of patellar instability
D. Quicker return to sports

Answer Key

QUESTION 1. Correct answer: **C** (see Introduction)

QUESTION 2. Correct answer: **C** (see Phase I: Protection)

QUESTION 3. Correct answer: **C** (see Phase I: Therapeutic Exercises)

QUESTION 4. Correct answer: **C** (see Criteria for Abandoning Nonoperative Treatment and Proceeding to Surgery or More Intensive Intervention)

POSTOPERATIVE REHABILITATION AFTER PROXIMAL REALIGNMENT PROCEDURES AND MEDIAL PATELLOFEMORAL LIGAMENT (MPFL) RECONSTRUCTION

Kentaro Suzuki, MD, Matthew Pifer, MD, Najeeb Khan, MD, Donald Fithian, MD, and Christopher M. Powers, PhD, PT

Indications for Surgical Treatment

- Medial patellofemoral ligament (MPFL) reconstruction is best used to treat episodic lateral patella instability because of excessive laxity of medial retinacular stabilizers.
- The ideal candidate has minimal pain between episodes of patella instability and seeks medical care primarily to address the occasional dislocation or subluxation.
- It is imperative that the surgeon document MPFL laxity by physical examination,[1] stress radiography,[2] and/or arthrometry[3] before committing to an MPFL reconstruction. Frequently, an examination under anesthesia is necessary to confirm laxity of the medial retinacular structures because of patient apprehension and discomfort in the clinic.

Brief Summary of Surgical Technique

Major Surgical Steps

- Examination under anesthesia includes an assessment of patella mobility. The diagnosis of patella instability requires that there be a soft or no end point to lateral patella displacement either at full extension or 30° flexion and that the patella be mobile enough during examination under anesthesia to displace it out of the trochlea with the knee at 30° flexion. A diagnostic arthroscopy may be done to diagnose and treat any chondral lesions on the lateral condyle and patella.
- A 3 cm vertical incision is made over the pes anserinus, and a semitendinosis hamstring autograft is harvested. Alternatively, an allograft tendon can be used. A longitudinal incision is made over the medial patella, and the medial patella is exposed subperiosteally. A long curved clamp is then used to develop the interval between the retinaculum and the capsule all the way to the medial femoral epicondyle such that the graft will ultimately lie between the capsular layer and the native MPFL.
- A 4.5 mm drill is used to create two right-angle tunnels in the proximal two-thirds of the patella. A short incision is made over the medial epicondyle, and a blind socket is drilled between the femoral epicondyle and adductor tubercle. Fluoroscopy and intraoperative isometry testing is used to confirm appropriate positioning of the femoral socket.
- The hamstring graft is fixated at the femur, passed deep to the retinacular layer toward the medial patella, and then passed through the patellar tunnels. With the patella centered in the trochlear groove at 30° knee flexion, there is neither slack nor tension in the graft. Each free end of the graft is doubled over and sutured

to itself. Excessive medial constraint should be avoided,[4-6] as overtightening the graft results in increased medial facet compression.

Details and Choices That May Affect Rehabilitation

Surgical

- Postoperative pain can interfere with active quadriceps contraction. Pain can also impede progress with range of motion (ROM). Operating at or near the medial epicondyle of the knee is often associated with postoperative stiffness because of the higher degrees of motion of the injured soft tissues relative to the femur during knee flexion and extension. It is important to address ROM aggressively in the early postoperative phase to avoid stiffness. Once motion has been established, medial pain and knee stiffness as a result of scarring at the femoral attachment of the graft is rarely a problem.
- Swelling, either as free intraarticular fluid (effusion) or as soft tissue edema, can interfere with ROM. In addition, effusion inhibits quadriceps function[7] and may be harmful to articular cartilage.
- If autograft hamstring is harvested and used, avoid excessive hamstring stretching and strengthening for the first 6 weeks.

Anesthesia

- If regional anesthesia is used, await return of full motor function before starting weightbearing exercises.

Before Surgery: Overview of Goals, Milestones, and Guidelines

GUIDING PRINCIPLES OF POSTOPERATIVE REHABILITATION

- The principles of rehabilitation after MPFL reconstruction are similar to those guiding rehabilitation following other ligamentous reconstructions of the knee, such as anterior cruciate ligament (ACL).
- Despite differences between MPFL and ACL reconstruction surgery, there are enough similarities in postoperative neuromuscular deficiencies to suggest that strategies found to be successful after ACL reconstruction should be considered for those who have undergone MPFL reconstruction.
- The keys are to address pain, ROM, quadriceps strengthening, and proximal lower limb control.
- Return of full ROM, pain control, and protected weightbearing are stressed in the early phases of recovery.
- Progression of strength training and return to functional activities follows lines of evidence regarding graft necrosis, remodeling, and tunnel ingrowth, which are most commonly associated with ACL reconstruction.
- It is important to have a thorough preoperative discussion with the patient regarding the potential risks, benefits, goals, and postoperative rehabilitation. The patient should have realistic expectations regarding postoperative pain and the need for active participation in healing, rehabilitation, and return to sports. Passively receiving surgery and then awaiting a desired result can lead to failure of the graft and delay (if not preclude) a return to the activities of daily living and sports.
- Return to sedentary work is usually possible 5 to 7 days after surgery once pain is controlled and narcotic usage is minimal. Family and/or friends should also be recruited to help during the postoperative period. Driving can be considered once off narcotics, weightbearing is comfortable, and distal neuromuscular control allows for normalized reaction time.[8] This can take up to 6 weeks.

Phase I: Immediate Postoperative Period (days first 14)

Goals

- Pain control
- Reduce swelling and effusion
- Normalize ROM
- Return of quadriceps activation

Clinical Pearls

- If regional anesthesia is used, await return of motor function before starting weightbearing exercises.
- Use leg elevation, circumferential wrap, and cryotherapy to reduce swelling and effusion.
- Early ROM is critical to reduce stiffness.
- Avoid hamstring stretches (if autograft is selected).

Management of Pain and Swelling

- Pain and swelling need to be addressed immediately postoperatively and controlled over the long term. Strict elevation of the limb and limited activity in the first 1 to 2 days postoperatively allows the acute inflammatory phase to pass without further perturbation by overaggressive therapy. During that time, cryotherapy is helpful,[9] whether in the form of ice packs or commercially available cold therapy units.

Details of the Following Treatments That Are Appropriate to the Phase of Rehabilitation

- The patient is allowed to bear weight as tolerated with crutches with a hinged knee brace locked in extension. Unlock the hinged knee brace at 2 to 3 weeks as quad strength and control returns. MPFL reconstruction is not affected by axial loading of the joint. For this reason, weightbearing is encouraged after surgery as

long as axial rotation of the limb is not allowed. The limb should be in a brace during weightbearing activities for 4 to 6 weeks postoperatively or at least until limb control is sufficient to prevent falls and rotational stress on the knee. Early weightbearing should follow a gradual progression from full protection in a rigid brace locked at full extension to an unlocked brace with crutches. Gradual increase to full weightbearing should be permitted as quadriceps strength is restored.

- Immediate, controlled ROM is not detrimental to fixation or graft development in well-positioned and securely fixed MPFL grafts.
- An early goal of rehabilitation after MPFL reconstruction is to reestablish full knee extension. Unlike ACL reconstruction, return of passive knee extension does not guarantee full active extension. For that to occur, attention must be focused on quadriceps strengthening. Pain and swelling can be mitigated with electrical stimulation, cold therapy, and compression wraps. Passive patellar glides should be instituted as soon as tolerated to reestablish normal passive patellar mobility within the trochlear groove in all directions (superiorly, inferiorly, medially, and laterally).
- Early application of neuromuscular electrical stimulation in combination with volitional contraction is used to minimize strength loss after surgery.[11]
- Treatment to enhance proximal control can be started preoperatively and then immediately after surgery. Postoperatively, patients should perform nonweightbearing exercises targeting the hip abductors, external rotators, and extensors. When performing strengthening exercises for the gluteus medius, the patient must take care to minimize the contribution of the tensor fascia lata, as contraction of this muscle contributes to medial rotation of the lower extremity. Once the patient can isolate the proximal muscles of interest in nonweightbearing, progression to weightbearing activities can begin.

Phase II: Postoperative (weeks 2 to 6)

Goals

- Normalize ROM
- Discontinue crutches
- Discontinue brace

Clinical Pearls

- ROM should be normalized in this phase.
- Quadriceps and hip muscle activation exercises in weightbearing should be emphasized.
- Return of quadriceps function should allow the clinician to unlock the brace.

Details of the Following Treatments That Are Appropriate to the Phase of Rehabilitation

- Return of passive flexion can be limited by poor surgical technique (e. g., misplaced graft) and by pain associated with dissection around the medial epicondyle. The goal is to exceed 90° flexion within 6 weeks postoperatively. If that goal is achieved, then it has been our experience that limited knee flexion will not be a problem. On the other hand, delay in achieving greater than 90° of knee flexion may allow scar tissue proliferation and formation of adhesions around the graft and within the medial knee soft tissues. Manipulation may be required to regain full knee motion if flexion past 90° is not accomplished by Week 6.
- Exercises to enhance proximal control in weightbearing should be emphasized. As with the nonweightbearing exercises, the patient must take care to minimize the contribution of the tensor fascia lata, as contraction of this muscle contributes to medial rotation of the lower extremity.

Phase III (weeks 6 to 10)

Goals

- Normalize gait pattern
- Normalize hip strength
- Improve quadriceps strength

Clinical Pearl

- As pain and swelling subsides and function returns, athletes are often tempted to return to their sport before clearance by their medical team (surgeon, therapist). Advise the patient to complete their rehabilitation before returning to sports.

TIMELINE 28-1: **Postoperative Rehabilitation After Proximal Realignment Procedures and Medial Patellofemoral Ligament (MPFL) Reconstruction**

PHASE I (weeks 0 to 4)	PHASE II (weeks 4 to 6)

• Weight-bearing as tolerated (WBAT) with crutches; brace locked in extension
• Unlock brace at 2–3 weeks as quad strength and control returns
• Passive ROM as tolerated
• Start nonweightbearing exercises targeting hip abductors, external rotators, and extensors
• Modalities, including cryotherapy and electrical stimulation
• Home exercises:
  • Passive knee extension (knee sags)
  • Passive knee flexion (heel slides)
  • Gentle quadriceps sets
  • Patellar mobilization
	• Gradually discontinue crutches
	• Discontinue brace at 6 wk
	• Normalize ROM

Details of the Following Treatments that Are Appropriate to the Phase of Rehabilitation

- Surgery of the extensor mechanism is particularly prone to causing quadriceps inhibition and dysfunction, and every effort should be made to regain quadriceps control, strength, and endurance. Gentle quadriceps setting exercises should be started immediately after the surgery to keep the patellar tendon and infrapatellar fat pad stretched to their full length and to restore neuromuscular control. Care must be taken to avoid open-chain active terminal knee extension (15° to full extension), as the stress on the patellofemoral is quite high in this range.[10] Resisted quadriceps and hamstring strengthening should be progressively employed as the initial pain subsides.
- The primary causes of quadriceps avoidance are pain, effusion, and quadriceps muscle weakness. As these impairments are addressed in other aspects of treatment, the clinician should keep in mind that resolution of symptoms may not readily translate into a normalized gait pattern. This is particularly evident in a patient with long-term pain and dysfunction. Movement patterns can be learned, and the patient may need to be reeducated with respect to key gait deficiencies. Electromyography (EMG) biofeedback can be an effective tool for this purpose (Figure 28-5).
- When postoperative quadriceps weakness and neuromuscular inhibition are superimposed on poor proximal control, unprotected weightbearing can result in abnormal forces on the healing graft. Assuming that 8 to 12 weeks are required for tendon-to-bone healing within tunnels to support graft tension without risk of slippage[13] care is needed to avoid any rotational activity during the first three postoperative months. Unprotected single-leg stance on the operated knee should be avoided until satisfactory proximal limb control has been achieved. The postoperative brace should be removed for resisted flexion and extension strengthening and other controlled rehabilitative exercises that do not cause knee valgus or axial rotational torque that would jeopardize the graft fixation.
- Care should be taken during weightbearing to prevent dynamic knee valgus and hip internal rotation, which can cause abnormal loads on the healing graft. This is important, as many patients with patellofemoral disorders have preexisting deficiencies in proximal limb control that can contribute to these motions.[12]
- Facilitation of normal gait is an essential component of the overall treatment plan. This is particularly important for the returning athlete (especially runners) in whom even a slight gait deviation can be compounded by repetitive loading. The clinician should pay particular attention to the quadriceps avoidance gait pattern (walking with the knee extended or hyperextended). Because knee flexion during weight acceptance is critical for shock absorption,[14] this key function must be restored to prevent the deleterious effects of high-impact tibiofemoral joint loading.

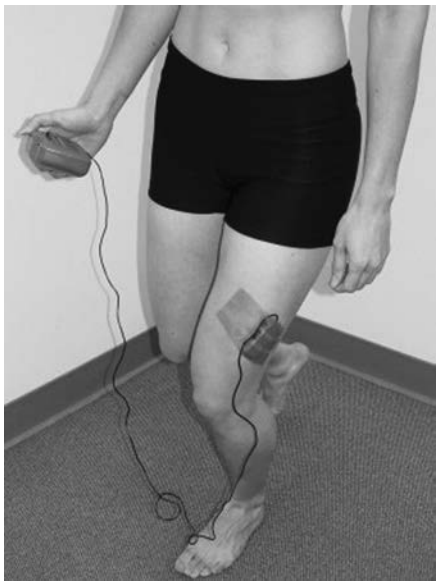

FIGURE 28-5. Electromyography biofeedback can be used to facilitate quadriceps recruitment during functional tasks. *(From Powers CM, Souza RB, Fulkerson JP. Patellofemoral joint. In Magee DJ, Zachazewski JE, Quillen WS, editors: Pathology and intervention in musculoskeletal rehabilitation. St Louis: Saunders Elsevier; 2008.)*

TIMELINE 28-1: **Postoperative Rehabilitation After Proximal Realignment Procedures and Medial Patellofemoral Ligament (MPFL) Reconstruction** (Continued)

PHASE III (weeks 6 to 10)	PHASE IV (weeks 10 to 14)	PHASE V (weeks 14 to 24)
• Normalize gait • Normalize hip strength • Improve quadriceps strength	• Functional and proximal control training • Weightbearing strength training of quadriceps, core, and hip stabilizers • Single-leg strength, balance, and control exercises • Plyometrics and sport-specific training	• Normalize strength and power of all major muscle groups • Dynamic limb control during sport-specific activities • Movement activities that simulate demands of their sport • Return to their sport or activity gradually • Plyometric training (e.g., jump training) • Maintain quadriceps and hip muscle strength (e.g., maintenance program)

Phase IV: Postoperative (weeks 10 to 14)

Goals

- Symmetric and normalized dynamic limb stabilization and control (single leg)
- Normalized quadriceps strength

Clinical Pearls

- Focus on functional training, dynamic limb stabilization, and control.
- Perform closed-chain quadriceps strengthening; avoid open-chain knee extension exercises.
- Unprotected single-leg stance on the operated knee should be avoided until satisfactory proximal limb control has been achieved.

Details of the Following Treatments That Are Appropriate to the Phase of Rehabilitation

- Functional training of the limb can begin in earnest 3 months after surgery. At this time, the patient should be introduced to the concept of neutral lower extremity alignment. This involves alignment of the lower extremity such that the anterior superior iliac spine (ASIS) and knee remain positioned over the second toe, with the hip positioned in neutral. Postural alignment and symmetrical strengthening should be emphasized during all exercises (see previous section of this chapter).
- Femoral strapping can be used to provide kinesthetic feedback and to augment muscular control and proprioception. Taping or bracing can also be used if pain is limiting the patient's ability to engage in a meaningful weight-bearing exercise program.
- Partial squats, which may have started already in a very controlled environment with supervision, can be advanced to incorporate a BOSU ball, or similar device, to facilitate proximal control. Close supervision is encouraged to ensure proper execution of these exercises. Once the patient understands the proper movement and goal of the task, continued performance in front of a mirror provides useful feedback.
- As strength, control, and balance progress, single-leg activities may be initiated. This is the final step before returning to full unrestricted activity. Considering that most patients are conditioned by their preoperative apprehension caused by patellar instability and some patients may not have performed single-leg squats on the operated leg for years before the operation, the patient may not progress to this stage before 5 to 6 months after the reconstruction. In any case, rehabilitation from this point onward requires careful assessment and progressive development of proximal lower limb control.

Phase V: Postoperative (weeks 14 to 24)

Goals

- Normalized strength and power of all major muscle groups
- Dynamic limb control during sport-specific activities
- No evidence of hip internal rotation or dynamic knee valgus during sport-specific activities

Clinical Pearls

- The athlete should begin to engage in movement activities that simulate demands of their sport.
- The athlete should be closely monitored for poor lower limb mechanics during this phase of rehabilitation.

Details of the Following Treatments That Are Appropriate to the Phase of Rehabilitation

- Patients are encouraged to return to their sport or activity gradually once they can achieve satisfactory single-limb dynamic control. With competitive or recreational athletes who will be returning to full participation, plyometric training (e.g., jump training) should be considered during this phase of the rehabilitation program. As patients, particularly athletes, return to sport activities, repetitive forces applied through the knee joint must be controlled adequately to allow continued healing of the injured or repaired tissues. Quadriceps and hip muscle strength should be maintained (e.g., maintenance program).

Criteria for Return to Sport

- Return to sport criteria:
  - Full and painless ROM
  - Absence of effusion and swelling
  - Satisfactory and symmetric proximal single-limb dynamic control during high-impact activities (e.g., landing from a jump, cutting, etc.)
  - Quadriceps, hamstring, and hip strength in at least 90% of uninjured leg
  - Psychologically ready to return to sports
- Patients can expect to return to unrestricted activities 6 months to 1 year postoperatively.

Evidence

Chen V, Chacko AT, Costello FV, et al: Driving after musculoskeletal injury. Addressing patient and surgeon concerns in an urban orthopaedic practice. *J Bone Joint Surg Am* 90:2791–2797, 2008.

The authors report on two surveys (one administered to patients, one to surgeons) regarding return to driving and the impact of musculoskeletal injury on driving. Overall, 73% of

patients reported that the inability to drive presented a minor or major difficulty, and greater than 35% of patients either began driving while still on narcotics or did not consult their doctor before driving. The authors highlight the medicolegal ramifications regarding the issues around returning to drive and describe the process that their institution used to develop standardized guidelines. The need for standardized guidelines from a large professional organization was emphasized. (Level V evidence)

Nomura E, Hoiuchi Y, Kihara M: A mid-term follow up of medial patellofemoral ligament reconstruction using an artificial ligament for recurrent patellar dislocation. *Knee* 7:211–215, 2000.

Case series of 27 MPFL reconstructions at average follow-up of 5.9 years. A double-staple fixation method was used to fix the artificial ligament at 60° of knee flexion with a minimal amount of tension (a tension spacer was placed to ensure that it was not overtightened). The authors report 96% good to excellent results, with only one case of recurrent patellar subluxation/dislocation and two cases with positive apprehension tests. Symptomatic implants (staples) were the most frequent complication. (Level IV evidence)

Palmieri-Smith RM, Kreinbrink J, Ashton-Miller JA, et al: Quadriceps inhibition induced by an experimental knee joint effusion affects knee joint mechanics during a single-legged drop landing. *Am J Sports Med* 35:1269–1275, 2007.

Laboratory study involving nine active subjects in which four experimental knee conditions were tested in the same subjects with a washout period: no effusion, subcutaneous lidocaine injection, low effusion (30 ml), and high effusion (60 ml). Using electromyographic, motion analysis, and force measurements, the subjects were analyzed doing drop landings. Both the high- and low-effusion conditions had significantly impaired vastus lateralis and vastus medialis muscle activity, but only the high-effusion condition had a significant increase in net ground reaction force and corresponding decreases in net knee extension moment and peak knee flexion angle. The results indicate that larger effusions lead to altered biomechanics, muscle activation, and landing forces. (Level V evidence)

Rodeo SA, Arnoczky SP, Torzilli PA, et al: Tendon-healing in a bone tunnel. A biomechanical and histological study in the dog. *J Bone Joint Surg Am* 75:1795–1803, 1993.

This is a study of 20 dogs that underwent bilateral transplantation of the long digital extensor tendon from the lateral femoral condyle into a tunnel through the proximal tibial metaphysis, with fixation on the medial tibia. At 2, 4, 8, 12, and 26 weeks, biomechanical and histologic analysis was performed after sacrifice. Over the postoperative period, the tendon–bone interface transformed from fibrous tissue to more organized collagen fibers with significant remodeling of the trabecular bone. The most dramatic increase in the strength of the interface occurred during the first 4 weeks. All specimens through 8 weeks failed at the tendon–bone interface, whereas at 12 and 26 weeks, failure occurred from slippage at the clamp or from midsubstance rupture. The authors recommend protecting a healing tendon–bone interface for 8 to 12 weeks postoperatively. (Level V evidence)

Shelbourne KD, Gray T: Anterior cruciate ligament reconstruction with autogenous patellar tendon graft followed by accelerated rehabilitation. A two- to nine-year followup. *Am J Sports Med* 25:786–795, 1997.

This study is a case series of 1057 patients with ACL reconstructions with 76% objective follow-up and 90% subjective follow-up at an average of 4 years postoperatively. The patients underwent an accelerated rehabilitation protocol with strengthening and functional agility occurring at weeks 2 to 5 and return to sport-specific activities at 5 weeks if quadriceps strength was sufficient. Mean time to completing at 100% was 6.2 months. Graft ruptures occurred in 2.6% of the patients, and 97% to 98% of patients (both acute and chronic) had KT arthrometry side-to-side differences of less than 5 mm. (Level IV evidence)

Souza RB, Powers CM: Differences in hip kinematics, muscle strength, and muscle activation between subjects with and without patellofemoral pain. *J Orthop Sports Phys Ther* 39:12–19, 2009.

This is a laboratory study comparing the hip biomechanics of 20 asymptomatic females with 21 females with patellofemoral pain. Motion analysis and EMG of the gluteus maximus and gluteus medius were used to analyze the biomechanics during running, drop jumps, and step-downs. Hip abductor and hip extension isometric strength was also tested using a dynamometer. Subjects with patellofemoral pain had a higher degree of peak hip internal rotation during the tests and lower peak hip abduction and extension torques in strength testing. The authors conclude that an assessment of hip kinematics and strength is critical in patients with patellofemoral pain. (Level V evidence)

Steinkamp LA, Dillingham MF, Markel MD, et al: Biomechanical considerations in patellofemoral joint rehabilitation. *Am J Sports Med* 21:438–446, 1993.

This is a biomechanical study of 20 patients comparing patellofemoral joint forces performing leg extension exercises versus incline leg presses. At 0° and 30°, knee moments, patellofemoral joint reaction forces, and patellofemoral joint stress values were higher during leg extensions than during leg presses. At 60° and 90°, patellofemoral stress, joint reaction force, and knee moments were higher for leg presses. The crossover points were between 46° and 51°, with the intersection occurring at 48.4° for patellofemoral joint stress. Leg presses are recommended for rehabilitation of patellofemoral pain because of the lower patellofemoral joint stress values at lower (functional) ranges of motion. (Level V evidence)

Multiple-Choice Questions

QUESTION 1. Choose the best indication for MPFL reconstruction:

A. Patellofemoral pain
B. First-time lateral patellar dislocation
C. Episodic lateral patellar instability
D. Episodic medial patellar instability

QUESTION 2. If an autograft hamstring is harvested and used to reconstruct the MPFL, avoid:

A. Regional anesthesia
B. Immediate ROM
C. Excessive hamstring stretching and strengthening for the first 6 weeks
D. Quad setting for the first 12 weeks

QUESTION 3. The principles that guide rehabilitation after MPFL reconstruction are similar to those guiding rehabilitation after which type of surgery?

A. Tibial tubercle osteotomy and anteromedialization
B. Lateral retinacular release and medial reefing
C. Anterior cruciate ligament reconstruction
D. Total knee arthroplasty

QUESTION 4. ROM exercises after MPFL reconstruction should start:

A. Three weeks after surgery to avoid detrimental effects to MPFL fixation at the patella
B. Six weeks after surgery to avoid detrimental effects to MPFL fixation at the femur
C. Immediately but must be controlled
D. Once proximal single-limb dynamic control has been attained

QUESTION 5. The final step before return to full unrestricted activity is:

A. Normalized gait pattern
B. Absence of effusion and swelling
C. Single-leg activities to achieve symmetric proximal single-limb dynamic control during high-impact activities
D. Removal of postoperative bandages

Answer Key

QUESTION 1. Correct answer: **C** (see Indications for Surgical Treatment)

QUESTION 2. Correct answer: **C** (see Brief Summary of Surgical Technique)

QUESTION 3. Correct answer: **C** (see Postoperative Rehabilitation: Overview of Goals, Important Milestones, and Guidelines)

QUESTION 4. Correct answer: **C** (see Postoperative Rehabilitation: Overview of Goals, Important Milestones, and Guidelines [Range of Motion])

QUESTION 5. Correct answer: **C** (see Postoperative Rehabilitation: Overview of Goals, Important Milestones, and Guidelines [Dynamic Limb Stabilization and Control])

POSTOPERATIVE REHABILITATION AFTER ANTEROMEDIALIZATION OF THE TIBIAL TUBERCLE

John Pryor Fulkerson, MD, Craig Alver, PT, and Erin L. Ives, PT, MS, OCS, CertMDT

Indications for Surgical Treatment

- Excessive lateral patella compression syndrome
- Lateral patellofemoral arthrosis
- Lateral patella tracking with lateral articular breakdown
- Painful distal and/or lateral patella chondral articular softening that has not responded to nonoperative or arthroscopic treatment

Brief Summary of Surgical Treatment

Major Surgical Steps

- Oblique osteotomy behind the tibial tubercle, tapered anteriorly at the distal aspect[1]
- Transfer the tibial tubercle anteriorly and medially by rotation of the osteotomy through a distal hinge of bone

FIGURE 28-6. Surgical incision.

- Secure fixation with two cortical lag screws into the posterior tibial cortex with compression (Figure 28-6)

Factors That May Affect Rehabilitation

Anesthetic

- Regional block will impair early motion in the first 24 to 48 hours but will be very helpful for immediate postoperative pain control

Surgical

- Fixation that is less secure or bone graft added in the osteotomy may require a longer period of limited motion and therefore impede the rehabilitation process

GUIDING PRINCIPLES OF POSTOPERATIVE REHABILITATION

- Understand the process of the surgical reconstruction
- Protect and progress ROM as appropriate for the healing bone and soft tissues
- Identify and correct lower extremity (LE) muscle imbalances

Phase I: Immediate Postoperative Period (days 0 to 14)[1]

Clinical Pearl

It is important during the immediate postoperative period to emphasize to the patient the importance of regaining full range of motion as quickly as possible. The patient needs to be instructed to bend the knee to a point that produces some level of discomfort that subsides once the stretch is completed. Stretching needs to be performed often (2 to 3 times a day) to gain the best results. Surgical fixation should permit this early motion.

Goals

- Protect the reconstruction
- Minimize pain and swelling in the lower extremity
- Initiate ROM exercises to promote healthy scar tissue

Protection

- Protection of the reconstructed knee includes the use of bilateral axillary crutches with a knee immobilizer.
- Weightbearing status is touch-toe weightbearing (TTWB) with a maximum of 20 lb exerted through the affected LE.

Management of Pain and Swelling

- Modalities including cryotherapy, TENS, and IFC stimulation; oral pain medications
- Cryotherapy, elevation, high-volt electrical stimulation, Kinesio taping (Figure 28-7)

Techniques for Progressive Increase in Range of Motion

Manual Therapy Techniques

- Mobilize the patella in inferior and superior directions along with correcting for any positional faults that may be present, such as lateral tilt

Soft Tissue Techniques

- Myofascial release and soft tissue mobilization around incision when proper healing has occurred

FIGURE 28-7. Kinesio tape positioning for edema reduction.

[1]*Prehabilitation, if appropriate, is described in the Nonoperative Rehabilitation section of this chapter.*

Stretching and Flexibility Techniques for the Musculotendinous Unit

- Gastrocnemius, hamstring, iliotibial band (ITB), and hip flexor stretches to promote knee extension and quadriceps stretching to promote knee flexion; ankle pumps for thrombosis prevention

Activation of Primary Muscles Involved in Injury Area or Surgical Structures

- Quadriceps, gluteal, and hamstring setting exercises should be initiated

Milestones for Progression to the Next Phase

- Achieve 0° to 90° of knee active range of motion (AROM) by 6 weeks from the date of surgery and full motion by 8 to 10 weeks
- Demonstrate independence with thrombosis prevention measures and ROM exercises
- Independent use of bilateral axillary crutches with TTWB through affected LE

Phase II: Postoperative (weeks 2 to 6)

Clinical Pearl

During this phase, OKC exercises for the hip are initiated, and correct form is crucial to good outcomes. Compensations in the form of faulty movement patterns will occur and need to be noted and corrected by the therapist. During side-lying abduction, the therapist needs to be sure that the patient is actually abducting from the hip joint and not compensating with lumbar side bending. During the side-lying clamshell exercise, the therapist also needs to be sure that the movement occurring is hip rotation and not lumbar spine rotation. These compensations may result in low back pain and a prolonged recovery for your patient.

Goals

- Continue to protect the reconstruction
- Minimize pain and swelling in the lower extremity
- Achieve full knee extension to flexion ROM
- Initiate open-chain LE strengthening exercises

Protection

- Protection continues with the use of bilateral axillary crutches
- Weightbearing can increase to partial weightbearing (PWB) 50% of body weight

Management of Pain and Swelling

- For pain: modalities including cryotherapy, TENS, and IFC stimulation
- Oral pain medications.
- For swelling: modalities including cryotherapy, high-volt electrical stimulation, and Kinesio taping

Techniques for Progressive Increase in Range of Motion

Manual Therapy Techniques

- Mobilize the patella in superior and inferior directions progressing the inferior glide with varying angles of knee flexion to promote full knee flexion AROM

Soft Tissue Techniques

- Myofascial release and soft tissue mobilization around the incision is continued in this phase to help promote return of full extension to flexion knee range of motion (ROM)

Stretching and Flexibility Techniques for the Musculotendinous Unit

- The stationary bike is a great tool for working flexion ROM at this time. The patient will begin with a rocking motion, inducing a flexion stretch in both forward and reverse directions until a complete revolution is possible.

TIMELINE 28-2: **Postoperative Rehabilitation After Anteromedial Tibial Tubercle Transfer**

PHASE I (weeks 0 to 2)	PHASE II (weeks 2 to 6)	PHASE III (weeks 6 to 10)
• Knee immobilizer • TTWB with bilateral axillary crutches • PT modalities • ROM (goal of 90°) • Patella mobilization as needed • TBS/TAS/TLS as recommended and tolerated • Thrombosis prevention	• Weightbearing can increase to PWB 50% of body weight with bilateral axillary crutches • PT modalities • Patella mobilization as needed • Achieve full knee extension-to-flexion ROM • Initiate OKC LE strengthening exercises	• FWB without assistive device with normal gait pattern • PT modalities • Patella mobilization as needed • Initiate CKC exercises for strength, balance, and proprioception • Maintain full knee extension-to-flexion ROM

- LE stretches are continued, including the hamstring, gastrocnemius, quadriceps, and hip flexor muscle groups, until full ROM is achieved at the knee.

Activation of Primary Muscles Involved in Injury Area or Surgical Structures

- Quadriceps, hamstring, and gluteal setting exercises continue and progress to open-chain exercises outlined in the following sections

Open and Closed Kinetic Chain Exercises

- OKC exercises, including straight leg raise (SLR) into flexion, abduction, adduction, and extension
- OKC and CKC exercises to address the hip muscles, including the clamshell and bridge

Milestones for Progression to the Next Phase

- Full knee extension to flexion ROM
- SLR in four directions without extension lag
- Effective use of crutches with PWB at 50%

Phase III: Postoperative (weeks 6 to 10)

Clinical Pearls

It has been documented that there is a correlation between hip ER weakness and patellofemoral dysfunction.[2] As strengthening is progressed with CKC activity in this phase, it is important to be aware of the patient's movement patterns. A common faulty movement pattern includes IR of the femur with a valgus movement at the knee. Correct activation of the hip ER can decrease this faulty movement pattern.

Goals

- Normalize gait without assistive devices
- Initiate CKC exercises for strength, balance, and proprioception
- Maintain full knee extension to flexion ROM

Protection

- The patient should be weaning from crutches at this point, with an emphasis placed on normalizing the gait pattern by the end of this phase. The patient will now be weightbearing as tolerated (WBAT) through the affected LE with the use of bilateral axillary crutches progressing to one crutch WBAT and finally to fulll weightbearing (FWB) at 10 weeks.

Management of Pain and Swelling

- Cryotherapy after therapy interventions to mitigate inflammation and soreness
- If swelling persists into this phase, the use of cryotherapy with high-volt stimulation can be effective

Techniques for Progressive Increase in Range of Motion

Manual Therapy Techniques

- Continue to monitor movement of the patella; at this point, grade 1 to 4 mobilizations of the knee for flexion or extension can be initiated

Soft Tissue Techniques

- Soft tissue mobilizations and myofascial release would be beneficial for any remaining adhesions

Stretching and Flexibility Techniques for the Musculotendinous Unit

- The stationary bike is continued at this time, with the patient making full revolutions with increasing resistance

TIMELINE 28-2: **Postoperative Rehabilitation After Anteromedial Tibial Tubercle Transfer** (Continued)

PHASE IV (weeks 10 to 14)	PHASE V (weeks 14 to 24)	PHASE VI (weeks 24 to 52)
• PT modalities as needed • Mobilizations as needed (patellofemoral and tibiofemoral) • Achieve normal gait pattern if not yet achieved • A/PROM to full if not yet achieved • Initiate prone quadriceps stretching • CKC: Leg presses and squats • OKC: May begin lightweight knee extensions at 10 to 12 weeks • OKC: Hamstrings and hip PREs • Controlled balance and proprioception exercises • Begin upper-body strengthening and endurance activities • Aquatic therapy may start as long as incision is healed	• Continue modalities and mobilizations as needed • Initiate partial lunges • Initiate walk-run program at 4 months • Initiate SLB exercises on even and uneven surfaces • Initiate plyometrics at 5 months • Initiate slide board activity at 16 to 20 weeks • Slow-speed sport-specific exercise at 20 weeks • Continue with OKC and CKC exercises	• Maintain full ROM • Continue OKC and CKC exercises as appropriate • Progress to full lunges with varying directions • Progress plyometrics • Increase speed of sport-specific exercises • Increase jogging time speed • Progress in-line running speed • Return to in-line running full speed • Return to limited sports with warning of risks • Full torsional sport (plant and cut) usually delayed until 1 yr after osteotomy

Sensorimotor Exercises

- Initiate balance and proprioception exercises for the LE seated on a therapy ball, then progress to single-leg stance (SLS) with the contralateral LE in a toe-touch position and, finally, SLS on the affected LE with a goal of maintaining the position for 30 seconds

Open and Closed Kinetic Chain Exercises

- Continuation of SLR in four positions of hip flexion, extension, abduction, and adduction with the addition of an ankle weight once extension lag is no longer present
- Clamshell with a weight above the knee for an added challenge
- Bridge progression to bridge with marching

Techniques to Increase Muscle Strength, Power, and Endurance

- The stationary bike at this point can be used for endurance with increasing resistance as tolerated

Functional Exercises

- Sit to stand from chair
- Two-inch step exercises, including anterior step-up, lateral step-up, and retro step-up

Milestones for Progression to the Next Phase

- FWB without assistive device with normal gait pattern
- Full extension to flexion ROM of the knee is maintained
- SLS with eyes open for 30 seconds

Phase IV: Postoperative (weeks 4 to 6)

Clinical Pearl

The literature has demonstrated improved knee function as a result of LE stretching, specifically at the hip.[3] As early as possible in this phase, prone quadriceps stretching should be initiated. Stretching the quadriceps in this position helps to stabilize the hip and decrease the potential for tortional forces on the knee. It also makes it easier to detect any rotation at the hip (ER/IR), which should be avoided. Passive knee flexion of 90° in prone by the therapist should be achieved before having the patient stretch independently. For comfort, a folded towel may be put under the thigh, raising it slightly off the table/floor.

Goals

- Normal gait if this has not been achieved
- Full pain-free ROM if this has not been achieved
- Strength MMT 4/5 for quadriceps and hamstrings
- Climb stairs reciprocally without pain

Management of Pain and Swelling

- Cryotherapy after interventions to mitigate inflammation and soreness
- If swelling persists into this phase, the use of cryotherapy with high-volt stimulation can be effective

Techniques for Progressive Increase in Range of Motion

- If ROM in the knee is not yet full, then it will continue to be addressed.

Manual Therapy Techniques

- Joint mobilization if needed for flexion and extension
- Patella mobilization if needed
- Often times, ROM is WNL and the patella is moving well by this point in rehabilitation

Soft Tissue Techniques

- If the incision remains tight, scar mobilization can be used

Stretching and Flexibility Techniques for the Musculotendinous Unit

- Quadriceps stretching (in prone) (Figure 28-8)
- Hamstring, gastrocnemius, and hip musculature self-stretching

Other Therapeutic Exercises

- Increase LE closed-chain strengthening
- Slowly progress to proprioceptive activities in standing
- Begin upper-body strengthening and endurance exercises

Activation of Primary Muscles Involved in Injury Area or Surgical Structures

- Leg presses/partial squats for quadriceps strengthening are introduced

FIGURE 28-8. Prone quadriceps self-stretch using a strap.

- Begin step-ups/step-downs
- Increase knee, hip, and calf strengthening

Sensorimotor Exercises

- Single-leg balance with eyes open and contralateral LE in toe-touch position
- Progress to single-leg balance (SLB) with eyes open and no contralateral involvement with the goal of maintaining position for 30 seconds

Open and Closed Kinetic Chain Exercises

- OKC: Continuation of SLR in four positions and other previous OKC exercises with increasing weight
- OKC: Open-chain light quadriceps strengthening can be started at 10 to 12 weeks postop. Open-chain quadriceps exercises should be initiated with light weight, 10 to 15 reps, and should be pain free
- OKC: Hamstring curls, seated
- CKC: Leg presses/partial wall squats, hip extension, calf raises. Advance to single-leg squats and calf raises as tolerated. Squats should initially be stopped at 50° to 60° of knee flexion, as research suggests that there is less patellofemoral joint force in this range and that it increases between 60° and 90°.[4]
- Also, because the goal is to restore quadriceps strength and correct patella tracking, there is research to support using isometric hip adduction with squats to help elicit the VMO and promote patella tracking.[5] (Figure 28-9)
- CKC: Step-ups/step-downs, usually starting with a 4-inch step. With step work, care should be taken to have the patient adduction and internal rotation of the hip
- CKC: Terminal knee extension with foot on ground, resistance behind knee
- Pool-based exercises for the UE and LE may be started at this point as long as the incision is healed

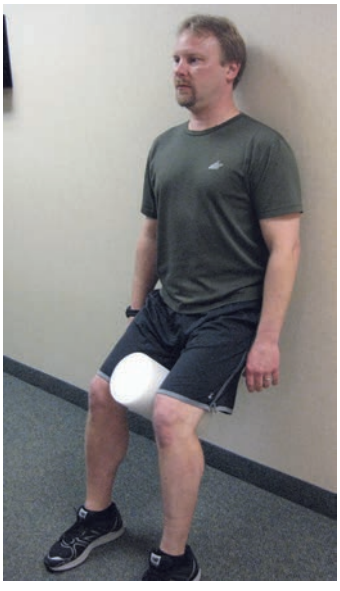

FIGURE 28-9. Wall squat with isometric hip adduction.

FIGURE 28-10. Hamstring curl with legs on therapeutic ball.

Techniques to Increase Muscle Strength, Power, and Endurance

- Increase resistance and time on bike as tolerated
- May begin using elliptical machine
- Increase walking time and speed slowly

Neuromuscular Dynamic Stability Exercises

- In standing, begin SLR in four directions with resisted tubing on surgical leg. This will improve balance and will facilitate core recruitment for total body stability.
- Also, exercises such as bridges on a Thera-Ball and hamstring curls on a Thera-Ball can be started, as they will also introduce core stability while working on LE strength (Figure 28-10).

Functional Exercises

- Step-ups and step-downs on stairs (start with 4-inch step)
- Make sure that technique is monitored
- Avoid hip adduction and internal rotation of the hip

Sport-Specific Exercises

- UE sport-specific drills for coordination can be started in a controlled environment, either sitting or standing on both legs

Milestones for Progression to the Next Phase

- Pain-free normal gait
- Able to climb stairs reciprocally without pain
- 4/5 quadriceps and hamstring strength
- Single-limb balance greater than 1 minute

Phase V: Postoperative (weeks 14 to 24)

Clinical Pearls

With the patient advancing to balance activities and increased dynamic stabilization exercises such as

lunges, great care needs to be placed on educating the patient in proper technique. Good alignment of the knee in relation to the hip and foot must be stressed. For instance, research has shown that a longer step with the lunge produces less patellofemoral joint force.[6]

Additionally, when higher-level dynamic stability exercises are initiated, it is imperative that form be monitored. In weightbearing, hip IR and adduction should be avoided when balancing, squatting, and jumping, as this can lead to lateral patella tilt and displacement.[7]

Goals

- 5/5 strength in quadriceps, hamstrings, and all hip musculature
- Single-limb balance of 2 minutes
- Return to jogging

Management of Pain and Swelling

- Ice after exercise

Techniques for Progressive Increase in Range of Motion

- Patients should have achieved full ROM by now. If not, follow previous guidelines.

Manual Therapy Techniques

- Continue previous techniques as needed

Soft Tissue Techniques

- Scar mobilization if required

Stretching and Flexibility Techniques for the Musculotendinous Unit

- Continue with previous stretching of lower extremities bilaterally

Other Therapeutic Exercises

- Progress previous LE strengthening
- Progress UE strengthening
- Initiate neuromuscular dynamic stability exercises
- Initiate walk/run program at 4 months
- Initiate plyometric exercises at 4 months

Activation of Primary Muscles Involved in Injury Area or Surgical Structures

- As before with progressive resistance

Sensorimotor Exercises

- Initiate SLB activities on uneven surfaces at 16 weeks.
- Initiate SLS exercises with a progression of opposite LE reach, bilateral UE reach, and weighted bilateral UE reach as tolerated, focusing on good control of the knee in relation to the foot and hip (Figure 28-11).

FIGURE 28-11. Single-leg stance with bilateral upper extremity reach.

- Add SLS with UE weighted ball toss against rebounder, standing on flat surface.
- Slide board activity may be started between 16 and 20 weeks postoperatively. Balance on uneven surfaces, such as Airex foam or DynaDisc and exercises on a BOSU ball may also be initiated at this time (Figure 28-12).

Open and Closed Kinetic Chain Exercises

- OKC: Progress to standing hip exercises with resistance from bands or machines
- OKC: Progress hamstring curls
- OKC: Progress knee extension exercises. Stay with 10 to 15 reps for three sets and continue to lower resistance
- CKC: Lunges, starting forward and progressing as tolerated. Oftentimes, it is necessary to start with partial

FIGURE 28-12. Squat on BOSU ball.

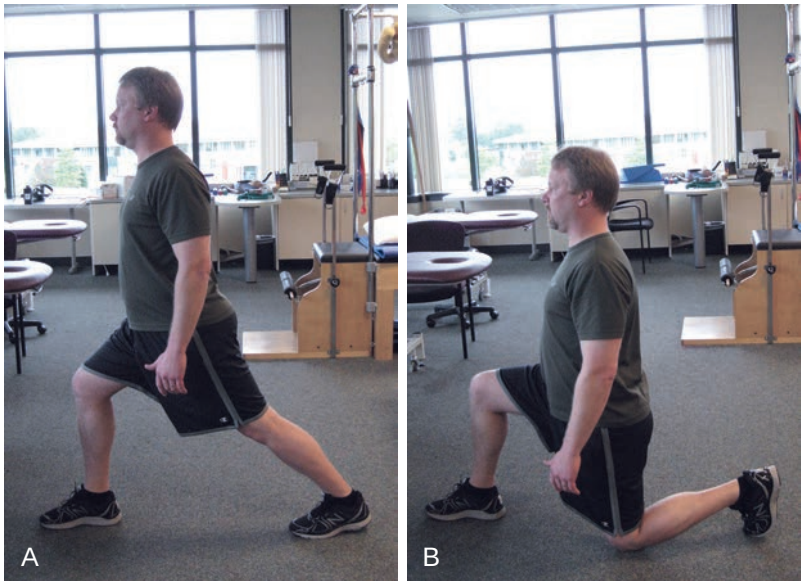

FIGURE 28-13. **A**, Partial lunge. **B**, Full lunge with long stride.

lunges (Figure 28-13). Of note: research supports a longer stride when performing a lunge to decrease the patellofemoral compressive force. Over time, a medicine ball with upper extremity reaching may be added to the lunge to incorporate core stabilization (Figure 28-14).
- CKC for upper body and core, such as pushups and planks, may be started

Techniques to Increase Muscle Strength, Power, and Endurance

- Increase weight on resistance exercises
- Initiate a walk/run program at 4 months. To do this, the patient must be pain free during a fast walk (at least 3.5 mph)

Neuromuscular Dynamic Stability Exercises

- Forward and sideways lunge on BOSU ball
- SLS with ball toss on uneven surfaces (Figure 28-15)
- Squats on BOSU ball; SLB on BOSU ball

Plyometrics

- Begin light plyometrics at 5 months as long as patient is pain free. Focus first on technique. Make sure the landing is soft and that the femur is not internally rotating or adducting (Figure 28-16).
- Slowly progress plyometrics, always focusing on form.
- Begin with bilateral jumps, progressing to toe taps on steps, step-ups, and step-overs and progress to one leg only as patient's control allows.

FIGURE 28-14. Lunge with upper extremities holding medicine ball.

FIGURE 28-15. Single-leg balance on DynaDisc with ball toss against rebounder.

FIGURE 28-16. **A**, Correct landing. **B**, Incorrect landing with right hip slightly adducted and internally rotated.

Functional Exercises

- Begin step-ups and step-overs, starting on a step and progressing to BOSU ball.
- Begin a walk/run program at 20 to 24 weeks as long as the patient is pain free.

Sport-Specific Exercises

- Continue sport-specific exercises for UEs
- May initiate slow-speed agility activities at 20 weeks if jogging and plyometrics have been pain free. These may include side shuffling, figure-eights, side-to-side carioca, etc.

Milestones for Progression to the Next Phase

- 5/5 strength throughout lower extremity
- Pain-free jogging
- Single-leg balance of 2 minutes
- Able to jump and land with good control pain free

Phase VI: Postoperative (weeks 24 to 52)

Clinical Pearl

Progression in this phase varies widely. It is not uncommon for an athlete who plays a contact sport to be out a full year before returning to the game. It is important to explain this to the patient early on and to set goals appropriately. Progression during this phase with regard to jumping, cutting, and speed/agility exercises must be slow and controlled.

Goals

- Return to in-line running full speed
- Return to limited sports with warning of risks
- Full torsional sport (plant and cut) usually delayed until 1 year after osteotomy

Management of Pain and Swelling

- Ice as needed after exercise

Techniques for Progressive Increase in Range of Motion

- ROM should be full and pain free at this point.

Stretching and Flexibility Techniques for the Musculotendinous Unit

- Patient should be instructed in the necessity of continuing LE stretching before and after exercise

Other Therapeutic Exercises

- The focus in this phase should be to get UE and LE strength back to preinjury levels.

Activation of Primary Muscles Involved in Injury Area or Surgical Structures

- Continue to strengthen quadriceps, hamstring, and hip musculature, progressing weight as tolerated.

Sensorimotor Exercises

- Advance balance and proprioceptive exercises to tolerance

Open and Closed Kinetic Chain Exercises

- OKC: Continue open-chain quadriceps, hamstring, and hip exercises
- CKC: Progress squats and leg presses to tolerance

Techniques to Increase Muscle Strength, Power, and Endurance

- Increase jogging time and speed
- Progress in-line running time and speed to tolerance

Neuromuscular Dynamic Stability Exercises

- Single-leg stance with UE band pulls, increasing resistance as control and balance allow

Plyometrics

- Advance plyometric exercises to tolerance, still focusing on good control of the knee in relation to the foot and hip

Sport-Specific Exercises

- During this phase, sport-specific exercises should be initiated, starting at slow speed and then increasing speed in a slow, progressive manner

Milestones for Progression to the Next Phase

- If isokinetic testing is available, less than 10% deficit of the involved side when compared to the noninvolved side
- No pain with agility/speed training activities

Criteria for Return to Sport

General

- Full motion and strength return
- Solid evidence of radiographic consolidation of the osteotomy
- Perform full-speed, sport-specific agility drills without pain

Sport-Specific

- The rehabilitation specialist and athletic trainers should, at this point, be able to develop a series of tests to ensure that the patient is ready to return to preinjury levels of activity.

After Return to Sport

Continuing Fitness or Rehabilitation Exercises

- General conditioning
- Continued LE strength and motion exercise

Exercises and Other Techniques for Prevention of Recurrent Injury

- As above

Evidence

Escamilla RF, Zheng N, Macleod TD, et al: Patellofemoral joint force and stress between a short and long step forward lunge. *J Orthop Sports Phys Ther* 38:681–690, 2008.

Research study using 18 subjects and 12 repetition max weight while performing forward lunge exercises. The study used EMG, ground reaction force, and kinematic variables to calculate patellofemoral joint force and stress as a function of knee angle. Patellofemoral joint force and stress were found to be significantly greater when performing a forward lunge with a short step versus a long step. Lunge with stride also produced greater force and stress than did the lunge without a stride. (Level II evidence)

Escamilla RF, Zheng N, Macleod TD, et al: Patellofemoral joint force and stress during the wall squat and one-leg squat. *Med Sci Sports Exerc* 41:879–888, 2009.

Research study using 18 subjects and 12 repetition max weight while performing wall squat short and long, as well as one leg squat. The study used EMG, force platform, and kinematic variables to calculate patellofemoral compressive forces and stress as a function of the knee angle. Results of the study found that patellofemoral force and stress were greater with these exercises between 60° and 90°, with differences depending on the exercise. (Level II evidence)

Farr J, Schepsis A, Cole B, et al: Anteromedialization, review and technique. *J Knee Surg* 20:120–128, 2007.

In this article, the authors share their extensive experience with the procedure to present the proper use and implementation of tibial tubercle ateromedialization. In essence, the procedure is best used to realign a chronically lateral overloaded patella that has led to lateral and/or distal patella articular breakdown and pain. The procedure effectively unloads the lateral and distal patella, thereby affording substantial pain relief and patellofemoral balance to the patient when the surgery and rehabilitation are properly performed. (Level III evidence)

Ireland ML, Willson JD, Ballantyne BT, et al: Hip strength in females with and without patellofemoral pain. *J Orthop Sports Phys Ther* 33:671–675, 2003.

This is a cross-sectional design study involving 30 females, 15 with knee pain and 15 without knee pain. Hip ER and ABD strength were measured using a hand-held dynamometer. The subjects with knee pain demonstrated 26% to 36% less knee strength than the control group.

Irish SE, Millward AJ, Wride J, et al: The effect of closed-chain exercises and open-kinetic chain exercise in muscle activity of vastus medialis oblique and vastus lateralis. *J Strength Cond Res* 24:1256–1262, 2010.

Research study comparing the effect of two closed-chain exercises and one open-chain exercise on VMO and VL activity. The study had 22 subjects and used surface EMG to compare VL and VMO activity while performing three different quadriceps strengthening exercises. Double-leg squat with isometric hip adduction was shown to produce the highest VMO : VL ratio, and the lunge produced the closest idealized ratio of VMO : VL. Open-chain knee extension was shown to produce significantly more VL activation than either of the closed-chain exercises. (Level II evidence)

Souza RB, Draper CE, Fredericson M, et al: Femur rotation and patellofemoral joint kinematics: a weightbearing magnetic resonance imaging analysis. *J Orthop Sports Phys Ther* 40:277–285, 2010.

This is a cross-sectional research study involving 15 females without knee pain and 15 females with patellofemoral pain. The study used weightbearing kinematic magnetic resonance imaging to compare patellofemoral joint kinematics and femoral rotation and patella rotation between the groups. The females in the patellofemoral group demonstrated both significantly greater medial (internal) femoral rotation and more lateral tilt than that of the pain-free group. (Level II evidence)

Tyler TF, Nicholas SJ, Mullaney MJ, et al: The role of hip muscle function in the treatment of patellofemoral pain syndrome. *Am J Sports Med* 34:630–636, 2006.

Thirty-five subjects with patellofemoral pain were evaluated and placed in a 6-week treatment program including hip abduction, flexion, and adduction strengthening along with iliopsoas and ITB stretching. The subjects that reported the most improvement demonstrated increased hip flexion strength and iliopsoas and ITB flexibility. (Level II evidence)

Multiple-Choice Questions

QUESTION 1. Initial protection of reconstructed knee includes the use of bilateral axillary crutches with a knee immobilizer. Weight-bearing status is TTWB with a maxim of:

A. 0 lb exerted through the affected LE
B. 5 lb exerted through the affected LE
C. 10 lb exerted through the affected LE
D. 20 lb exerted through the affected LE

QUESTION 2. Sensorimotor exercises such as balance and proprioception should be initiated:

A. Never
B. During Phase II
C. During Phase III
D. During Phase IV

QUESTION 3. Robert's postrehabilitation of anteromedial tibial tubercle transfer should include:

A. Only open-chain exercises
B. Only closed-chain exercises
C. Both A and B
D. Neither A nor B

QUESTION 4. Which manual and soft tissue techniques are permitted in Phase I s/p anteromedial tibial tubercle transfer?

A. Patella mobilization superiorly and inferiorly
B. Myofascial release
C. Soft tissue mobilization
D. All are correct

QUESTION 5. As long as the patient is pain free, you can begin a walk-run program at weeks:

A. 28 to 32
C. 24 to 28
D. 16 to 20
D. 20 to 24

Answer Key

QUESTION 1. Correct answer: **D** (see Phase I: Protection)

QUESTION 2. Correct answer: **C** (see Phase III)

QUESTION 3. Correct answer: **C** (see Phase IV)

QUESTION 4. Correct answer: **D** (see Phase I)

QUESTION 5. Correct answer: **D** (see Phase V)

Chapter 29

Patellar and Quadriceps Tendinopathy

INTRODUCTION

Christopher C. Kaeding, MD

Epidemiology

Age

- 16 to 35 years

Sex

- Occurs in both males and females, with a predilection for males

Sport

- Basketball
- Lacrosse
- Soccer
- Football

Position

- Positions requiring sudden start/stop and or jumping movements

Pathophysiology

Intrinsic Factors

- Enthesis is at risk for tendinosis.
- This junction of tendon/bone joins materials with different modulus of elasticity.
  - This causes an area of stress concentration.
  - Thus producing peak loads at the enthesis.
  - These peak loads place enthesis at risk for overload pathological processes.

Extrinsic Factors

- A high volume of high loading episodes without required periods of rest/recovery
  - In positive adaptive environment, a tenocyte will produce growth factors such as TGF beta 1 and ILGF 1.
  - This can result in increased tendon fiber size and number and thus greater tendon tensile strength.
  - If loading surpasses threshold of a positive adaptive response, degenerative process can start.
- Plyometric loading of tendon
  - Tendons are viscoelastic and more stiff at higher loading rates.
  - Thus plyometric exercise can result in significant higher tendon loads.

Traumatic Factors

- Overuse injury that occurs from:
  - High volume (frequency, duration + intensity) of explosive, plyometric type of quadriceps contractions
  - Without required recovery period
  - Puts enthesis at highest risk for tendinosis
- Tenocyte de-differentiates into a more generic mesenchymal cell
  - Loses spindle shape, becomes round
- This cell produces catabolic signals that lead to tendon matrix degeneration.
  - These include substance P, calcitonin related gene peptide, and matrix metalloproteases.
  - Inflammation does not have a significant role during this process.
  - Prostaglandin E, a marker for inflammation, is not found in tendinosis.
- Early in the process there is a ingrowth of neovasculature and neurofilaments.
  - Neurofilaments/substance P may be source of pain.
  - No evidence for inflammation as source of pain.
- Once established, tendinosis cell/function appears to be recalcitrant

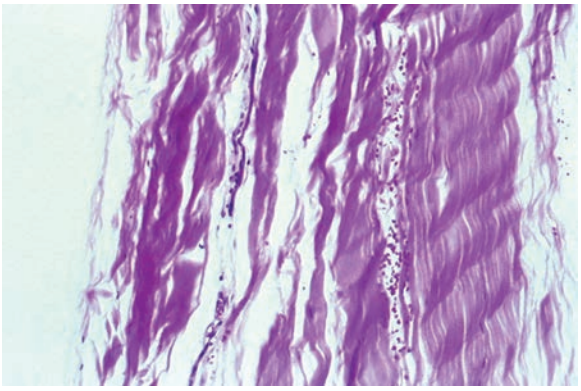

FIGURE 29-1. Normal tendon histology.

- Understimulation theory
  - Because of overloading there is a yet to be defined disruption of normal mechanotransduction by tenocyte.
  - Unable to detect tensile loads, the tenocyte starts to function more and more like a tendinosis cell, which does not support normal tendon matrix.
  - With lose of support of normal tenocyte and catabolic signals from the tendinosis cell, the matrix degenerates.

Classic Pathological Findings

- Normal tendon (Figure 29-1)
  - Tightly packed collagen fibers in longitudinal alignment
  - Slight waving pattern
  - Difficult to see spindle-shaped tenocytes
  - No discernible ground substance
- Tendinosis lesion (Figure 29-2)
  - Disorganized /fragmented/widely spread collagen
  - Mucoid ground substance
  - Sparse spindle shaped tenocytes
  - Hypercellularity
  - Round plump cells
  - Increased vascularity
  - Increased nerve filaments

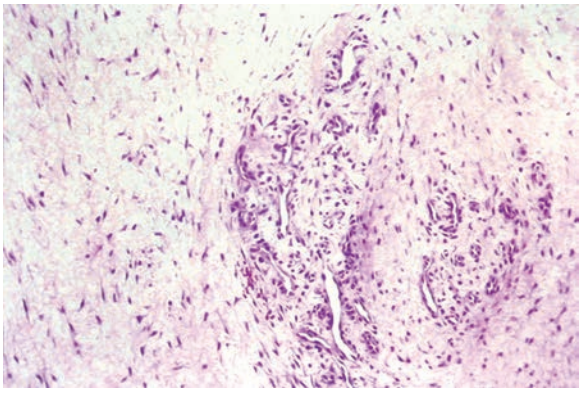

FIGURE 29-2. Tendinosis lesion histology.

Clinical Presentation

History

- Typically insidious onset of symptoms
- Patient localizes pain to inferior pole of patella
- Pain is typically increased with loading of the patella tendon
- Clinical classification of severity
  - Type 1: Sore after activity, but does not notice pain while playing
  - Type 2: Pain with activity, but not enough to affect play
  - Type 3: Pain impairs athlete's ability to train and perform.

Physical Examination

Abnormal Findings

- Tenderness of proximal patella tendon at the inferior pole of the patella
- May have some mild swelling or fullness in the area
- Pain on significant active quadriceps loading of tendon

Pertinent Normal Findings

- No effusion
- Ligaments stable
- No joint line tenderness
- Patella tracking is symmetrical
- Full range of motion
- No erythema or warmth to touch

Imaging

- Ultrasound will reveal an anechoic area
- MRI (Figures 29-3 and 29-4)
  - Area most often involved is proximal, posterior tendon in mid/medial portion or tendon

FIGURE 29-3. Sagittal MRI image of normal patella tendon.

FIGURE 29-4. Sagittal MRI image of patella tendinosis.

- Tendon is thickened
- Increased signal within the thickened portion of tendon

Differential Diagnosis

- Patella-femoral pain syndrome
  - Pain is typically described in more generalized fashion about anterior knee
  - There is no point tenderness at inferior pole of patella
  - May not have history of high volume of ballistic quadriceps contractions
- Patella-femoral chondrosis
  - Likely to have patella-femoral crepitus
  - May have mechanical symptoms of catching, clicking or locking
  - Imaging (x-ray/MRI) likely to demonstrate chondral erosions
  - Does not have point tenderness at inferior pole of patella
- Osgood Schlatter's disease
  - Occurs during the adolescent growth spurt. Patella tendinosis is rare in this age group.
  - Point of maximal tenderness is at the distal patella tendon insertion, as opposed to the proximal patella tendon origin in tendinosis.
  - Typically has prominence and tenderness over tibial tubercle.

Treatment

Nonoperative Management

- All of the following have been reported in the literature as treatment options for "chronic tendinitis" or tendinosis.
- Most have been reported to have 80% to 95% success rates.
- Very few, if any, have supportive high-quality controlled studies.
  - Rest
  - Diathermy
  - Deep friction massage
  - Extracorporal shock wave
  - Electric stimulation
  - Ultrasound
  - Magnets
  - Hyperbaric oxygen
  - Free radical scavengers
  - Sclerotherapy
  - Platelet-rich plasma (PRP) injection
  - Corticosteroids
  - Needling
  - Autologous blood injection
  - Nitric oxide
  - Eccentric exercise
  - Prolotherapy
  - Unloading devices
  - Pulsed electromagnetic fields
  - Acupuncture
  - NSAIDs (nonsteroidal antiinflammatory drugs)
  - DMSO (dimethylsulfoxide)
  - Cold laser
  - Radiofrequency ablation
  - Matrix metalloproteinase inhibitors
  - Stem cell injection
- A summary of several of the more common nonoperative treatments follows:
- Rest
  - Has been shown to be effective in acute overuse situation
  - Has not been shown to be effective in established tendinosis lesions
- NSAIDs/corticosteroids
  - May be of benefit in acute injury, if used for only a short period
  - Have not been shown to be effective in resolving established tendinosis
  - High or prolonged use may impair tendon healing
- Nitric oxide
  - Lab studies have shown some beneficial effects on tendon healing
  - Clinical studies mixed
  - Need further controlled trials and assessment of optimal dosing protocol
- Extracorporeal shock wave therapy (ECSW)
  - Conflicting evidence of clinical efficacy
  - Need more controlled trials and evaluation of optimal treatment protocols
- Platelet-rich plasma
  - Basic science studies have demonstrated beneficial effects on tendon healing in lab
  - Clinical studies mostly poorly controlled and mixed in results
  - Strongest evidence of clinical efficacy is for lateral epicondylar lesions
- Matrix metalloproteinase (MMP) inhibitors
  - Work by inhibiting catabolic effects of matrix metalloproteases
  - Some initial encouraging clinical results

  - Need further studies on efficacy and optimal treatment protocols
- Sclerotherapy
  - Aims to sclerose blood vessels of tendinosis lesion, often using ultrasound guidance
  - Some evidence of efficacy in producing pain relief
    - May be related to ablation of neurofilaments accompanying blood vessels
  - Has not been shown to reverse tendinosis pathology
- Eccentric exercises
  - Strongest evidence of efficacy in treating tendinosis
  - Best studied for Achilles lesions
  - Continuing to establish optimal treatment protocols

Guidelines for Choosing Among Nonoperative Treatments

- No good evidence that rest, corticosteroids, or NSAIDs are likely to provide lasting relief of an established patella tendinosis lesion.
- Eccentric exercises have the strongest level of evidence of clinical efficacy.
- ECSW, nitric oxide, sclerotherapy, and PRP have encouraging evidence, but further studies are needed.
- MMP inhibitors and stem cells are early in the evaluation process.

Surgical Indications

- Surgery is indicated when
  - There is a well-defined and well-established lesion.
  - Pain is significantly impairing the desired activity level.
  - Nonoperative measures have failed.
  - The patient understands expected outcomes and risks.

Aspects of History, Demographics, or Exam Findings That Affect Choice of Treatment

- Factors favoring operative treatment include
  - Longstanding lesion
  - High level of pain/disability
  - Well-established and well-defined lesion on MRI
  - Failure of nonoperative treatments
- Factors favoring nonoperative treatment
  - Recent onset
  - Poorly delineated on MRI
  - Lower levels of pain/disability

Aspects of Clinical Decision Making When Surgery Is Indicated

- The patient decides to proceed with surgery after understanding risks and expected outcomes of surgical treatment.
- Decision regarding timing of surgery
  - Patient expectations
  - Schedule and priority of competitions and training regimens
- Should an arthroscopy also be performed?
- Should excision of bone from the inferior patella be included in the procedure?
- Should a biological adjuvant treatment be added?
  - Stem cells, platelet rich plasma, etc.?

Evidence

Alfredson H, Pietila T, Jonsson P, et al: Heavy-load eccentric calf muscle training for the treatment of chronic Achilles tendinosis. *Am J Sports Med* 26:360–366, 1998.

This study provides evidence of the efficacy of eccentric exercise in treating tendinosis lesions. (Level IV evidence)

This study, a randomized and controlled trial, did not demonstrate a benefit of topical glyceryl trinitrate patches in tendinopathy. (Level I evidence)

Magnussen R, Dunn W, Thomson A: Nonoperative treatment of midportion Achilles tendinopathy: A systematic review. *Clin J Sport Med* 19(1):54–64, 2009.

This paper provides a review of the level of evidence of various nonoperative treatments of tendinosis of the Achilles. (Level IV evidence)

Orchard J, Massey A, Brown R, et al: Successful management of tendinopathy with injections of the MMP-inhibitor aprotinin. *Clin Orthop Relat Res* 466(7):1625–1632, 2008.

This study is one of the first to report positive results with treating tendinosis with an MMP inhibitor. (Level IV evidence)

Paoloni J, Appleyard R, Nelson J Murrell G: Topical glyceryl trinitrate treatment of chronic noninsertional Achilles tendinopathy. *JBJS Am* 86:916–922, 2004.

This study demonstrated a beneficial effect of nitric oxide on tendinosis(Level II evidence)

Popp J, Yu J, Kaeding C: Recalcitrant patellar tendonitis. Magnetic resonance imaging, histologic evaluation, and surgical treatment. *Am J Sports Med* 25:218–222, 1997.

This study provides an over view of the MR imaging, histologic appearance and surgical treatment of patella tendinosis. (Level IV evidence)

Schyber T, Weidler C, Lerch K, et al.: Achilles tendinosis is associated with sprouting of substance P positive nerve fibres. *Ann Rheum Dis* 64:1083–1086, 2005.

This study is one of several studies that document the presence of substance P and new nerve filament growth in tendinosis lesions (Level IV evidence)

Van Leeuwen M, Zwerver J, Van den Akker-Scheek I: Extracorporeal shockwave therapy for patellar tendinopathy: A review of the literature. *Br J sports Med* 2008 [epub ahead of print].

This paper provides an overview of the literature regarding the efficacy of ECSW as treatment of tendinosis. (Level V evidence)

Multiple Choice Questions

QUESTION 1. Tendinosis is a chronic overuse condition of tendon that is characterized by

A. chronic inflammation with high PGE levels.
B. decreased number and size of cells.
C. decreased vascularity and innervation.
D. increased number of abnormal cells.

QUESTION 2. The nonoperative treatment of tendinosis with the least amount of evidence of efficacy is

A. rest and NSAIDs.
B. sclerotherapy.
C. shockwave therapy.
D. eccentric exercises.

Answer Key

QUESTION 1. Correct answer: **D** (see Classic Pathological Findings)

QUESTION 2. Correct answer: **A** (see Nonoperative treatments)

NONOPERATIVE REHABILITATION OF PATELLAR TENDINOPATHY

John DeWitt, PT, DPT, SCS, ATC, and Christopher C. Kaeding, MD

GUIDING PRINCIPLES OF NONOPERATIVE REHABILITATION

- Identify intrinsic and external risk factors for patellar tendinopathy.
- Evaluate efficacious nonoperative treatment interventions.
- Discuss appropriate return to sport criteria to prevent recurrence.
- Pain
  - Progress eccentrics if less than 5/10 pain.
  - Progress all other interventions if pain-free only.

Phase I (weeks 0 to 2)

Protection

- No running or jumping
- Can do non-bounding exercise (elliptical, bike, swimming) if pain free to maintain cardiopulmonary endurance.

Management of Pain and Swelling

- Ice massage

Techniques for Progressive Increase in Range of Motion

- Five-minute bike warmup
- Lumbosacral mobility (i.e., cat/camel exercise)
- Hip flexor and quadriceps flexibility (before and after activity)
  - Assisted: Prone with opposite hip flexion to isolate soft tissue
  - Self: Use belt or stand
- Patellar tendon mobility (before activity)
  - Instrument assisted soft tissue mobilization[1]
  - Cross-friction mobilization

Neuromuscular Dynamic Stability Exercises

- Activation exercise
  - Gluteal activation (Figure 29-5)
    - Bilateral activation
    - Reciprocal activation (frog leg-position)

FIGURE 29-5. Frog-leg gluteus activation.

FIGURE 29-6. A,B, Functional rolling to activate lumbosacral stabilizers.

- Transversus abdominis
  - Bilateral activation
- Functional roll patterns (Figure 29-6)
- Posterior weight shifts against wall

- Eccentrics (assist with concentric phase) (Figure 29-7)
  - Squats on decline board, partial weight bearing (Shuttle, Total Gym)
  - Progress from partial to full weight-bearing resistance able to complete if <5/10 pain
  - Three sets × 15 repetitions (reps)
- Stability exercise with correct mechanics (i.e., no pelvic drop, knee valgus, or excessive anterior weight)
  - Strengthening
    - Balance on stable surface
    - Side lying abduction/clam shell series (Figure 29-8)
    - Hip hike on single leg

TIMELINE 29-1: **Nonoperative Rehabilitation of Patellar Tendinopathy**

PHASE I (weeks 0 to 2)

- 5-min bike warmup
- Lumbosacral mobility (i.e., cat/camel exercise)
- Hip flexor and quadriceps flexibility (before and after activity)
  - Assisted: Prone with opposite hip flexion to isolate soft tissue
  - Self: use belt or stand
- Patellar tendon mobility (before activity)
  - Instrument assisted soft tissue mobilization
  - Cross-friction mobilization
- Neuromuscular interventions
  - Activation exercise
    - Gluteal activation
      - Bilateral activation
      - Reciprocal activation (frog leg-position)
    - Transversus abdominis
      - Bilateral activation
    - Functional roll patterns
    - Posterior weight shifts against wall
  - Eccentrics (assist with concentric phase)
    - Squats on decline board, partial weight bearing (Shuttle, Total Gym)
    - Begin at 30% and progress resistance if <5/10 pain
    - Three sets × 15 repetitions
  - Stability exercise (i.e., no pelvic drop, knee valgus, or excessive anterior weight)
    - Strengthening
      - Balance on stable surface
      - Side-lying abduction/clamshell series

PHASE II (weeks 2 to 4)

- Mobility
  - Lumbosacral mobility (i.e., cat/camel exercise)
  - Hip flexor and quadriceps flexibility (before and after activity)
    - Assisted: prone with hip in flexion to isolate soft tissue
    - Self: progress to half-kneel with knee flexed
  - Patellar tendon mobility (before activity)
    - Instrument assisted soft tissue mobilization
    - Cross-friction mobilization
- Neuromuscular interventions
  - Activation exercise
    - Gluteal activation
      - Add tall knee and half-kneel position
  - Transverse abdominis
    - Add UE/LE movements. use feedback device
    - Functional roll patterns
  - Eccentrics (assist with concentric phase)
    - Squats on decline board - partial weight bearing (Shuttle, Total Gym)
    - Progress 50%–75% resistance if <5/10 pain
    - Three sets × 15 repetitions
  - Stability exercise (i.e. no pelvic drop, knee valgus or excessive anterior weight)
    - Posterior weight shifts (if needed)
    - Lumbopelvic stability exercise
      - Double leg support
    - Strengthening
      - Advance balance to unstable surface/add perturbations
      - Single leg squat (Romanian deadlift)
      - Advance side-lying abduction/clamshell series
      - Hip hike on single leg with unstable surface
    - Bounding (appropriate landing mechanics)
      - Begin jump squats and jogging on Shuttle

FIGURE 29-7. Partial weight-bearing decline eccentrics on Shuttle.

Milestones for Progression to the Next Phase

- Appropriate gluteal maximus, transversus abdominis, and multifidi activation patterns. Tactile cueing, observation and external feedback devices can be used to ensure appropriate activation[2] (i.e., no knee flexion with prone leg extension to assess appropriate gluteal activation).
- No compensatory movements with stability exercise (i.e., no pelvic drop, knee valgus or excessive anterior weight).
- Complete weight bearing eccentrics with less than 5/10 pain.

Phase II (weeks 2 to 4)

Protection

- Begin jogging, jumping on Shuttle.
- No full weight-bearing running

Management of Pain and Swelling

- Ice massage

Techniques for Progressive Increase in Range of Motion

- Lumbosacral mobility (i.e., cat/camel exercise)
- Hip flexor and quadriceps flexibility (before and after activity)
  - Assisted: Prone with hip in flexion to isolate soft tissue
  - Self: Progress to half-kneel with knee flexed (Figure 29-9)
- Patellar tendon mobility (before activity)
  - Instrument-assisted soft tissue mobilization (Figure 29-10)
  - Cross-friction mobilization

TIMELINE 29-1: Nonoperative Rehabilitation of Patellar Tendinopathy (Continued)

PHASE III (weeks 4 to 8)

- Protection: begin FBW jogging, alternate with non-bounding intervention
- Mobility
  - Dynamic warmup
    - Inchworms, Spidermans, walking lunges (10 repetitions each)
    - Patellar tendon mobility (before activity if needed)
  - Instrument-assisted soft tissue mobilization
    - Cross-friction mobilization
- Neuromuscular interventions
  - Activation exercise
    - Progress functional roll patterns
  - Eccentrics (lowering phase only phase)
    - Squats on decline board, FWB
      - Progress 5-10 lb/week beginning at 10% BW if <5/10
    - Begin stepdowns
    - 4″ step at 4 weeks
    - 6″ step at 6 weeks
    - Three sets × 15 repetitions
  - Stability exercise (i.e., no pelvic drop, knee valgus, or excessive anterior weight)
  - Advance lumbopelvic stability exercise
    - Single leg support
  - Strengthening
    - Advance balance on unstable surface/add perturbations
    - Single leg squat (Romanian deadlift)
      - Add resistance, unstable surface
    - Split lunge with chop and lift
    - Resisted band walking
    - Step-up 12 onto plyo box
  - Bounding (appropriate landing mechanics)
    - Begin double leg jumping on Shuttle or Total Gym
      - Three sets × 15 repetitions
  - Initiate walk jog progression

PHASE IV (weeks 8 to 12)

- Protection
  - Progress jog progression, alternate with nonbounding exercise
  - Begin sports-specific activity if nor worsening of symptoms
- Treatment for pain/swelling: ice massage is needed
- Mobility
  - Dynamic warmup
    - Inchworms, Spidermans, walking lunges, 10 repetitions each
  - Patellar tendon mobility (before activity if needed)
  - Instrument-assisted soft tissue mobilization
  - Cross-friction mobilization
  - Neuromuscular interventions
    - Activation exercise
  - Progress functional roll patterns
    - Eccentrics (lowering phase only phase)
    - Squats on decline board, FWB
      - Progress 5-10 lb/week if <5/10
      - Three sets × 15 repetitions
    - Step downs
      - 8″ step three sets × 15 repetitions
      - Stability exercise (i.e., no pelvic drop, knee valgus or excessive anterior weight)
    - Strengthening
      - Step-up 24 inch ploy box—go onto toe
      - Progress all LE strengthening exercise
    - Bounding (appropriate landing mechanics)
      - Single leg jumping on Shuttle or Total Gym
        - Three sets × 15 repetitions
      - Begin double leg hop down on 4″
        - Progress to 6″ to 12″ step as form improves
        - Three sets × 15 repetitions
    - Sports-specific drills
    - Progress walk jog progression

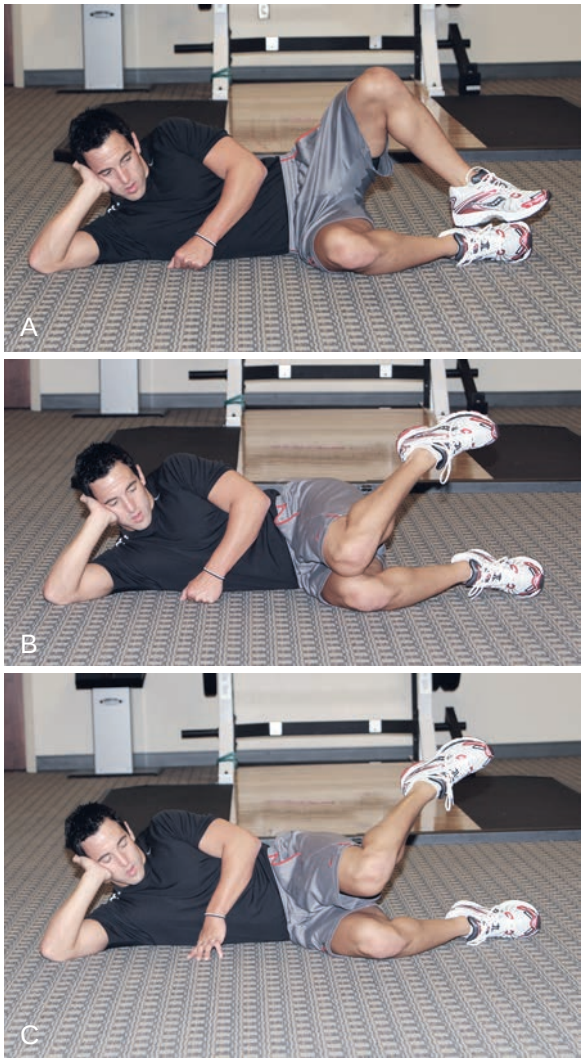

FIGURE 29-8. A–C, Clamshell series.

FIGURE 29-9. Prone hip flexor stretching.

FIGURE 29-10. Instrument-assisted cross-friction mobilization.

Neuromuscular Dynamic Stability Exercises

- Activation exercise
  - Gluteal activation
  - Progress to functional positions (i.e., tall kneel [Figure 29-11] and half-kneel positions)
  - Transverse abdominis/multifidi
    - Add UE/LE movements with pelvic stability exercise. Use internal (isometric cueing) and external (dynamic stabilizer, electronic) feedback device.
  - Functional roll patterns (see Figure 29-6)
  - Eccentrics (assist with concentric phase)
    - Squats on decline board—partial weight bearing less than 5/10 pain (Shuttle, Total Gym)
    - Progress 50% to 75% resistance if less than 5/10 pain
    - Three sets × 15 repetitions

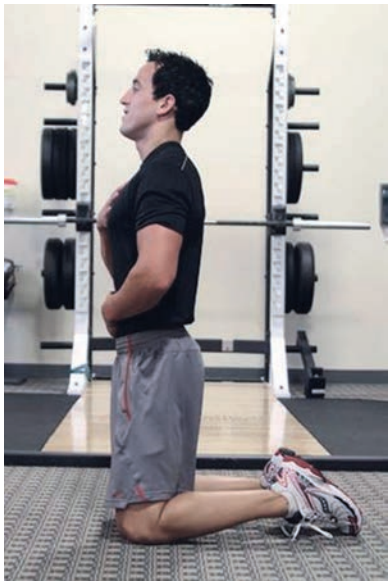

FIGURE 29-11. Tall kneel.

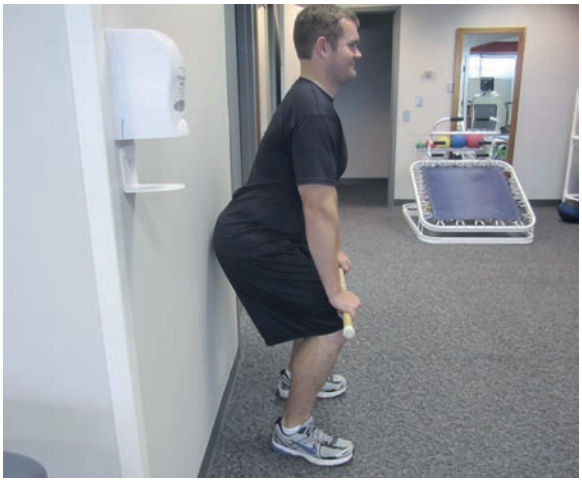

FIGURE 29-12. Posterior weight shifts.

- Stability exercise (avoid pelvic drop, hip add, knee valgus, or excessive anterior weight)
- Posterior weight shifts (if needed) (Figure 29-12)
- Lumbopelvic stability exercise
  - Advance to unsupported double leg work (three sets 10 to 15 repetitions)
  - Planks (two to three sets × 60 seconds)
  - Chop/lift activities (three sets 10 to 15 repetitions)
  - Strengthening
  - Add unstable surface/foam to exercise
- Bounding (avoid pelvic drop, knee valgus, or excessive anterior weight) (Figure 29-13)
  - Jogging on Shuttle (1 to 2 minutes × 5 to 10 sets with no exacerbation of symptoms)

Milestones for Progression to the Next Phase

- Appropriate gluteal maximus, transversus abdominis and multifidi activation patterns. Tactile cueing, observation, and external feedback devices can be used to ensure appropriate activation[2] (i.e., no knee flexion with prone leg extension to assess appropriate gluteal activation).
- No compensatory movements with stability exercise (i.e., no pelvic drop, knee valgus, or excessive anterior weight)
- Complete weight-bearing eccentrics with less than 5/10 pain.

Phase III (weeks 4 to 8)

Protection

- Begin FBW jogging.
- May utilize nonbounding exercise 20 to 30 minutes if unable to complete jogging (bike, elliptical, swimming, etc.).

Management of Pain and Swelling

- Ice massage

Techniques for Progressive Increase in Range of Motion

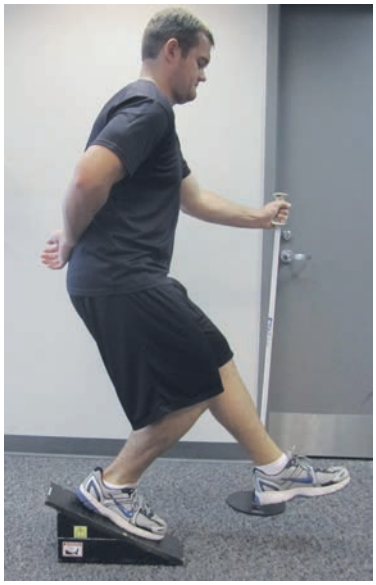
- Dynamic warmup
  - Inchworms, Spidermans, walking lunge (10 repetitions each) (Figure 29-14)
- Patellar tendon mobility (before activity if needed)
  - Instrument assisted soft tissue mobilization
  - Cross-friction mobilization

Neuromuscular Dynamic Stability Exercises

- Activation exercise
  - Progress functional roll patterns
- Eccentrics (lowering phase only phase)
  - Squats on decline board, FWB (Figure 29-15)
    - Progress 5 to 10 lb/week if less than 5/10
  - Three sets × 15 repetitions

FIGURE 29-13. A,B, Bounding exercises.

FIGURE 29-14. Dynamic warmups. **A,** Inchworm. **B,C,** Spiderman. **D,** Walking lunge.



.**FIGURE 29-15.** Full weight-bearing squats on decline board

FIGURE 29-16. Step downs.

- Begin step downs (Figure 29-16)
  - 4" step at 4 weeks
  - 6" step at 6 weeks
  - Three sets × 15 repetitions
- Stability exercise (Advance with good mechanics: no pelvic drop, hip add, knee valgus or excessive anterior weight)
  - Lumbopelvic stability exercise
  - Advance from double to single leg support if appropriate mechanics are maintained.
- Strengthening
  - Advance balance on unstable surface/add perturbations (three sets 10 to 15 repetitions)
  - Single leg squat
    - Add resistance, unstable surface (three sets 10 to 15 repetitions)
  - Split lunge with chop and lift (three sets 10 to 15 repetitions)
  - Resisted band walking (three sets 10 to 15 repetitions)
  - Step-up 12 onto ploy box (three sets 10 to 15 repetitions)
- Bounding (appropriate landing mechanics)
  - Begin double leg jumping on Shuttle or Total Gym
    - Three sets × 15 repetitions
- Initiate walk/jog progression
  - The Walk/Jog program (Table 29-2) is to be performed in a step-by-step fashion. The program can be varied to meet individual situations. The patient should be progressing at a minimum of 1 day on, 1 day off basis with increased time off between bouts given on individual basis.
  - If painful, stop jogging. Once pain-free restart at the previous level to avoid re-aggravation.

Phase IV (weeks 8 to 12)

Protection

- Only advance with jogging and sports specific-activity (speed and agility drills) if pain free.
- Eccentrics can be continued if less than 5/10 pain.

Management of Pain and Swelling

- Ice massage is needed

Techniques for Progressive Increase in Range of Motion

- Dynamic warmup
  - Inch worms, Spidermans, walking lunge
    - Ten repetitions each (see Figure 29-14)
- Patellar tendon mobility (before activity if needed)
  - Instrument assisted soft tissue mobilization
  - Cross-friction mobilization

Neuromuscular Dynamic Stability Exercises

- Activation exercise
  - Progress functional roll patterns (see Figure 29-6)
- Eccentrics (lowering phase only phase)
  - Squats on decline board, FWB
    - Progress 5 to 10 lb/week if less than 5/10
    - Three sets × 15 repetitions
  - Step downs
    - 8" step
    - Three sets × 15 repetitions
- Stability exercise (i.e., no pelvic drop, hip add, knee valgus, or excessive anterior weight)
  - Strengthening
    - Step-up 24-inch plyo box—go onto toe
    - Progress all LE strengthening exercise
    - Bounding (ensure good mechanics with symmetrical landing and avoid jump/hop down off plyo boxes)
    - Single leg jumping on Shuttle or Total Gym
    - Three sets × 15 repetitions
    - Begin double leg hop down on 4"
    - Progress to 6" to 12" step as form improves
    - Three sets × 15 repetitions
    - Sports-specific drills (multidirectional, agility and speed activities such as dot and ladder drills) (Figure 29-17)
    - Progress walk/jog progression (Table 29-1)

Milestones for Progression to Advanced Sport-Specific Training and Conditioning

- Demonstrate no greater than Blazina's Phase I criteria.
- Hip flexor/quadriceps flexibility symmetry
- No compensatory movements with functional testing (i.e., no pelvic drop, hip add, knee valgus, or excessive anterior weight)
- Victorian Institute of Sport Assessment scale—Patellar tendinopathy (VISA-P) score of 60 or better

FIGURE 29-17. A–C, Sports-specific drills (dot and ladder drills).

Criteria for Abandoning Nonoperative Treatment and Proceeding to Surgery or More Intensive Intervention

- Lack of progression or exacerbation with rehabilitation program
- Blazina Phase III greater than 3 to 4 months without change (Table 29-2)
- Unable to change from Kennedy's Phase IV criteria (see Table 29-1)

Tips and Guidelines for Transitioning to Performance Enhancement

- Athletes need to be reminded on appropriate warm-up and corrective mobility techniques before sports-specific training to help correct and prevent compensatory movement patterns.
- Sports-specific training can be progressed only if pain is felt after activity; however, no symptoms should be noted before or during activity.

Table 29-1 The Walk-Jog Program

	Warm-up	Jog	Walk	Repetitions	Cool Down
Step I	5 min	1 min	3 min	5	5 min
Step II	5 min	1 min	2 min	7	5 min
Step III	5 min	2 min	1 min	7	5 min
Step IV	5 min	3 min	1 min	5	5 min
Step V	5 min	5 min	1 min	4	5 min
Step VI	5 min	20 min continuous		1	5 min
Step VII	5 min	Jog every other day reaching 30 min and increase pace			5 min

Adapted from OSU Sports Medicine walk/jog progression (www.sportsmedicine.osu.edu).

Table 29-2 A Guide to Progression and Criteria to Modify Sport

	Blazina's Tendinopathy Stages	Kennedy's Tendinopathy Stages
Phase I	No significant pain during athletic activity, but discomfort afterward	Pain after activity
Phase II	Pain before and after activity, but not enough during activity to alter their performance	Pain at the beginning and after activity
Phase III	Pain is severe enough that performance is affected and the athlete's volume of activity has to be modified	Pain at the beginning, during, and after activity, but performance is no affected
Phase IV	Tendon rupture	Pain at the beginning, during, and after activity, and the performance is affected

For the purposes of these guidelines, Blazina's classification is used.
Adapted from Rutland.

Performance Enhancement and Beyond Rehabilitation: Training/ Trainer and Optimization of Athletic Performance

- It is important to recognize intrinsic and extrinsic risk factors of patellar tendinopathy to prevent re-injury.
- The following should be considered when designing a performance enhancement program:
  - Intrinsic factors
    - Thigh weakness
    - Thigh hypomobility
    - Ankle DF hypomobility
    - Higher waist to hip ratio
  - Extrinsic factors
    - Sex (male)
    - Competition level (elite)
    - Sport (volleyball and basketball)
    - Hard surface
    - Lifting weights
    - Higher jumping performance

Specific Criteria for Return to Sports Participation: Tests and Measurements

- Demonstrate no greater than Blazina's Phase I criteria.
- Less than 10% side to side difference with isokinetic quadriceps strength
- Less than 10% side to side difference with functional testing (single leg, triple, crossover hopping)
- Restore symmetrical hip flexor/quadriceps and ankle DF joint mobility and muscle-tendon flexibility
- No compensatory movements with functional testing (hopping, FMS, single leg squat, etc.)
- VISA-P score of 70 or greater

Evidence

Alfredson H, Pietila T, Jonsson P, et al: Heavy-load eccentric calf muscle training for the treatment of chronic Achilles tendinosis. *Amer J Sports Med* 26(3):360–366, 1998.

Prospective study of 15 recreational athletes with average age of 44.3 ± 7.0 years of age treated with 12-week eccentric training program. At 6 months all 15 patients returned to preinjury running levels. A comparison group of 15 athletes treated with conventional therapy (no eccentrics) showed no improvement. (Level II evidence)

Gaida JE, Cook JL, Bass SL, et al: Are unilateral and bilateral patellar tendinopathy distinguished by difference in anthropometry, body composition, or muscle strength in elite female basketball players. *Br J Sports Med* 38:581–585, 2004.

This cross-sectional design studied 39 elite female basketball players to determine risk factors associated with unilateral and bilateral patellar tendinopathy. Unilateral tendinopathy has identifiable risk factors, whereas bilateral did not include body composition and eccentric strength. (Level III evidence)

Van der Worp H, van Ark M, Zwerver J, et al: Risk factors for patellar tendinopathy in basketball and volleyball players: A cross-sectional study. *Scand J Med Sci Sports* 1–8, 2011.

Cross-sectional study of 53 Dutch basketball and volleyball players ranging from 18 to 35 years of age. Risk factors for patellar tendinopathy included being male, age, playing at an elite level, and playing volleyball. Within the volleyball subset, being an outside hitter and middle blocker increased risk of patellar tendinopathy. (Level III evidence)

Young MA, Cook JL, Purdam ZS, et al: Eccentric decline squat protocol offers superior results at 12 months compared with traditional eccentric protocol for patellar tendinopathy in volleyball players. *Br J Sports Med* 39:102–105, 2005.

Prospective randomized control design of 17 elite volleyball players with imaging-confirmed patellar tendinopathy. Players were randomly designed to a 12-week eccentric or step up protocol and monitored and each showed significant improvement from baseline at the 12-week and 12-month time period using VISA-P and VAS measures. There was a greater likelihood of clinical improvement in the decline group at 12 weeks, suggesting great clinical gains throughout rehabilitation. VAS scores did not differ between groups at 12 months. (Level I evidence)

Multiple Choice Questions

QUESTION 1. Which extrinsic risk factor is a potential contributor to patellar tendinopathy?

A. Female gender
B. Ankle dorsiflexion hypomobility
C. Sport (volleyball and basketball)
D. Quadriceps weakness

QUESTION 2. Which bonding exercise should be avoided to limit deleterious stress through the patellar tendon?

A. Hop/jump done from elevated surface
B. Agility drills
C. Broad jumping
D. Hop/jump ups onto elevated surface

QUESTION 3. What pain response recommendations should be used when performing eccentric exercise to treat patellar tendinopathy?

A. Pain-free only
B. Less than 3/10
C. Less than 5/10
D. Greater than 7/10

QUESTION 4. Which criteria should be used before returning to sport?

A. 10% limb symmetry index with hop testing
B. 25% quadriceps difference with isokinetic strength testing
C. Moderate compensation with functional movements
D. Less than 5/10 with sports-specific tasks

QUESTION 5. Which exercise provides the most stress to facilitate soft tissue healing for a patient suffering patellar tendinopathy?

A. Single leg squat on a flat surface
B. Single leg squat on an incline surface
C. Single leg squat on decline surface
D. Single leg squat on an unstable surface

Answer Key

QUESTION 1. Correct answer: **C** (see Guiding Principles of Nonoperative Rehabilitation box)

QUESTION 2. Correct answer: **D** (see Phase IV)

QUESTION 3. Correct answer: **C** (see Phase I)

QUESTION 4. Correct answer: **A** (see Phase IV).

QUESTION 5. Correct answer: **C** (see Phase I)

POSTOPERATIVE REHABILITATION AFTER PATELLAR TENDINOPATHY DEBRIDEMENT

John DeWitt, PT, DPT, SCS, ATC, and Christopher C. Kaeding, MD

Indications for Surgical Treatment

- Lack of progression or exacerbation with rehab program
- Blazina Grade III greater than 3 to 4 months without change (see Nonoperative Rehabilitation)
- Unable to change from Kennedy's Phase IV criteria (see Nonoperative Rehabilitation)

Brief Summary of Surgical Treatment

Major Surgical Steps

- Localize lesion on MRI
- Expose lesion via anterior tendon splitting approach
- Excise abnormal tissue
- Excise any inferior patella spurring
- Repair defect
- Perform multiple longitudinal tenotomies
- Close peritenon, subcutaneous tissue, and skin

Factors That May Affect Rehabilitation

- The size of the lesion and the subsequent extent of the excision may result in significant compromise of the patella tendon integrity. If tendon is significantly compromised (greater than 30%) the patient would require more and longer protection from loading and a longer time to recover and reconstitute full strength to minimize risk of complete tendon rupture postoperatively.

Other Surgical Techniques and Options

- May consider adding platelet-rich plasma to the defect at the end of the procedure. This would not affect postoperative rehabilitation.

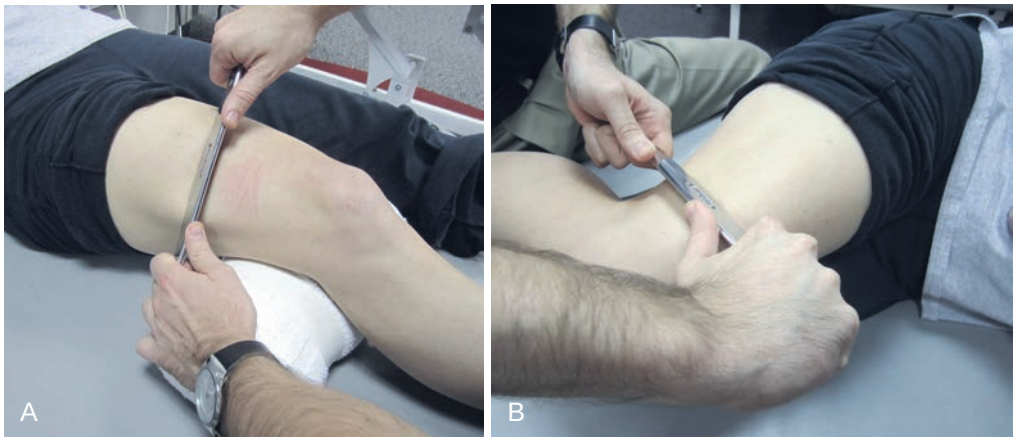

FIGURE 29-18. ITB (**A**) and quad ST (**B**) mobilizations.

GUIDING PRINCIPLES OF POSTOPERATIVE REHABILITATION

- Understand surgical procedure and soft tissue healing parameters.
- Protect surgical site and ensure soft tissue healing.
- Correct proximal stability and mobility impairments.
- Avoid exercise that place excessive load on the patellar tendon (leg extension, squatting beyond 90°, excessive jumping).
- Phases are both time- and criterion-based.

Phase I (days 0 to 14)[1]: Immediate Postoperative Period

Clinical Pearl

Early mobilization in a protected range is essential to facilitate soft tissue healing and prevent scarring. Non-resistance biking can be progressed 10–20 min/day after 14 days.

Goals

- Normalize gait without brace or crutches
- Knee ROM 0° to 90°
- Symmetrical quad contraction with heel lift
- No exacerbation of symptoms with ADLs

Protection

- Week 1: Hinged brace locked in extension WBAT with crutches.
- Week 2: Brace can be unlocked to 90° if good quad activation and no pain with ADLs. Brace can be removed once gait is normalized by day 14 if good quad control.

[1]Prehabilitation, if appropriate, is described in the Nonoperative Rehabilitation section of this chapter.

Management of Pain and Swelling

- Ice, NSAIDs, modalities

Techniques for Progressive Increase in Range of Motion

- Increase ROM:
  - Week 1: 0° to 60°
  - Week 2: 0° to 90°

Manual Therapy Techniques

- Gentle patellar mobilization (grades I to II).

Soft Tissue Techniques

- Quad/ITB soft tissue mobilization after week 1 (Figure 29-18)

Stretching and Flexibility Techniques for the Musculotendinous Unit

- Mobility techniques for the musculotendinous unit; hamstring/ITB stretching
- AAROM knee flexion per preceding range restrictions

Other Therapeutic Exercises

- UE ergometry

Activation of Primary Muscles Involved in Injury Area or Surgical Structures

- Progress quad activation emphasizing heel off. Begin gluteal and transversus abdominis activation exercises (see Figure 29-5).

Open and Closed Kinetic Chain Exercises

- Hip abduction and extension straight leg raise with brace
- May discontinue brace at day 7 if good quad control (no extensor lag)

Milestones for Progression to the Next Phase

- No pain at 90° degrees of flexion
- Normalization of gait

- Good quad control with exercise
- No exacerbation with ADLs

Phase II (weeks 2 to 4 postoperatively)

Clinical Pearl

Activation of lumbopelvic stabilizers and gluteals are important to facilitate proximal stability, prevent distal compensatory motion (especially excessive anterior weight shift), and avoid excessive stress through the patellar tendon.

Goals

- 120° knee flexion without pain
- No compensatory movement patterns with weight bearing exercise
- No pain after activity or physical therapy

Protection

- Discontinue brace and crutches if no gait deviation and good quad control.

Management of Pain and Swelling

- Ice, modalities if needed for pain
- Vasocompression device if needed for swelling

Techniques for Progressive Increase in Range of Motion

- Progress knee flexion ROM per tolerance.

Manual Therapy Techniques

- Continue patellar mobilizations (mobs) if quad set is painful

Soft Tissue Techniques

- Continue ITB and quad/hip flexor mobilizations

Stretching and Flexibility Techniques for the Musculotendinous Unit

- Begin pain-free quad/hip flexor stretches; continue ITB and hamstring stretches.

Other Therapeutic Exercises

- Increase biking to 20 minutes without resistance.
- Deep water jogging
- Swimming with pull buoy
- Progress neuromuscular lumbopelvic stability program
- Begin UE strength training in seated position.

Activation of Primary Muscles Involved in Injury Area or Surgical Structures

- Gluteus maximus activation progression (frog-leg progress, standing). Avoid kneeling positions.
- Teach posterior weight shifting in squat position (see Figure 29-12)
- Begin total body rolling activities (see Figure 29-6)

Sensorimotor Exercises

- Single leg balance
  - Progress from stable to unstable surface
  - Include opposite LE movements (touch toe, resistance band, etc.)

TIMELINE 29-2: **Postoperative Rehabilitation After Arthroscopic Patellar Tendon Debridement**

PHASE I (weeks 1 to 2)	PHASE II (weeks 2 to 6)
• Brace locked in extension WBAT • ROM: 0–60 week 1, 0–90 week 2 • PT modalities for pain control • Gentle patellar mobilizations • Gentle quad sets • ITB/quad soft tissue mobilization • Transversus abdominis and gluteus activation • Abduction SLR in brace	• D/C brace if good quad control and no pain with ADLs • PT modalities • ROM: 0°–120° and progress per tolerance • Biking without resistance/deep water jogging 10–20 minutes • Continue soft tissue and joint mobs as needed • Begin single-leg balance exercise • CKC partial weight bearing strengthening, progress to full weight bearing (emphasis on posterior weight shift and avoid going below 60°) • Progress to heel touch off 4″ step if good form • Heel/toe raise • OKC/CKC hip strengthening

Open and Closed Kinetic Chain Exercises

- OKC
  - Progress SLR in all directions
  - Initiate clamshell progression (see Figure 29-8)
- CKC
  - Partial weight-bearing squats (Shuttle, Total Gym, Ex)
  - Begin wall squat
  - Bridge progression
    - Double leg, marching, single leg
  - Progress to heel touch on 4" step if good form
  - Heel/toe raises

Milestones for Progression to the Next Phase

- No pain during or after activity and/or physical therapy
- Restore normal ROM.
- Restore quad strength to 4+/5.
- Restore hip abduction strength to 5/5.
- No compensatory movement with CKC activity

Phase III (weeks 6 to 12 postoperatively)

Clinical Pearl

Exercises should be progressed to increase neuromuscular balance and stability by adding unstable surfaces and/or single leg positions. Excessive strain to the patellar tendon should be avoided by correcting LE compensations (especially excessive anterior weight shift).

Goals

- Complete 20 heel touches on 6" to 8" step without compensation.
- Begin walk/jog progression without pain.
- Begin sport-specific and cutting drills without pain or compensation.
- Progress to strengthening and balance activities without exacerbation.

Management of Pain and Swelling

- Ice cup if needed for pain
- Compression stocking or knee sleeve may be used if needed to control swelling.

Techniques for Progressive Increase in Range of Motion

Soft Tissue Techniques

- Use roller to mobilize ITB and quads after warmup.

Stretching and Flexibility Techniques for the Musculotendinous Unit

- Advanced quad/hip flexor and ankle DF stretches should be performed before and after activity.

Other Therapeutic Exercises

- 10 to 20 minutes of biking with mild resistance
- Swimming
- Normal UE strength training can be resumed

Activation of Primary Muscles Involved in Injury Area or Surgical Structures

- Progress core stability and functional rolling

TIMELINE 29-2: **Nonoperative Rehabilitation of Long Head of Biceps Tendinitis/Tendinosis** (Continued)

PHASE III (weeks 6 to 12)	PHASE IV (weeks 12 to 16)

• PT modalities as needed
• Quad/hip flexor and ankle DF stretching
• Biking/elliptical (no stair climbing) 20–30 minutes
• Progress balance exercise, use unstable surface or rhythmic stabilization
• CKC strengthening using single leg and multidirectional/lateral positions
• Single leg squat
  • Avoid going below 60°
  • Avoid pelvic drop, knee valgus, and anterior weight shift compensation
• Begin jogging on shuttle
• Practice landing mechanics on even ground
• Begin walk/jog progression if the following criteria are met
• 20 single leg squats on 4" step with good form
• No gait asymmetries or pain with jogging
• No pain with PT or ADL activity
	• PT modalities if needed
	• Initiate dynamic warmup and self-stretching program
	• Progress CKC strengthening and balance in functional patterns (chop/lift)
	• Single leg squat
	  • 60° to 90°
	  • Avoid pelvic drop, knee valgus, and anterior weight shift compensation
	• Reverse leg press
	• Single leg jumping on shuttle/Total gym or in pool
	• Double and single leg jumping with good mechanics
	• Single leg hop ups onto step
	  • Begin with 4" and increase height until symmetrical with uninvolved leg
	  • Only progress if good mechanics
	• Advance jogging progression
	• Begin ladder and cutting/change of direction drills
	  • 50%–75% intensity (weeks 12–14)
	  • 75%–100% intensity (weeks 14–16)
	• May return to sport is the following criteria are met:
	  • Less than 10% quad difference with isokinetic testing
	  • Less than 10% difference limb symmetry index with SL hopping tests
	• No pain during or after bounding or sports-specific exercise

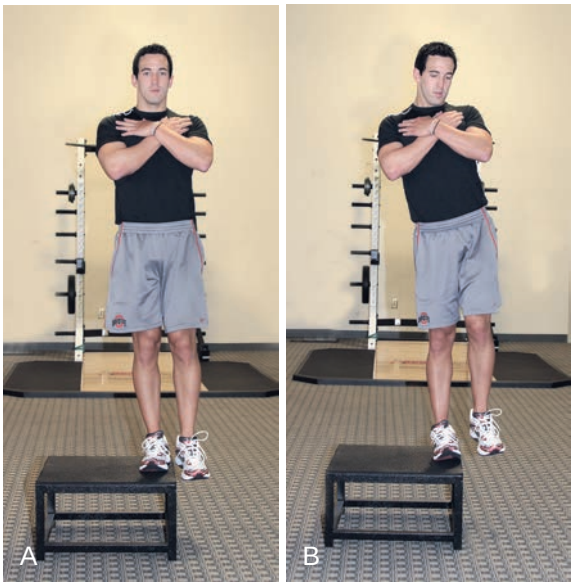

FIGURE 29-19. Hip hikes.

Sensorimotor Exercises

- Advance strengthening to single leg positions and use unstable surfaces

Open and Closed Kinetic Chain Exercises

- Heel touch beginning with 4" step (progress to 6" to 8")
- Single balance/strengthening
  - Hip hikes (Figure 29-19)
  - Romanian dead lifts (Figure 29-20)
  - Lower extremity clocks
- Step up and step downs (pain free and with good control) (Figure 29-21)
- Resisted lateral side-stepping

Techniques to Increase Muscle Strength, Power, and Endurance

- Advance endurance and strengthening exercise if good form and no pain during or after activity.

Neuromuscular Dynamic Stability Exercises

- Practice landing mechanics on even surface

FIGURE 29-20. Romanian dead lift.

FIGURE 29-21. Step up.

Plyometrics

- Begin partial weight bearing jogging on Shuttle or Total Gym.
- Criteria to begin jogging program
  - 20 single leg squats on 4" step with good form
  - No gait asymmetries or pain with jogging
  - No pain with PT or ADL activity

Milestones for Progression to the Next Phase

- No lower extremity compensation with strengthening exercise
- Symmetrical restoration of muscle length
- Restore normal strength
- No pain with walk-jog progression or cutting activity

Phase IV (weeks 12 to 16 postoperatively)

Clinical Pearl

Exercises to promote quad strength and flexibility should be advanced to include sports-specific and bounding components if no pain and good form. Exercise or activity causing compensatory movement patterns should be modified to correct motion.

Goals

- Less than 10% quad difference with isokinetic testing
- Less than 10% difference limb symmetry index with SL hopping tests
- No pain during or after bounding or sports-specific exercise
- No lower extremity compensatory movement patterns with activity and bounding activity

FIGURE 29-22. Split lunge with lift.

Management of Pain and Swelling

- Ice cup if needed for pain
- Knee sleeve if needed for swelling

Techniques for Progressive Increase in Range of Motion

- 5- to 10-minute warm up (light jog or bike) followed by dynamic warmup (see the following) before activity (see Figure 29-14).
  - 10 inchworms
  - 10 walking knee to chest stretches
  - 10 walking lunges (no excessive anterior weight shift)
  - 10 skipping bounds

Activation of Primary Muscles Involved in Injury Area or Surgical Structures

- Continue gluteus activation progression if needed.
- Continue rolling if unable to complete correctly.

Open and Closed Kinetic Chain Exercises

- Add unstable surface and/or rotational movements to strengthening program in previous phase
- Advance step-up/down height
- Chop/lifts in half-kneel or split lunge position (Figure 29-22)
- Slide board (Figure 29-23)
- Single leg squat 60° to 90° (Figure 29-24)
- Leg press and reverse leg press (Figure 29-25)

Clinical Pearl

Improving quadriceps strength and proximal stability are important to help prevent risk factors for reinjury.

Plyometrics

- Single leg jumping on shuttle/Total gym or in pool
- Double and single leg jumping with good mechanics
- Single leg hop ups onto step (14 weeks)
  - Begin with 4" and increase height until symmetrical with uninvolved leg
  - Only progress if good mechanics

Functional Exercises

- Begin ladder and cutting/change of direction drills (see Figure 29-13)
  - 50% to 75% intensity (12 to 14 weeks)
  - 75% to 100% intensity (14 to 16 weeks)
- Advance jogging activity (see Table 29-3)

Sport-Specific Exercises

- Begin sports-specific exercise
  - 50% to 75% intensity (12 to 14 weeks)
  - 75% to 100% intensity (14 to 16 weeks)

FIGURE 29-23. Slide board.

FIGURE 29-24. Single-leg deep squat (60° to 90°).

Milestones for Progression to the Next Phase

- May return to sport is the following criteria are met
  - Less than 10% quad difference with isokinetic testing
  - Less than 10% difference limb symmetry index with SL hopping tests
  - No pain during or after bounding or sports-specific exercise

Criteria for Return to Sport

General

- Less than 10% quad difference with isokinetic testing
- Less than 10% difference limb symmetry index with SL hopping tests
- Greater than 70 score on VISA-P questionnaire
- No pain during or after bounding or sports-specific exercise

Sport-Specific

- Volleyball
  - Complete aquatic or partial weight bearing jumping program without pain before full weight-bearing exercise.

FIGURE 29-25. Reverse leg press.

Table 29-3 Basic Walk to Jog Program

	Run	Walk	Reps	Days
Phase I	1 minutes	1–5 minutes	2	2
Phase II	2 minutes	1–4 minutes	2	2
Phase III	3 minutes	1–3 minutes	2	2
Phase IV	4 minutes	1–2 minutes	2	2
Phase V	5 minutes	1 minutes	2	2

Take at least one rest day in between each workout, non-impact cross training during off days. Take at least one complete rest day a week.
If pain develops or other symptoms return, or if the phase cannot be completed, the athlete should not progress until able to complete it without symptoms.
Complete only one phase per day.

  - Implement approach, jump, and landing techniques beginning at 50% week 1, 75% week 2, 100% week 3 after criteria to sport have been met.
  - Being sport specific activity on sand volleyball court.
  - Correct restoration of preinjury jump high and landing kinematics before unrestricted return to sport.
  - Include dynamic warmup before activity.
  - No more than Phase I on Blazina scale with sport
- Basketball
  - Complete aquatic or partial weight bearing jumping program without pain before full weight bearing exercise.
  - Implement dribbling, jumpstop, and landing techniques beginning at 50% week 1, 75% week 2, 100% week 3 after criteria to sport has been met
  - Correct restoration of pre-injury jump high and landing kinematics before unrestricted return to sport
  - Include dynamic warmup before activity
  - No more than Phase I on Blazina scale with sport

After Return to Sport

Continuing Fitness or Rehabilitation Exercises

- Implement dynamic warmup and continue LE mobility exercise before and after exercise.
- Avoid exercise/jogging on concrete.
- Continue quad strength, hip stability, and landing balance exercises 3 days/week.
- Avoid resisted leg extension and excessive anterior lunge with activity.

Exercises and Other Techniques for Prevention of Recurrent Injury

- Normalize quad strength and power.
- Avoid jogging or conditioning on concrete surface.
- Use cross training to limit excessive stress through the patellar tendon (aquatics/nonbounding exercise).
- Implement dynamic warmup with focus on quad and ankle DF mobility.
- Assess anthropometric data (i.e., hip to waist ratio) to address need for interventional program.

Evidence

Backman LJ, Danielson P: Low range of ankle dorsiflexion predisposes for patellar tendinopathy in junior elite basketball players. *Amer Jour Sports Med* 39(12):2626–2633, 2011.

Prospective cohort design study of 90 junior elite basketball players to analyze if low ankle dorsiflexion increase risk of patellar tendinopathy over a 12 month time period. Players with less than 35.6° ankle dorsiflexion were at a significant risk for patellar tendinopathy. (Level II evidence)

Cucurulo T, Louis ML, Thaunat M, et al: Surgical Treatment of patellar tendinopathy in athletes. A retrospective multicentric study. *Orthop Trauma* 935:578–584, 2009.

Multicenter study evaluating 64 patients with patellar tendinopathy, 10 undergoing surgical intervention because of the failure of conservative treatment. At 24 months f/u 87% had improved Blazina score and 63% returned to preinjury sport level. Surgical intervention had an 80% success rate. (Level IV evidence)

Kraemer R, Knobloch K: A soccer-specific balance training program for hamstring muscle and patellar and Achilles tendon injuries: An interventional study in premier league female soccer. *Am J Sports Med* 37(7):1384–1393, 2009.

This cohort study evaluated the effectiveness of a proprioceptive training program to decrease LE injuries. At the end of the 3-year training period, noncontact hamstring injuries, patellar, and Achilles tendinopathies were significantly reduced. (Level III evidence)

Lian OB, Engebretsen L, Bahr R: Prevalence of jumper's knee among elite athletes from different sports. *Am J Sports Med* 33(4):561–567, 2005.

Cross-sectional study of 50 Norwegian male and female athletes at the national level following nine sports. Volley and basketball had the highest incidence of patellar tendinopathy. (Level IV evidence)

Lorbach O, Diamantopoulous A, Paessler HH: Arthroscopic resection of the lower patellar pole in patients with chronic patellar tendinosis. *J Arthro Rel Surg* 24(2):167–172, 2008.

Prospective study evaluating the clinical results of arthroscopic resection of lower patellar post in patient with patellar tendinosis. Satisfactory results were found at 24-month follow up with subjective questionnaires and all patients returned to previous sporting activity. (Level IV evidence)

Pascarella A, Alam M, Pascarella F, et al: Arthroscopic management of chronic patellar tensinopathy. *Am J Sports Med* 38(9):1975–1983, 2011.

Case series design of 64 patients (27 who were professional) with patellar tendinopathy undergoing arthroscopic surgery. Significant improvement in symptoms and function were achieved following surgical intervention for up to 3 years. Results indicate that some patients may not be able to achieve pre-symptoms sporting level and with a 9.6% failure rate. (Level IV evidence)

Multiple Choice Questions

QUESTION 1. Initial precautions following tendinopathy debridement include

A. 50% WB with brace locked in extension.
B. 50% WB with brace open 0° to 90°.
C. WBAT with brace locked in extension.
D. WBAT with brace open 0° to 90°.

QUESTION 2. Early neuromuscular activation techniques are focused on which of the following muscles?

A. Gluteals
B. Hamstrings
C. Gastrocs
D. Adductors

QUESTION 3. Which of the following sports has the highest incidence of patellar tendinopathy?

A. Basketball
B. Soccer
C. Volleyball
D. Football

QUESTION 4. To reduce stress on the patellar tendon, which of the following exercises should be avoided?

A. OKC leg extensions
B. Single leg squat 0° to 90°
C. Lunges with good mechanics
D. Stepups

QUESTION 5. Which of the following would require additional precautions and time to facilitate healing of the patellar tendon?

A. Debridement of patella spurring
B. Utilization of platelet rich plasma
C. Excision of abnormal tissue
D. Tendon compromised greater than 30%

Answer Key

QUESTION 1. Correct answer: **C** (see weeks 0 to 2)

QUESTION 2. Correct answer: **A** (see weeks 2 to 4)

QUESTION 3. Correct answer: **C** (see Criteria for Return to Sport)

QUESTION 4. Correct answer: **A** (see Guiding Principles of Postoperative Rehabilitation)

QUESTION 5. Correct answer: **D** (see Details and Choices That May Affect Details of Rehabilitation)

BEYOND BASIC REHABILITATION: RETURN TO BASKETBALL AFTER OPERATIVE TREATMENT FOR PATELLAR TENDINOPATHY

John DeWitt, PT, DPT, SCS, ATC, and Christopher C. Kaeding, MD

Introduction

- According to current research, basketball and volleyball players have the highest incidence, 32% and 45%, respectively, of patellar tendinopathy compared with other athletes at an elite level.
- External factors, including jumping frequency, change of direction, and intensity specific to basketball can lead to overload of tissue, contributing to patellar tendinopathy morphology.

Aspects of Basketball That Require Special Attention in Rehabilitation

- Include dynamic warm-up before activity/sport.
- Restore quadriceps strength and power.
- Restore quadriceps/hip flexor muscle length.
- Normalize lumbopelvic-hip stability.
- Continue with sport if no greater than Blazina Phase I.
- Correct landing mechanics.

Literature

- There is limited evidence to guide return to sport decisions after surgical treatment of patellar tendinopathy.
- It is important to understand the need to normalize patellar tendinopathy risk factors to prevent reinjury.
- Both intrinsic and extrinsic risk factors should be considered and a graduated integration to allow tissue to adapt to higher levels of stress is crucial.
  - Intrinsic factors
    - Quadriceps weakness
    - Quadriceps hypomobility
    - Ankle DF hypomobility
    - Higher waist to hip ratio
    - Altered landing mechanics
    - Patellar tendon abnormality
  - Extrinsic factors
    - Sex (male)
    - Competition level (elite)
    - Sport (volleyball and basketball)
    - Hard surface
    - Lifting weights
    - Playing at least 12 hours/week and/or lifting weight 5 hours/week
    - Higher jumping performance

Phase I: Off Season

Periodization

- Periodization is dependent on the philosophy, time, and resources of the coaching and strength/conditioning staff.

TIMELINE 29-3: **Return to Basketball After Surgical Treatment for Patellar Tendinopathy**

PHASE I (off season)	PHASE II (preseason)	PHASE III (in season)
• Restore movement patterns • Identify dysfunctional pattern (shoulder mobility, straight leg raise, deep squat, rotatory stability, pushup, etc.) • Strength program • Days 1 and 3 • Teach triple extension • Deadlift • Stepups/downs (small plyo box) • Hip hikes/lateral stepping with resistance • Day 2 • Core/balance training • Pushup with row • Plyometric training (1–3×/week) • Cardiorespiratory training • Nonbounding aerobics (2–3 times/week) • Cycling/swimming/elliptical • Hip hike	• Restore movement patterns • Use corrective strategies dependent on dysfunction (daily) • Strength program • Day 1 • Deadlift • Increase depth of squat if good form (0° to 90°) • Cleans • Step ups/downs (large plyo box) • Day 2 • Core/balance training • Pushup with row • Medicine ball drills • Cardiorespiratory training • Focus on sport specific conditioning • Suicide lines, stationary bike, interval training • 1 : 3 work/rest cycle • Plyometric training • Agility • Day 1 • Dot drills • Ladder drills	• Restore movement patterns • Use corrective strategies dependent on dysfunction (daily) • Strength program • Day 1 • Teach triple extension • Deadlift • Cleans • Day 2 • Medicine ball drills • Cardiorespiratory training • None • Plyometric training • None

- Linear periodization has historically been the most commonly utilized mode and will be used as a general template.
- More importantly, correcting movement patterns and teaching proper technique are paramount to avoid reinjury and improve performance.

Program Design/Performance Training Program

- Focus on correcting associated risk factors of patellar tendinopathy, nonbounding aerobic and high duration/low intensity strength training. Avoid drop down plyometrics.

Neuromuscular Training

- Lumbopelvic-hip neuromuscular activation
  - Transversus abdominis, multifidi, and gluteal maximus activation with feedback
- Correct movement patterns (e.g., double and single leg squat)
  - Use assistance (UE support, resistance band, cueing, etc.) to correct abnormal sagittal and frontal plane mechanics (i.e., excessive anterior weight shift, dynamic knee valgus, hip adduction)

Restoration of Mobility

- Thoracic spine (e.g., extension over roll: two sets × 10 repetitions)
- Ankle DF (e.g., anterior half lunge: two sets × 10 repetitions)
- Quad/hip flexor (prone static and dynamic stretching: three sets × 30 seconds)

Strength Program

- Three times per week
- Days 1 and 3
  - Teach triple extension
  - Deadlift
    - Assisted (if needed) to prevent excessive anterior weight shift
    - Double leg
    - Single leg
    - Increase depth of squat if good form (0° to 90°)
    - Use straight and knee leg movements
  - Step ups/downs (small plyometrics [plyo] box)
  - Hip hikes/lateral stepping with resistance
  - Three sets × 12 to 15 repetitions
  - 90 seconds between reps
- Day 2
  - Core/balance training
    - Chops/lifts
    - Three sets × 12 to 15 reps
    - Planks
    - Two sets × 45 to 60 seconds
  - Pushup with row
  - Three sets × 12 to 15 repetitions

Plyometric Training (one to three times per week)

- Knee tuck jumps two sets × 10 repetitions
- Lateral cone hops two sets × 10 repetitions
- Box jump up two sets × 5 repetitions
- 50 to 90 seconds between sets

Cardiorespiratory Training

- Nonbounding aerobics (two to three times per week)
  - Cycling/swimming/elliptical

Phase II: Preseason

Program Design/Performance Training Program

- Maintain power and strength gained in the off season.
- Focus on higher intensity sports-specific conditioning and speed/agility work.
- Circuit training at basketball intensity.

Neuromuscular Training

- Lumbopelvic-hip neuromuscular activation
  - Transversus abdominis, multifidi, and gluteal maximus activation with feedback
- Correct movement patterns (e.g., double and single leg squat)
  - Use assistance (UE support, resistance band, cueing, etc.) to correct abnormal sagittal and frontal plane mechanics (i.e., excessive anterior weight shift, dynamic knee valgus, hip adduction)

Restoration of Mobility

- Thoracic spine (e.g., extension over roll: two sets × 10 repetitions)
- Ankle DF (e.g., anterior half-lunge: two sets × 10 repetitions)
- Quad/hip flexor (prone static and dynamic stretching: three sets × 30 seconds)

Strength Program

- Two times per week
- Day 1
  - Teach triple extension
  - Deadlift
    - Assisted (if needed) to prevent excessive anterior weight shift
    - Double leg
    - Single leg
    - Increase depth of squat if good form (0° to 90°)
  - Cleans
  - Step ups/downs (large plyo box)
  - Three sets × 10 repetitions
  - 30 to 50 seconds between sets
- Day 2
  - Core/balance training
    - Chops/lifts
    - Three sets × 12 to 15 repetitions
    - Planks
    - Two sets × 45 to 60 seconds
  - Single leg balance training program
  - Pushup with row
  - Three sets × 10 repetitions
  - Medicine ball drills (three sets × 8 repetitions each)

- Basketball plyo pushups: Athlete is in a pushup position, straddling the basketball with both hands. Lower down halfway to the ground. Explode off the floor and catch and stabilize on the basketball and hold for a one count. Toss off and land softly on the floor.
- Medicine ball rotation throws: Face a wall with a medicine ball in the hands around chest height. Quickly throw the medicine ball at a predetermined target at the wall. Have hands out in front and ready to absorb the rebound of the ball off the wall. Catch the ball and throw back.
- Slam downs: Stand with feet parallel and knees slightly bent. Pull medicine ball back behind head and forcefully throw ball down on the ground as hard as possible. Catch the ball on the bounce from the ground and repeat according to prescribed repetitions.
- Squat throws: Start with ball positioned at waist level with knees slightly bent. Quickly squat lowering ball to calf level and explode up throwing the ball as high as possible directly overhead. Let the ball bounce once, reposition, and repeat drill. This exercise is important to develop posterior chain strength.

Cardiorespiratory Training

- Focus on sport-specific conditioning
  - Suicide lines, stationary bike, interval training
  - 1:3 work/rest cycle
  - One to three times per week

Plyometric Training

- Lateral cone hops 2 sets × 10 repetitions
- Single leg jump 2 sets × 5 repetitions
- Combine jumps and agility/ladder drills
- Avoid pain and consider using pool if needed
- 50 to 90 seconds between sets
- One to two times per week

Agility Drills

- Emphasis always should be placed on good form and landing mechanics.
- Day 1
  - Cone drills
    - T-drill: 5 to 10 sets
    - Two cones are set up 5 yards apart and two cones 6 yards apart to make a T
    - Run to the top of the T, shuffle to the right top cone, then left, return to the center cone, pivot, and sprint back to the start.
    - Z-drill: 5 to 10 sets
    - Place three sets of Cones 5 yards apart and 5 yards wide. Side shuffle from cone 1 to cone 2, Start at cone 1, shuffle slide to cone 2, use a drop step to change direction and slide to cone 3, and so on through the series of cones.
    - U drill: 5 to 10 sets
  - Players run in a U pattern from baseline under basket on one side, to the foul line, then to the block on other side of basket, and receive a short pass. They do a jump stop, square up, and shoot the ball off the glass.
  - Ladder drills
    - Ickey shuffles: 5 to 10 sets
      - Step into the box with the left foot and immediately follow with the right foot. Step outside the box with the left foot. Step forward with the right foot into the next box. Step into the second box with the left foot and step outside of the box with the right foot. Continue in a side-to-side fashion for the entire ladder.
    - Ollie shuffle: 5 to 10 sets
      - Stand to the side facing the ladder. Quickly jump in a scissor-like motion alternating each foot to shuffle laterally through the ladder.
    - Single leg diagonals: 5 to 10 sets
      - Start on one foot to the right of the ladder. Jump into the first square, then jump left outside between squares 1 and 2, back into the second square, jump right between squares 2 and 3, back into the third square. Repeat this diagonal pattern throughout.

Phase III: In Season

Program Design/Performance Training Program

- Maintain strength/balance, prevent overload.
- Use multidirectional activities with emphasis on correct movement patterns.
- Use dynamic warmup to maintain lower extremity mobility (quadriceps, ankle dorsiflexion, spinal mobility, etc.)

Neuromuscular Training

- Lumbopelvic-hip neuromuscular activation
  - Transversus abdominis, multifidi, and gluteal maximus activation with feedback
- Correct movement patterns (e.g., double and single leg squat)
  - Use assistance (UE support, resistance band, cueing, etc.) to correct abnormal sagittal and frontal plane mechanics (i.e., excessive anterior weight shift, dynamic knee valgus, hip adduction)

Restoration of Mobility

- Thoracic spine (e.g., extension over roll: two sets × 10 repetitions)
- Ankle DF (e.g., anterior half lunge: two sets × 10 repetitions)
- Quad/hip flexor (prone static and dynamic stretching: three sets × 30 seconds)

Strength Program

- Two times per week
- Day 1
  - Teach triple extension
  - Deadlift
    - Assisted (if needed) to prevent excessive anterior weight shift
    - Double leg
    - Single leg
    - Increase depth of squat if good form (0° to 90°)

- Cleans
- Three sets × eight repetitions
- 30 to 50 seconds between sets
- Day 2
  - Medicine ball drills (three sets × eight repetitions each)
    - Basketball plyo pushups
    - Medicine ball wall throws
    - Medicine ball rotation throws
    - Slam down
    - Squat throws

Sports Performance Testing

General Information

- General history
- Subjective questionnaires
- Medical history
- Sports injury history
- Surgical history
- Chronic conditions/medication

Objective Tests

- Body composition tests (hip to waist ratio)
- Functional movement screen[1]
- Lower extremity functional test (Figure 29-26)
- Symmetrical vertical jump

Specific Criteria for Progression to the Next Stage to Determine Readiness for Basketball

- No compensatory movement patterns (No gross asymmetry or abnormal landing/squatting mechanics)
- No more than Blazina Phase I with activity (pain after activity only).

Recommended Ongoing Exercises

- A dynamic warmup designed to improve mobility neuromuscular activation can be implemented prior to rehabilitation or sport program.
- Quadriceps and ankle DF mobility/muscle-tendon flexibility should be continued both before and after activity.
- Strength training should be continued both before and after activity.

Evidence

Chaouach A, Brughelli M, Chamari K, et al: Lower limb maximal dynamic strength and agility determinants in elite basketball players. *J Strength Cond Res* 23(50):1570–1577, 2009.

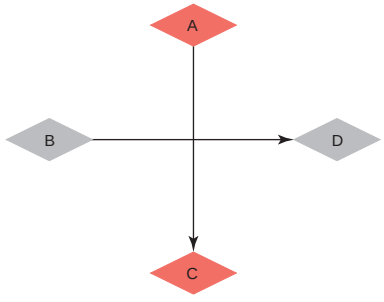
Cohort study to examine relationship between 1RM squat and basketball-specific tests in fourteen elite basketball players. Squat 1Rm was significantly related to 5-, 10-, and 30-m sprint time and recommended for inclusion in conditioning program. (Level II evidence)

Khlifa R, Aouadi R, Hermassi S, et al: Effects of plyometric training program with and without added load on jumping ability in basketball players. *J Strength Cond Res* 24(11):2955–2961, 2010.

Twenty-seven players randomly assigned to three groups: a control group (no plyometric [plyo] training), plyo group, and loaded plyo group to compare jumping performance. Following at 10-week plyo program, the loaded plyo group significantly improved jumping performance than the control or plyo group. The plyo group demonstrated significantly better jumping performance than control. (Level I evidence)

Santos EJ, Janeira MA: Effects of complex training on explosive strength in adolescent male basketball players. *J Strength Cond Res* 22(3):903–909, 2008.

A control group of 10 and experimental group of 15 young male athletes, aged 14 to 15 years old were assessed using functional performance tests after a 10-week in-season training program using weight training and plyometrics. The



30ft long by 10ft wide

1. Forward run
2. Retro run
3. Side shuffle right and left
4. Cariocas right and left
5. Figure-8 run right and left
6. 45-degree cuts right and left
7. 90-degree cuts outside leg right and left
8. 90-degree cuts inside leg (crossover cut) right and left
9. Forward run
10. Retro run

experimental group demonstrated significantly better values on power and agility tests compared with their control counterparts. (Level II evidence)

Tabor MA, Davies GJ, Kernozek TW, et al: A multicenter study of the test-retest reliability of the Lower Extremity Functional Test. *Sport Rehabil* 11:190–220, 2002.

Multicenter reliability study of the lower extremity functional test using 57 collegiate male and female athletes at two institutions without pathology, ICC values of .95 and .97 were established at separate locations indicating good test-retest reliability. (Level III evidence)

Zemkova E, Hamar D: The effect of 6-week combined agility-balance training on neuromuscular performance in basketball players. *Jour Sport Med Phys Fitness* (3):262–267, 2010.

This randomized controlled study of 34 elite female basketball compared functional outcome following a 6-week agility training on either stable or unstable surface. The experimental group using an unstable surface demonstrated significantly better neuromuscular performance. There was no difference in jumping performance. (Level I evidence)

Multiple Choice Questions

QUESTION 1. A dynamic warmup should focus on which of the following impairments in an athlete with a history of patellar tendinopathy?

A. Thigh/quadriceps weakness
B. Gluteal weakness
C. SL balance deficits
D. Hamstring weakness

QUESTION 2. Which of the following strengthening exercise is best to improve posterior chain strength?

A. Basketball plyo pushup
B. Medicine ball slam downs
C. Medicine ball rotation throw
D. Medicine ball squat throws

QUESTION 3. To maximize quadriceps strength which of the following squats should be used?

A. SL squat 0° to 20°
B. SL squat 0° to 60°
C. SL squat 0° to 90°
D. SL straight leg deadlift

QUESTION 4. Which of the following times is considered "average" when testing a male collegiate athlete using the Lower Extremity Functional Test?

A. Less than 90 seconds
B. Less than 100 seconds
C. Less than 110 seconds
D. Greater than 110 seconds

QUESTION 5. The purpose of the off-season conditioning program is to

A. focus on nonbounding aerobic and high duration/low intensity strength training.
B. focus on higher intensity sports-specific conditioning and speed/agility work.
C. focus on high intensity/low duration strength training.
D. focus on sport-specific plyometric training.

Answer Key

QUESTION 1. Correct answer: **A** (see Phase I)

QUESTION 2. Correct answer: **D** (see Phase II)

QUESTION 3. Correct answer: **C** (see Phase III)

QUESTION 4. Correct answer: **B** (see Figure 29-26)

QUESTION 5. Correct answer: **A** (see Phase I)

POSTOPERATIVE REHABILITATION AFTER REPAIR OF PATELLAR AND QUADRICEPS TENDON

J. Martin Leland, MD, and Philip J. Malloy, MS PT, SCS

Indications for Surgical Treatment

- A complete rupture of the quadriceps or patellar tendon
- A partial rupture of greater than 50% of the quadriceps or patellar tendon with an inability to perform a straight leg raise or hold the knee extended against gravity
- A partial rupture of the quadriceps or patellar tendon which fails extensive conservative therapy and continues to cause pain and an inability to return to activity

Brief Summary of Surgical Treatment

Major Surgical Steps

- Identify the ruptured tendon and debride the end of the tendon to healthy tissue.

- Prepare the patella using a burr or rongeur to create a cancellous bony trough to accept the tendon.
- Use two high strength sutures for the repair, weaving them through the medial and lateral halves of the tendon with a Krackow stitching technique.
- Drill three small vertical holes in the patella to pass the sutures through, with the two central strands passing through the central hole.
- Tie the two sutures on the far side of the patella with the knee in full extension, pulling the tendon into the trough created in the patella.
- Reinforce the repair with high strength suture or Mersilene tape woven through the tendon, through the medial and lateral retinaculum, around the far pole of the patella and tied (a "relaxing suture" taking tension off of the repair).[1]
- Repair retinacular tears with interrupted stitches and close the wound in layers.

Factors That May Affect Rehabilitation

Anesthetic

- Regional nerve blocks may be used to aide in comfort in the immediate postoperative period.

Surgical

- Before closure, the surgeon should begin to flex the knee and assess the arc of motion that can be achieved without putting stress across the repair. The patient should be limited to no motion beyond this stress-free arc for the first 6 weeks postoperatively. Complexity of the tear and quality of the repair must be appreciated when determining the rate of advancement through the rehabilitation phases.[1]

Other Surgical Techniques and Options

- Mid tendon ruptures can be repaired using an end-to-end repair as is frequently performed in Achilles tendon ruptures. A "relaxing suture" would also be recommended in these situations.[1]
- Complex tears or poor tissue quality should be advanced slowly through the rehabilitation phases, giving the tissues additional time for healing before significant strain is applied.

Guiding Principles of Postoperative Rehabilitation

- Appreciate the severity of the injury and the quality of the surgical repair.
- Open communication between surgeon and therapist regarding range of motion that can be achieved without putting stress across the repair.
- Understand tendon healing time frames.
- Respect ROM guidelines during phases of healing.
- Once full range of motion is obtained, focus on restoring symmetrical strength in the lower extremities before return to play to prevent reinjury.

*Phase I (days 0 to 14): Immediate Postoperative Period**

Clinical Pearl

> Quadriceps tendon rupture is a rare event in athletes less than 40 years old. Communication between surgeon and therapist regarding range of motion and weight-bearing restrictions is critical to promote compliance in the athletic population. The patient must demonstrate proper technique with passive range of motion and home exercises before he or she is released to perform them independently to ensure appropriate protection is given to healing tissue.

Goals

- Control postoperative pain.
- Manage postoperative swelling and effusion.
- Educate patient on protection of the repair.
- Initiate early controlled passive range of motion beginning at 1 week postoperatively to prevent stiffness (0° to 45°).
- Educate patient on weight-bearing restrictions and appropriate use of crutches.

Protection

- Weight bearing is restricted to PWB 25% body weight for the first 2 weeks using bilateral axillary crutches.
- The patient is placed in a hinged knee brace that is locked at 0° extension at all times including for sleep. The patient may unlock for exercise beginning at 1 week postoperatively.
- The patient is instructed to avoid active quadriceps contraction to protect the repair.

Management of Pain and Swelling

- Treatment for pain/analgesia
  - Oral pain medication
  - Avoid the use of NSAIDs for the first 2 weeks postoperatively because of inhibition of the inflammatory cascade.
  - Modalities such as TENS, Hi Volt, and interferential current electrical stimulation can be used to modulate pain.
  - Cryotherapy is emphasized to assist with controlling postoperative pain.
- To decrease swelling
  - Vasopneumatic compression with elevation is emphasized postoperatively to manage swelling and edema.
  - Modify activities such as minimizing time spent with lower extremity in a dependent position.[2]
  - Initiate ankle pumps to promote lower extremity blood flow and prevent calf musculature atrophy.

**Prehabilitation, if appropriate, is described in the Nonoperative Rehabilitation section of this chapter.*

Techniques for Progressive Increase in Range of Motion

Manual Therapy Techniques

- Patellar mobilizations in the medial and lateral direction can be used to prevent postoperative arthrofibrosis.[3,4]

Soft Tissue Techniques

- Gentle lymphatic massage can be used to assist with postoperative swelling.

Stretching and Flexibility Techniques for the Musculotendinous Unit

- Initiate gastrocnemius stretching with a strap to promote calf flexibility
- Ankle circles to promote ankle ROM

Other Therapeutic Exercises

- Avoid any total body or upper extremity strengthening that puts the operative extremity in a dependent position because of the increase in swelling that would result.

Activation of Primary Muscles Involved in Injury Area or Surgical Structures

- A submaximal quadriceps setting can be initiated under the guidance of a rehabilitation professional.[4,5–7]
- Neuromuscular electrical stimulation (NMES) may be useful in assisting with quadriceps activation.[5]

Milestones for Progression to the Next Phase

- Pain and swelling control
- Wound healing of incision site
- Passive knee flexion to 45°
- Independent ambulation in brace locked in full extension with assistive device

Phase II (weeks 2 to 6 postoperatively)

Clinical Pearl

Patellar mobilizations in all directions are important in preventing arthrofibrosis during this phase.[3,4] Restoring passive range of motion is important to prevent postoperative knee stiffness, but care always must be taken to not stress the healing repair.[3] Modalities such as NMES may be useful in facilitating quadriceps activation to promote control and assist with eliminating extensor lag during a straight leg raise.[5] This will also assist the patient to transition to weight bearing as tolerated without stress across the repair.

Goals

- Restore 0° to 90° of passive knee motion by 6 weeks (0° to 60° by 4 weeks and 90° by 6 weeks): This should be limited to the stress-free arc that was determined by the surgeon intraoperatively.
- Initiate straight leg raise in brace locked at 0° of extension.
- Initiate weight bearing as tolerated with brace locked in extension.
- Initiate multi plane straight leg raise using the hip stabilizers to promote proximal stability (hip abduction, adduction, extension).

Protection

- Progress to weight bearing as tolerated in brace locked in extension beginning at 2 weeks postoperatively based on patent's pain and swelling.
- Continue use of brace at all times locked in extension except during structured physical therapy sessions.

TIMELINE 29-4: **Postsurgical Rehabilitation After Repair of Patellar or Quadriceps Tendon**

PHASE I (weeks 1 to 2)	PHASE II (weeks 3 to 6)	PHASE III (weeks 6 to 10)
• Partial weight bearing 25% foot flat gait pattern • Hinged brace locked at 0° extension • Pain control through use of oral analgesics • Cryotherapy with vasopneumatic for swelling control • No NMES week 1 • NO PROM week 1 • Begin seated PROM 0° to 45° (week 2) • Begin sub maximal quadriceps setting week 2 • Activity modification to manage swelling	• Progress to weight bearing as tolerated in brace locked at 0° extension • Cryotherapy and vasopneumatic for swelling control • Begin patellar mobilizations and scar massage when incision is healed • Soft tissue mobilization to quadriceps and hamstrings • Upper body ergometer for cardiovascular • Upper body strengthening and core stabilization avoiding quadriceps activation • Seated flexion PROM to 0° to 60° 2 to 4 weeks • Seated flexion PROM 0° to 90° 4 to 6 weeks • NMES to quadriceps • Initiate straight leg raises in brace and progress to out of brace • Begin multiplane hip musculature strengthening and progress as tolerated	• D/C brace and restore normal symmetrical gait weeks 6 to 7 • Cryotherapy as needed for swelling • Begin active assisted and active knee ROM 0° to 120° • Joint and soft tissue mobilization as tolerated • Core stability and total arm strengthening as tolerated • Stationary bike once 110° active flexion is achieved • Begin short arc quadriceps exercise 30° to 0° • Initiate and progress single leg balance and proprioceptive exercises • Double leg closed chain lower extremity strength progression to 30° flexion

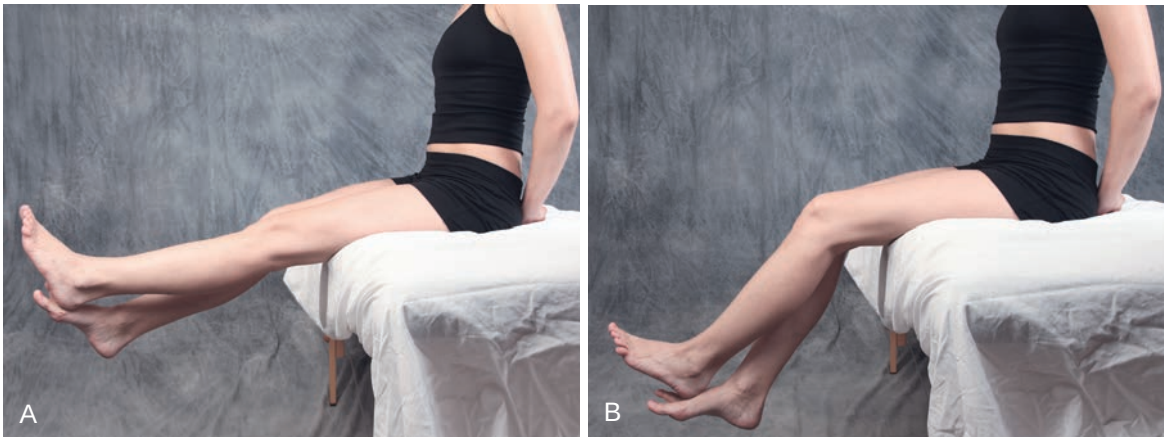

FIGURE 29-27. Seated passive knee flexion using uninvolved leg.

- The patient may doff the brace for showering beginning at 2 weeks. It is recommended that the patient use a shower seat with the knee maintained in extension at all times.

Management of Pain and Swelling

- Treatment for pain/analgesia
  - Oral analgesics as needed weaning to non-narcotic medication for residual pain. (NSAIDs may be initiated at 2 weeks postoperatively.)
  - Cryotherapy should be continued to manage pain and swelling.
  - Be aware of increased pain as weight bearing is increased and modify or limit activities as necessary.
- To decrease swelling:
  - Use of nonsteroidal antiinflammatory medication as indicated for continued postoperative swelling.
  - Continue with lymphatic massage, ankle pumps, and cryotherapy to reduce residual swelling.
  - Ankle pumps are initiated to promote lower extremity blood flow and prevent calf musculature atrophy.

Techniques for Progressive Increase in Range of Motion

Manual Therapy Techniques

- Patellar mobilizations in all directions should begin at week 2 based on the quality of wound healing to prevent postoperative scarring and adhesion of the anterior knee.[4]
- If lacking full extension, begin tibiofemoral joint mobilizations to restore terminal extension.[4]
- Continue passive knee flexion exercises progressing to 90° as tolerated (0° to 60° by 4 weeks and 0° to 90° by 6 weeks). Limit to the stress-free arc determined intraoperatively (Figures 29-27 to 29-29).

Soft Tissue Techniques

- Initiate soft tissue mobilization to the quadriceps and hamstrings to assist with passive knee flexion and extension.
- Initiate scar mobilization based on quality of wound healing.

TIMELINE 29-4: **Postsurgical Rehabilitation After Repair of Patellar or Quadriceps Tendon** (Continued)

PHASE IV (weeks 10 to 14)	PHASE V (weeks 14 to 24)	PHASE VI (weeks 24 to 52)
• PT modalities as needed • Restore full active and passive knee ROM (<5° uninvolved) • Advance stretching to restore flexion symmetry • Mobilizations as needed for flexion and extension • Begin and progress cardiovascular endurance with elliptical trainer and treadmill uphill walking • Begin long arc quads without resistance • Progress double leg strengthening squat depth • Initiate short arc single leg squats • Progress balance and proprioceptive training • Initiate mid-range lunge progression	• PROM: maintain full motion • Mobilizations as needed • TBS/TAS/TLS activities as recommended and tolerated • Cardiovascular training as tolerated • Advance single leg strengthening (weeks 14 to 18) • Advance balance and proprioceptive exercises (weeks 14 to 18) • Initiate agility drills (week 18) • Begin return to running progression (week 20) • Begin plyometrics (week 24)	• PROM: maintain full motion • Mobilizations as needed • Lower extremity flexibility exercises • TBS/TAS/TLS activities as recommended and tolerated • Advanced plyometric and jump training (week 24 to 26) • Initiate and complete a return to sport progression (week 26 to 30) • Closed chain lower extremity strength maintenance program • Balance and proprioceptive training as needed

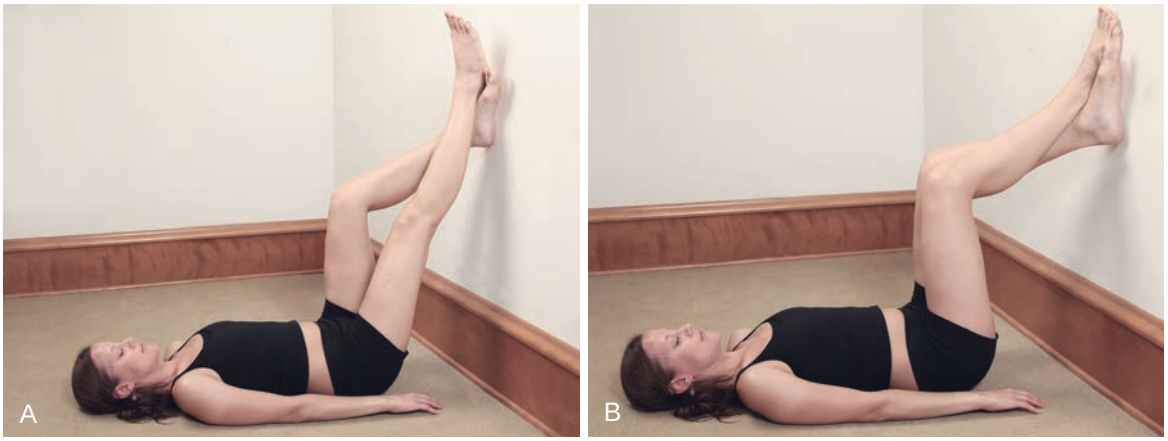

FIGURE 29-28. Supine wall slides.

Stretching and Flexibility Techniques for the Musculotendinous Unit

- Initiate supine passive hamstring, ITB, and adductor stretching with knee in full extension.

Other Therapeutic Exercises

- Upper body ergometer for cardiovascular endurance
- May initiate upper body and core stabilization with knee locked in brace. Avoid quadriceps activation with any strengthening exercise.
  - Abdominal crunches
  - Seated trunk rotations with resistance band
- Isometric contraction of all lower extremity musculature can begin during this phase to prevent atrophy.

Activation of Primary Muscles Involved in Injury Area or Surgical Structures

- Elevate the heel on a bolster during quadriceps sets if the patient is lacking terminal extension.
- Straight leg raises can be initiated in a locked brace (Figure 29-30).
- Utilization of NMES to the quadriceps may assist in facilitating activation.[5]

Sensorimotor Exercises

- Begin weight shifting exercises to promote appropriate weight transfer during gait.
- Initiate single leg balance in brace locked in extension to facilitate single limb support during stance phase of gait cycle (Figure 29-31).

Open and Closed Kinetic Chain Exercises

- Emphasize proximal stability through the initiation of multiplane hip stabilization such as hip abduction, adduction, and extension in the supported position[8] (Figures 29-32 and 29-33).
- Begin clam progression (Figures 29-34 and 29-35).

Milestones for Progression to the Next Phase

- Passive knee range of motion 0° to 90° or as limited by the intraoperative stress-free arc
- Normal patellar mobility in all planes
- Elimination of extensor lag with straight leg raises
- Minimal swelling
- Initiate weight-bearing exercise and restore weight-bearing status as tolerated in brace.

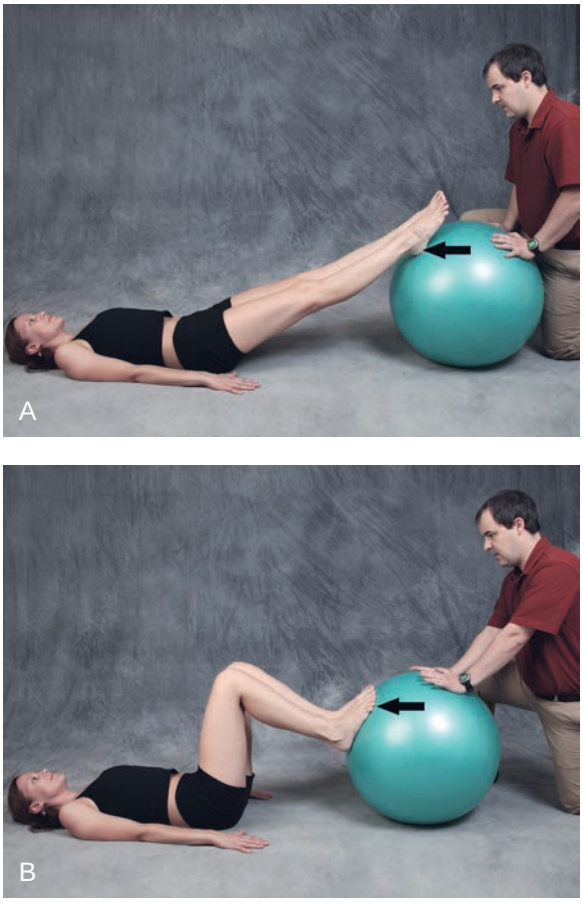

FIGURE 29-29. Supine passive flexion with exercise ball.

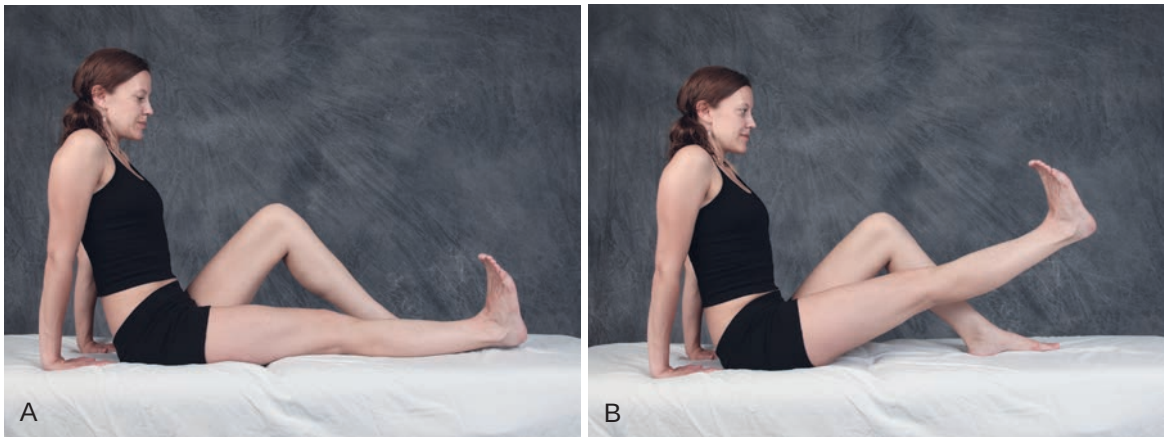

FIGURE 29-30. Straight leg raise.

FIGURE 29-31. Single leg balance on level surface.

FIGURE 29-33. Prone leg raises.

FIGURE 29-34. Side-lying clam exercise.

FIGURE 29-32. Side leg raises.

FIGURE 29-35. Side-lying clam exercise with resistance band.

Phase III (weeks 6 to 10 postoperatively)

Clinical Pearl

The brace may be removed for ambulation once the patient exhibits good strength with straight leg raise testing. Appropriate quadriceps control must be emphasized when returning to brace-free ambulation. Avoid increasing postoperative effusion and emphasize proper motor control when initiating closed chain exercises to prevent anterior knee pain.

Goals

- Restore knee range of motion 0° to 120°.
- Minimize postoperative swelling and muscle inhibition.
- Eliminate extensor lag with straight leg raises (three sets × 15 reps without brace) to discontinue brace use for ambulation and initiate closed chain strengthening.
- Restore symmetrical gait pattern without assistive device and brace.
- Initiate double leg closed chain strengthening in limited range of motion 0° to 30°.

Protection

- Unlock brace 0° to 90° for initial ambulation until the athlete is able to achieve straight leg criteria mentioned in the preceding.
- Gradually wean out of brace over a 1- to 2-week period depending on quad control during walking.[2]

Management of Pain and Swelling

- Treatment for pain/analgesia: NSAIDs as needed
- To manage swelling:
  - Initiate cryotherapy as needed after exercise.
  - Modify activity as needed if swelling persists.

Techniques for Progressive Increase in Range of Motion

Manual Therapy Techniques

- Advance to 0° to 120° of active knee range of motion using manual techniques as needed.
- Tibiofemoral joint mobilizations to restore arthrokinematics during open chain active knee flexion and extension.
- Tibial rotation mobilizations are useful in restoring end ranges of knee flexion and extension assisting the screw home mechanism.
- Femoral and tibial anterior and posterior glides can also be initiated during this phase to promote joint mobility and range of motion.

Soft Tissue Techniques

- Utilize soft tissue mobilizations as needed to promote tissue extensibility, especially at the repair site.

FIGURE 29-36. Avoid aggressive passive flexion stretching.

Stretching and Flexibility Techniques for the Musculotendinous Unit

- Continue lower extremity stretching and begin Thomas hip flexor stretching.
- Avoid aggressive prone quadriceps stretching to avoid stress across the repair[6] (Figure 29-36).

Other Therapeutic Exercises

- Upper body ergometer for cardiovascular endurance
- Begin zero resistance stationary biking when 110° of flexion is achieved.
- Advance core stabilization initiating a plank progression (Figures 29-37 and 29-38).
- Initiate deep water aqua jogging.[4]

Activation of Primary Muscles Involved in Injury Area or Surgical Structures

- Progress quadriceps activation to include open chain short arc quadriceps and standing terminal knee extension with resistance band[9,10] (Figures 29-39 and 29-40).
- Progress straight leg raises to include light ankle weights once good quadriceps control is established.
- Initiate exercise ball double leg assisted squats (Figure 29-41).

FIGURE 29-37. Prone planks.

FIGURE 29-38. Prone planks with opposite hip extension.

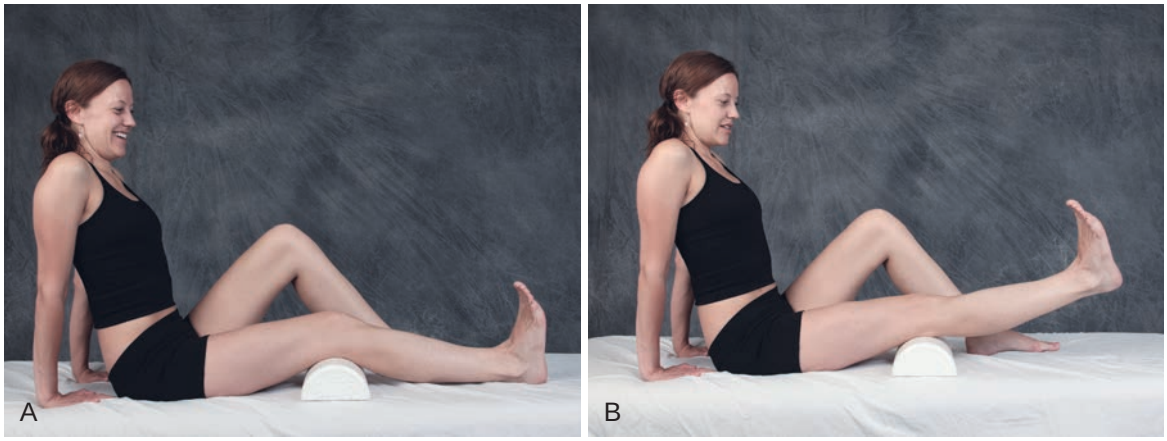

FIGURE 29-39. Short arc quadriceps exercise.

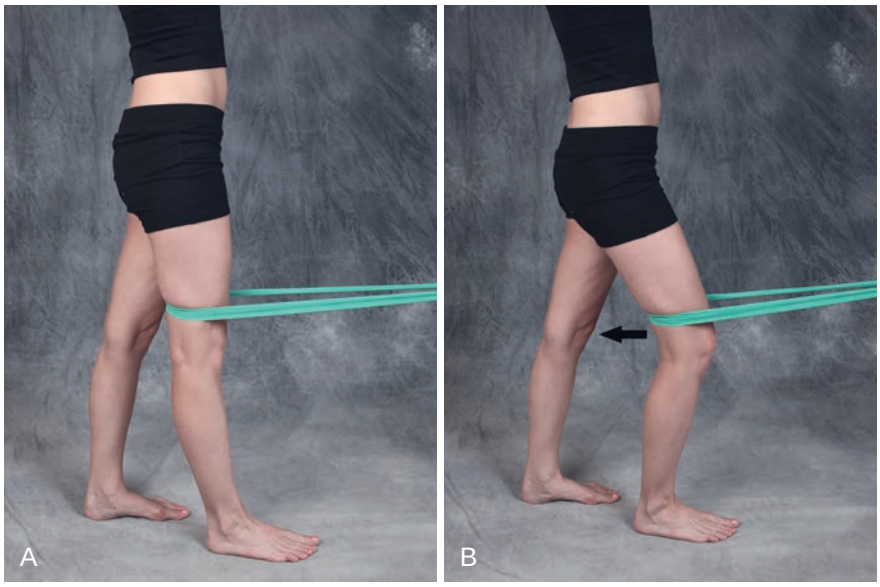

FIGURE 29-40. Standing terminal knee extension with resistance.

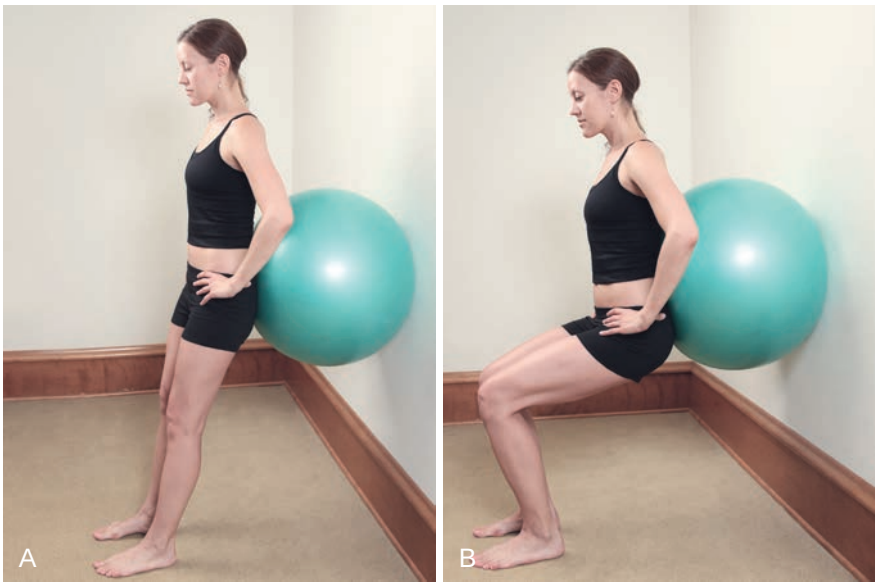

FIGURE 29-41. Assisted wall squats with exercise ball.

Sensorimotor Exercises

- Single leg balance progressing from with brace to without brace on level surface.
- Progress to single leg balance on unstable surface such as a foam pad, Dyna-disc, or BOSU (Figure 29-42).

Open and Closed Kinetic Chain Exercises

- Progress OKC multiplane straight leg raises with ankle weights.
- Begin manual resisted diagonal patterns to promote motor control.
- Initiate concentric-eccentric quadriceps in sitting between 0° and 45° (avoid resistance).
- Initiate closed chain standing one-third knee bends (0° to 30°) in brace progressing to out of brace[4,10] (Figure 29-43).

FIGURE 29-42. Single leg balance on BOSU.

Neuromuscular Dynamic Stability Exercises

- Initiate seated exercise ball core stability exercise to promote trunk control.

Milestones for Progression to the Next Phase

- Symmetrical gait pattern with good quadriceps control
- Knee AROM to 0° to 120°
- Ability to perform double leg knee squat to 30° without anterior knee pain and good control
- Minimal swelling after activity

Phase IV (weeks 10 to 14 postoperatively)

Clinical Pearl

Emphasize prolonged holds with double leg strengthening to promote muscular endurance. Educate the athlete on lower extremity position and proper alignment during exercise to avoid undue stress on anterior knee that can cause patellofemoral pain.

Goals

- Restore symmetrical knee active range of motion (less than 5° loss).
- Progress closed chain double leg strengthening 0° to 60°.
- Initiate step training promoting restoration of eccentric quadriceps control.
- Eliminate swelling and joint effusion.

Management of Pain and Swelling

- Continue the use of NSAIDs for any residual pain or inflammation.

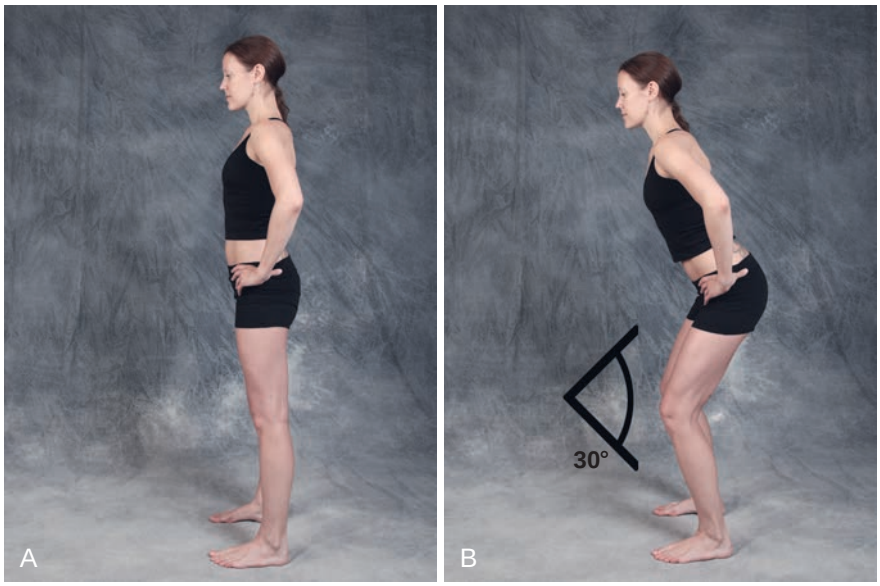

FIGURE 29-43. One-third knee bends.

Techniques for Progressive Increase in Range of Motion

Manual Therapy Techniques

- Tibiofemoral joint mobilization should continue to promote normal arthrokinematics and symmetrical joint motion during open and closed chain exercise.

Soft Tissue Techniques

- Initiate PNF contract-relax stretching for quadriceps.
- Advanced soft tissue mobilization can now include deep tissue mobilizations to improve flexion range of motion.

Stretching and Flexibility Techniques for the Musculotendinous Unit

- Prone manual knee flexion stretching can be initiated to restore symmetrical knee flexion.
- Dynamic quadriceps stretching can also be initiated during this phase.
- Continue lower extremity stretching of all muscle groups focusing on two joint muscles (i.e., hip flexor, hamstrings, quadriceps, gastrocnemius).

Other Therapeutic Exercises

- Advance stationary biking to include resistance (maintain 80 to 120 rpm).
- Initiate elliptical trainer.
- Initiate treadmill uphill walking (7% to 12% grade).[3]
- Progress core stability as tolerated in all positions.

Activation of Primary Muscles Involved in Injury Area or Surgical Structures

- Progress quadriceps activation to include step progression (4- to 6-inch step)[10] (Figure 29-44).
- Long arc quadriceps extensions 90° to 0° without resistance.[10]

Sensorimotor Exercises

- Continue to progress single leg balance on altered surface to promote endurance.
- Incorporate upper extremity and trunk patterns and movements into single leg balance exercises.[9]

Open and Closed Kinetic Chain Exercises

- Gradually advance knee range of motion during double leg closed chain strengthening.
- Begin double leg squats with side to side weight shifts to promote single limb stability.
- Progress step training promoting eccentric control of the knee and hip.

FIGURE 29-44. Lateral step-down.

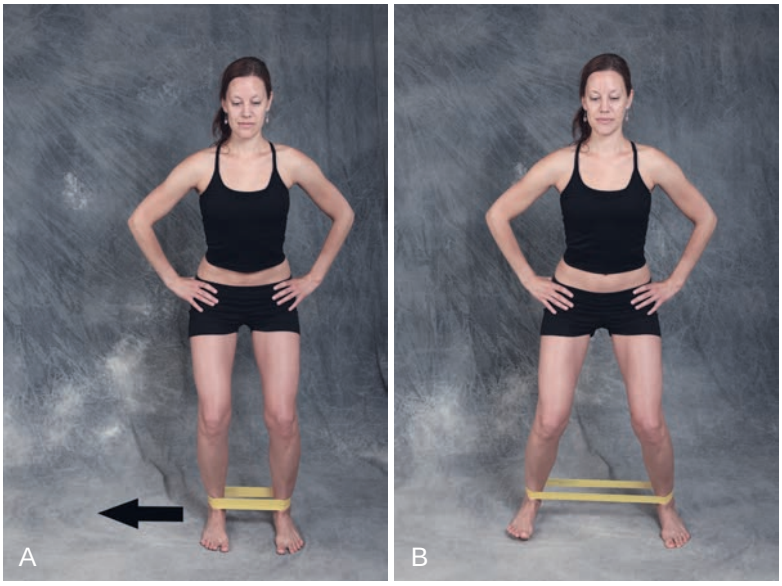

FIGURE 29-45. Side-step with resistance band.

- Begin single leg static holds at 20° of knee flexion to promote endurance for single leg strengthening.
- Begin resisted side stepping (Figure 29-45).

Techniques to Increase Muscle Strength, Power, and Endurance

- Begin double leg stance chopping exercises.
- Incorporate resisted upper extremity motions into single leg static holds to promote core stability and motor control.

Neuromuscular Dynamic Stability Exercises

- Continue to advance lower extremity diagonal patterns to include trunk and upper extremity in all positions.[9]

Milestones for Progression to the Next Phase

- Restoration of symmetrical knee range of motion
- Pain free with activities of daily living
- Ability to ascend and descend an 8-inch step with good control of lower extremity
- No anterior knee pain during or after strengthening exercises

Phase V (weeks 14 to 24 postoperatively)

Clinical Pearl

Avoid anterior knee pain with advancing single leg strengthening. Emphasize motor control with advanced strengthening exercises. Sport-specific positions should be used when developing strengthening programs for athletes during this phase.

Goals

- Shift focus to strengthening by beginning agility and sport-specific training.
- Initiate plyometric and functional training.
- Restore cardiovascular fitness and endurance.
- Complete a lateral step down test with appropriate form and control.

Techniques for Progressive Increase in Range of Motion

Manual Therapy Techniques

- If range of motion is less than uninjured side, advanced to aggressive joint mobilizations (grade 4 to 5) to restore full mobility.
- If range of motion is still limited at 4 months postoperatively, manipulation under anesthesia in the operating room should be considered.

Stretching and Flexibility Techniques for the Musculotendinous Unit

- Continue quadriceps stretching as needed to restore symmetrical flexibility in Thomas Test position

Other Therapeutic Exercises

- Initiate advance cardiovascular training using treadmill, elliptical trainer, stationary biking, and aquatic workouts.
  - Jogging progression can be initiated on a treadmill.
- Continue performing core stability exercises as part of home and gym workout routine.
- Advance upper body weight training as tolerated without restrictions.

Activation of Primary Muscles Involved in Injury Area or Surgical Structures

- Add resistance to open chain quadriceps strengthening between 60° and 0° once full range of motion is achieved.

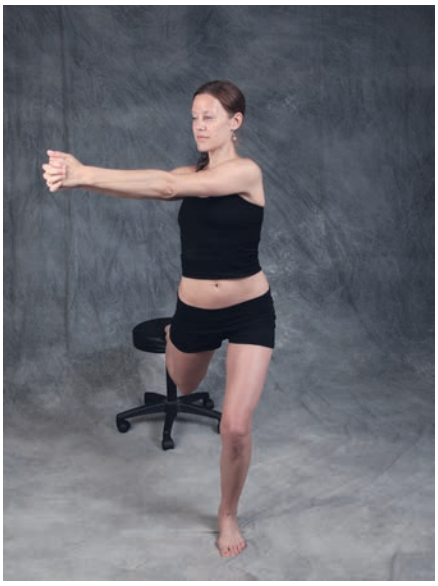

FIGURE 29-46. Balance squat with trunk rotations.

Sensorimotor Exercises

- Advance balance and proprioceptive training as tolerated (Figure 29-46)

Open and Closed Kinetic Chain Exercises

- Initiate single leg supported squatting[4,11] (Figure 29-47).
- Progress single knee bends to 60° flexion (Figure 29-48).

Techniques to Increase Muscle Strength, Power, and Endurance

- Advance lower extremity weight training for quadriceps, hamstrings, proximal hip stabilizers (external rotators and gluteals), and gastrocnemius.
- The athlete may gradually return to a modified weight training program with strength and conditioning coach or trainer (avoid Olympic lifts until next phase).

Neuromuscular Dynamic Stability Exercises

- Begin lunge progression advancing from split lunge to single plane to multiplane.[11]
- Diagonal trunk patterns with single leg squatting to promote single limb and trunk control.

Plyometrics

- Initiate double leg plyometric training at 4 months postoperatively.[12]
- Progress plyometric training from single plane hopping to multiplane.[12,13]

Functional Exercises

- Begin initial agility consisting of lateral shuffle and carioca.
- Advanced agility such as W cuts, Z cuts, and chop downs can begin at 5 months postoperatively.[3]

Sport-Specific Exercises

- Initiate a return to running progression.
- Sport specific activities that do not involve eccentric loading or explosive movements can begin toward the middle of this phase such as shooting baskets, volleying during tennis, setting or bumping in volleyball, or walk through movements.

Milestones for Progression to the Next Phase

- Completion of a lateral step down test with appropriate form and control compared with uninvolved[14] (see Figure 29-44).

FIGURE 29-47. Balance squats.

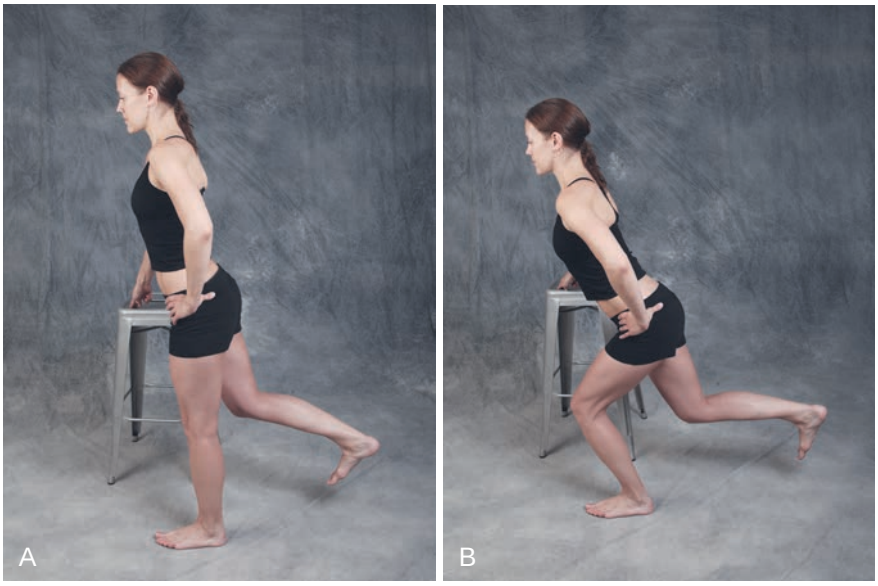

FIGURE 29-48. Single knee bends.

- Pain free with initial and advanced agility exercises.
- Proper form and control with double leg plyometric exercises.

Phase VI (weeks 24 to 52 postoperatively)

Clinical Pearl

> The complete clinical picture of the athlete should be taken into account before return to competition, which will include strength assessment and return to sport testing. A gradual re-introduction to competition is recommended to ensure that appropriate endurance is attained to prevent reinjury caused by fatigue.

Goals

- Restoration of 90% strength compared with uninvolved lower extremity with isokinetic testing of the quadriceps.
- Completion of single limb hop testing or functional return-to-sport testing.[4,13]
- Return to competition.

Techniques to Increase Muscle Strength, Power, and Endurance

- May begin Olympic lifting techniques that can be useful to focus on strength and power.
- Focus on building endurance of quadriceps, hamstrings, gluteals/hip abductors, gastrocnemius, and hip adductors.

Neuromuscular Dynamic Stability Exercises

- Advance upper and lower extremity integrated movement patterns focusing on coordination, speed, and control.

Plyometrics

- Initiate single leg plyometric training.
- Advance plyometric and sport-specific jump training emphasizing eccentric control with landing.

Functional Exercises

- Advance agility drills emphasizing speed during this phase.

Sport-Specific Exercises

- Begin noncontact practicing and sport-specific drills.
- Gradually add contact drills to practice routines.

Milestones for Progression to the Next Phase

- Restoration of 90% strength compared with uninvolved lower extremity with isokinetic testing.[6,11,14]
- Successful completion of single limb functional hop testing or return to sport testing.

Criteria for Return to Sport

General

- Pain free and no apprehension with sport-specific activities
- Symmetrical active knee range of motion (<5° difference for flexion)
- 90% quadriceps strength of uninvolved leg with isokinetic testing at 180° and 360° per second
- Successful completion of single limb functional hop testing or return to sport testing

Sport-Specific

- Football: acceleration, multidirectional cutting and muscular endurance equivalent to preinjury levels. The

athlete must demonstrate these while playing his or her position in a scrimmage situation without deficiency.
- Competitive weight lifting: symmetrical lower extremity strength and endurance with a focus on power. This must be performed through the entire range of movement of all required lifts.

After Return to Sport

Continuing Fitness or Rehabilitation Exercises

- Advanced core stability training as part of normal workout routine
- Plyometric training

Exercises and Other Techniques for Prevention of Recurrent Injury

- Consider screening athletes for use of steroids, which can lead to unusual tendon ruptures.
- Evaluate and instruct in proper lower extremity landing mechanics that may prevent injury.
- Lower extremity stretching and flexibility exercises
- Core stabilization and motor control
- Maintain eccentric knee and hip control with advanced strengthening.
- Maintain sport-specific cardiovascular endurance.

Evidence

Enad JG, Loomis LL: Patellar tendon repair post-operative treatment. *Arch Phys Med Rehabil* 81:786–788, 2000.

This is a prospective analysis of 10 patients consecutively undergoing patellar tendon repair over a 1-year period. Five patients were treated with immobilization in a cast and isometric exercise and the five patients were treated with early mobilization and isometrics. There was no significant difference between the groups over a mean 16-week period.

Feil S, Newell J, Minogue C, et al: The effectiveness of supplementing a standard rehabilitation program with superimposed neuromuscular electrical stimulation after anterior cruciate ligament reconstruction: A prospective single blind, randomized study. *Am J Sports Med* 39:1238–1247, 2011.

This single-blind randomized control trial examined the use of superimposed neuromuscular stimulation as an adjunct to a standard rehabilitation program following ACL reconstruction. They found that the use of neuromuscular electrical stimulation in addition to standard rehabilitation was effective at improving quadriceps torque, single leg hop testing, and Lysholm knee scores compared to a control. (Level I evidence)

Fives G: Patellar and quadriceps tendon repair. In Cioppa-Mosca J, Cahill JB, Cavanaugh JT, et al, editors: *Post surgical rehabilitation guidelines for the orthopedic clinician*, St. Louis, MO, Mosby, pp 393–406, 2006.

This chapter is a review of a rehabilitation protocol following a quadriceps or patellar tendon rupture. It offers review of literature on a functional approach to rehabilitation.

McGinty G, Irrang JJ, Pezzullo D: Biomechanical considerations for rehabilitation of the knee. *Biomechanics* 15:160–166, 2000.

This article provides a review of the arthrokinematics and osteokinetics of the knee during open and closed chain motion. This understanding is crucial for clinicians when developing rehabilitation programs for patients following knee injury or surgery. (Level IV evidence)

Millett PJ, Johnson B, Carlson J, et al: Rehabilitation of the arthrofibrotic knee. *Am J Orthop* 32:531–538, 2003.

This review article provides a framework for a rehabilitation following surgical intervention for arthrofibrosis. The rehabilitation progression for these patients is similar to athletes with patellar or quadriceps tendon rupture.

Millett PJ, Wickiewicz TL, Warren RF: Motion loss of ligament injuries to the knee. Part 1. Causes. *Am J Sports Med* 29:664–675, 2001.

This article is a review of the causes of motion loss following knee ligament injury or surgery to the knee. It discusses the factors that can influence motion loss, which may assist clinicians in developing an approach to the management of this condition.

Myer GD, Paterno MV, Ford KR, et al: Rehabilitation after anterior cruciate ligament reconstruction: Criteria based progression through return to sport. *JOSPT* 36:385–402, 2006.

This review article demonstrates a progression for an athlete following ACL reconstruction through return to sport. It provides clinical outcome measures that are useful for measuring return to sport function following knee surgery.

West JL, Keene JS, Kaplan LD: Early motion after quadriceps and patellar tendon repairs: Outcomes with single-suture augmentation. *Am J Sports Med* 36(2):316–323, 2008.

This retrospective case series examined 50 patients with quadriceps or patellar tendon ruptures repaired primarily and augmented with a "relaxing suture." One week postoperatively patients began full weight bearing in an extension brace and range of motion 0° to 55°. By 6 months, all patients reached their preinjury levels of activity and no patients lacked more than 10° of active extension. All were classified as good or excellent results by the Lysholm score. (Level IV evidence)

Multiple Choice Questions

QUESTION 1. To prevent injury to the healing tendon in the first 6 weeks postoperatively, range of motion should be

A. prevented for 4 to 6 weeks before starting gentle motion.
B. limited to 0° to 60° by 4 weeks and 0° to 90° by 6 weeks.
C. limited to the stress-free arc determined intraoperatively.
D. unrestricted but limited by the pain threshold of the patient.

QUESTION 2. In the immediate postoperative period (first 14 days), pain and swelling may be treated with

A. NSAIDs, TENS, cryotherapy, and elevation of the extremity.
B. narcotics, interferential current electrical stimulation, cryotherapy, and activity modification.
C. Elevation, Hi Volt, soaking the knee in cool baths, and narcotics.
D. TENS, cryotherapy, NSAIDs, and patellar mobilizations in the superior-inferior directions.

QUESTION 3. During which time frame should the athlete restore knee active range of motion equal to the uninjured side?

A. 2 to 6 weeks
B. 6 to 10 weeks
C. 10 to 14 weeks
D. 14 to 18 weeks

QUESTION 4. Which of the following exercises should NOT be used to increase strength during the 14- to 24-week postoperative period?

A. Plyometric training
B. Lunge progression
C. Olympic lifting techniques
D. Single leg supported squatting

QUESTION 5. After return to sport, techniques that can be used to prevent recurrent injury include all of the following EXCEPT

A. screening athletes for use of steroids.
B. lower extremity stretching and flexibility exercises.
C. evaluation of and instruction in proper lower extremity landing techniques.
D. strength training using primarily high weights with few repetitions.

Answer Key

QUESTION 1. Correct answer: **C** (see Brief Summary of Surgical Technique)

QUESTION 2. Correct answer: **B** (see Phase I)

QUESTION 3. Correct answer: **C** (see Phase IV)

QUESTION 4. Correct answer: **C** (see Phase V)

QUESTION 5. Correct answer: **D** (see After Return to Sport)

Chapter 30

Meniscus Injuries

INTRODUCTION

Frank R. Noyes, MD

Epidemiology

- Meniscus tears are among the most common injuries treated by orthopaedic surgeons.
- Approximately 1 million meniscal surgeries are performed each year,[1] with more than 50% done in patients 45 years of age or older.
- It has been estimated that the incidence of meniscus tears in athletes is 61 in 100,000.[2]
- Although early studies reported a male-female ratio of this injury of 3:1,[3] more recent data suggest a fairly even distribution according to gender.[4]
- Approximately 60% of meniscus tears occur in patients aged 20 to 49.[4]
- Meniscus tears usually occur in two demographic populations: young, active patients who sustain a specific knee injury (usually during sports) and patients who are greater than 50 years of age who never had an injury, but develop degenerative tears
- Asymptomatic degenerative tears are common in middle-aged and older adult patients.[5]
- Common sports associated with meniscus tears are soccer, skiing, handball, basketball, wrestling, football, gymnastics, and tennis.[4]

Pathophysiology

Intrinsic Factors

- Acute ACL rupture: associated meniscus tears in approximately 60%[6]
- Chronic ACL deficiency: increased shear forces, risk of giving-way
- Varus (medial meniscus) or valgus (lateral meniscus) malalignment

Traumatic Factors

- Common mechanisms include a sudden twist, change in direction, jumping, pivoting, or deep knee flexion.
- Commonly occurs with other knee injuries such as an ACL rupture.

Classic Pathological Findings

- Tibiofemoral joint line pain
- Locking or clicking medial or lateral tibiofemoral compartment
- Posterior knee pain with flexion greater than 90°
- Knee effusion
- Lack of pain-free extension

Clinical Presentation

History

- Knee injury involving sudden twist, change in direction, jumping, pivoting, or deep knee flexion
- Frequently encountered in knees with ACL ruptures
- Tibiofemoral joint line pain, swelling, locking, catching

Physical Examination

Abnormal Findings

- Tibiofemoral joint line pain on palpation
- Pain with full flexion
- Lack of pain-free full knee extension
- Positive McMurray test: internal or external rotation knee flexion produces pain, clicking, crepitus

- Meniscal displacement during joint compression indicated by popping, clicking, catching
- Tenderness on palpation at the posterolateral aspect of the joint at the anatomic site of the popliteomeniscal attachments

Pertinent Normal Findings

- Symptoms: lack of pain with activities, rotational knee movements
- No joint line tenderness
- Negative provocative meniscus tests (McMurray)
- Full knee motion without pain

Imaging

- Radiographs: lateral 30° of flexion, patellofemoral axial, weight bearing posteroanterior 45° of flexion
- Knees with varus or valgus malalignment: full standing hip-knee-ankle weight-bearing radiographs to measure weight-bearing line, mechanical axis
- MRI using a proton-density weighted, high-resolution, fast-spin echo sequence or similar techniques for enhanced articular cartilage resolution

Differential Diagnosis

- Medial or lateral ligament acute tear producing tibiofemoral joint pain
- Saphenous neuritis, complex regional pain syndrome producing medial pain, tenderness to palpation
- Lateral patellofemoral subluxation syndrome producing pain in medial retinacular structures, medial patellar-meniscal ligament attachments (pain anterior to superficial medial collateral ligament)
- Medial tibial stress fracture, pes tendonitis with pain along anteromedial tibial region just distal to joint line
- Lateral iliotibial band friction syndrome with pain, tenderness just proximal to lateral tibiofemoral joint

Treatment

Nonoperative Management

- Rest, activity modification
- Oral nonsteroidal antiinflammatory medications
- Physical therapy

Guidelines for Choosing Among Nonoperative Treatments

- Degenerative meniscus tears with positive MRI, often asymptomatic; do not require surgery (Figure 30-1)
- Degenerative meniscus tears with episodic pain, clicking in sedentary patient
- Patient willing to modify activities
- Patient unwilling to undergo arthroscopy
- Patient unwilling or unable to follow postoperative rehabilitation program
- Severe loss tibiofemoral joint space, majority of symptoms related to arthritis

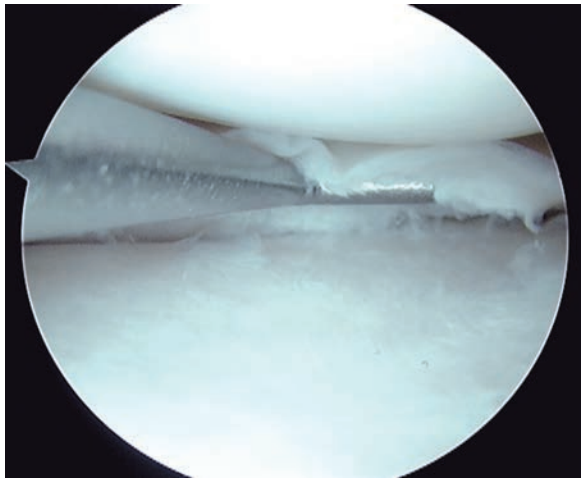

FIGURE 30-1. A degenerative longitudinal medial meniscus tear in a 55 year-old woman. *(Reprinted with permission from Noyes FR, Barber-Westin SD: Meniscus tears: Diagnosis, repair techniques, and clinical outcomes. In Noyes' knee disorders: surgery, rehabilitation, clinical outcomes, Philadelphia, 2009, Saunders, pp. 733–771. Fig. 28-3-G.)*

Surgical Indications

- Unstable meniscus tear (locking, pain, giving way), particularly in younger or active patient who will usually require meniscectomy if intervention not performed using meniscus repair[7]
- Unresolved tibiofemoral joint pain
- Giving way, recurrent joint effusion
- Associated painful meniscus cyst

Aspects of History, Demographics, or Exam Findings that Affect Choice of Treatment

- Patient requires functional, pain-free knee as soon as possible for occupation or sports activities.
- Failed conservative treatment, unresolved tibiofemoral joint pain more than 2 months
- Patient willing to comply with postoperative rehabilitation, activity restrictions
- Degenerative tears, delay surgery if symptoms are episodic, livable

Aspects of Clinical Decision Making When Surgery Is Indicated

- Tear must be classified according to type, location, quality of tissue, damage to meniscus tissue and remaining meniscus bed in order to decide on repair versus excision (Figure 30-2).[8]
- Peripheral single longitudinal tears: repairable in all cases, high success rate (Figure 30-3)
- Middle third region, complex tears (horizontal, flap, radial, double and triple longitudinal) often repairable, evaluate individual basis (Figures 30-4, 30-5, 30-6)[9,10]
- Special cases considered for repair include lateral meniscus tear with a meniscal cyst (Figure 30-7), posterior horn popliteomeniscal attachment tear (Figure 30-8), and posterior meniscus root attachment tear (Figure 30-9).
- Small longitudinal tears (less than 10 mm in length) left in situ

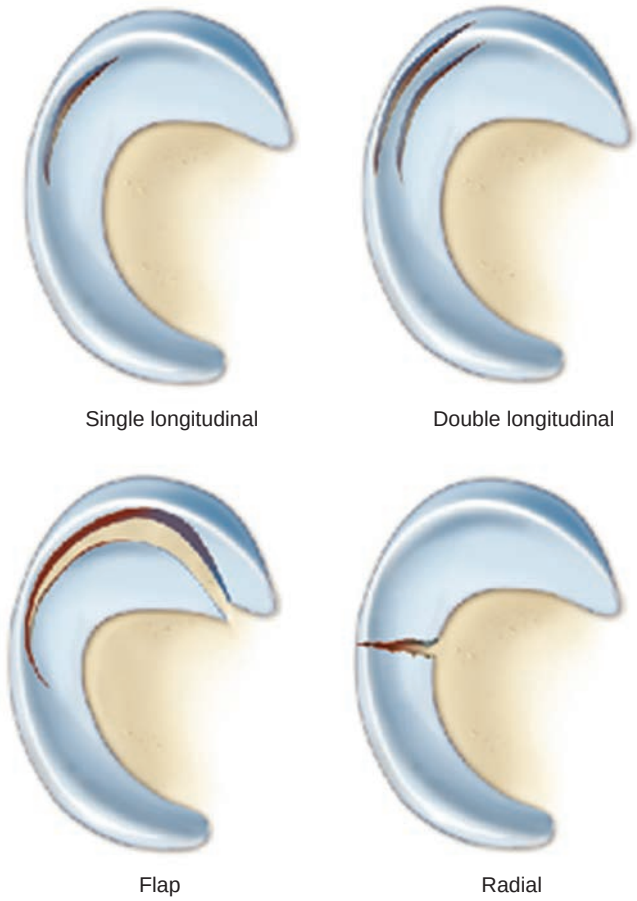

FIGURE 30-2. Illustrations of the common complex and avascular meniscus tear patterns. Note the single-plane configuration of the single longitudinal and radial tears and the multiplane (complex) configuration of the double longitudinal and flap tears. *(Redrawn with permission from Noyes FR, Barber-Westin SD. Meniscus tears: Diagnosis, repair techniques, and clinical outcomes. In Noyes' knee disorders: surgery, rehabilitation, clinical outcomes, Philadelphia, 2009, Saunders, pp. 733–771. Fig. 28-1.)*

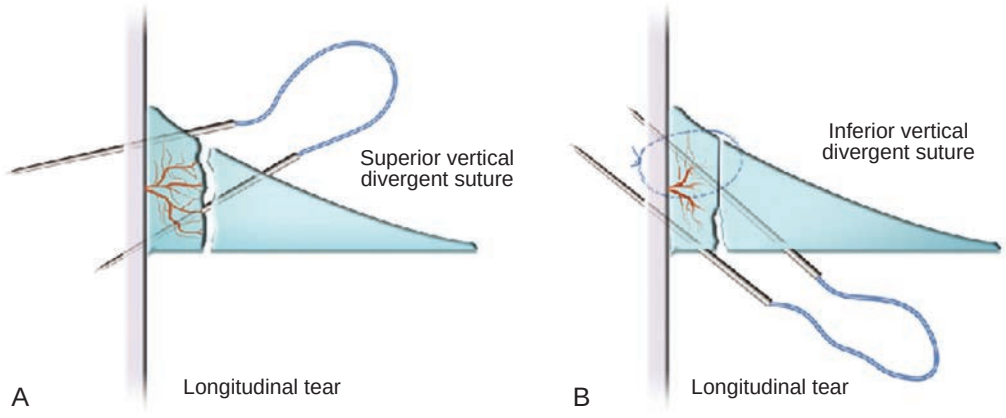

FIGURE 30-3. Double-stacked vertical suture pattern used in the repair of longitudinal meniscus tears. **A,** The superior sutures are placed first to close the superior gap and to reduce the meniscus to its bed. **B,** Then, the inferior suture is placed through the tear to close the inferior gap. *(Redrawn with permission from Noyes FR, Barber-Westin SD. Meniscus tears: Diagnosis, repair techniques, and clinical outcomes. In Noyes' knee disorders: surgery, rehabilitation, clinical outcomes, Philadelphia, 2009, Saunders, pp. 733–771. Fig. 28-10.)*

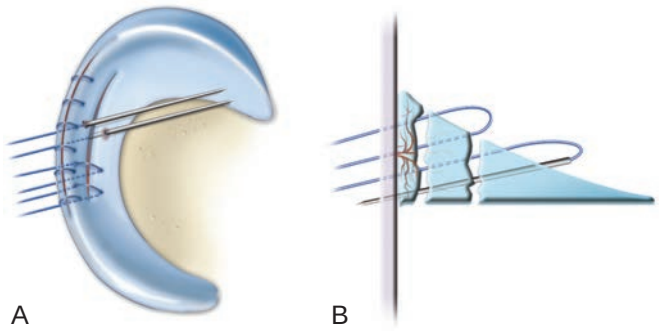

FIGURE 30-4. Double-stacked repair technique for double longitudinal tears. The peripheral tear is repaired first with superior and inferior vertical divergent sutures (**A**), followed by repair of the inner tear in the same fashion (**B**). *(Redrawn with permission from Noyes FR, Barber-Westin SD. Meniscus tears: Diagnosis, repair techniques, and clinical outcomes. In Noyes' knee disorders: surgery, rehabilitation, clinical outcomes, Philadelphia, 2009, Saunders, pp. 733–771. Fig. 28-12.)*

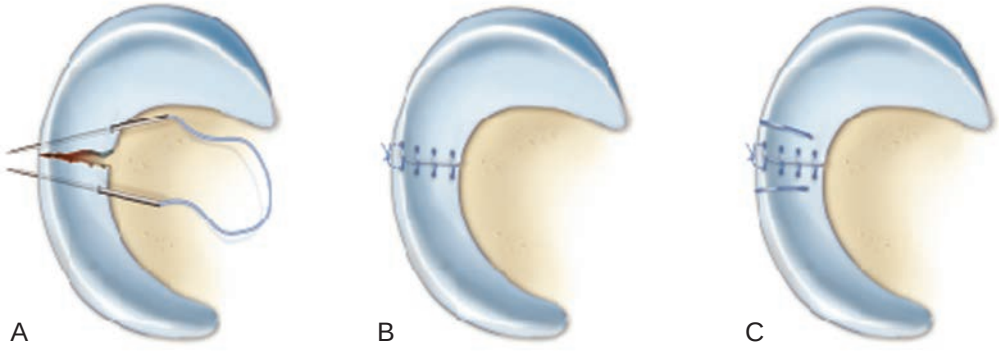

FIGURE 30-5. Repair technique for radial meniscus tears. The inner sutures (**A**) are placed first, followed by the peripheral sutures (**B**). The first suture needle is placed midway through the meniscus body, then used to apply a circumferential tension to reduce the tear gap, and then advanced through the posterior meniscus bed. The second suture needle is placed in a similar manner. This reduces the radial gap, allowing subsequent sutures to be placed. Usually 3 to 4 sutures are placed superiorly and two sutures, inferiorly. **C,** Occasionally superior vertical divergent sutures are placed along the tear site to help stabilize the repair. *(Redrawn with permission from Noyes FR, Barber-Westin SD. Meniscus tears: Diagnosis, repair techniques, and clinical outcomes. In Noyes' knee disorders: surgery, rehabilitation, clinical outcomes, Philadelphia, 2009, Saunders, pp. 733–771. Fig. 28-14.)*

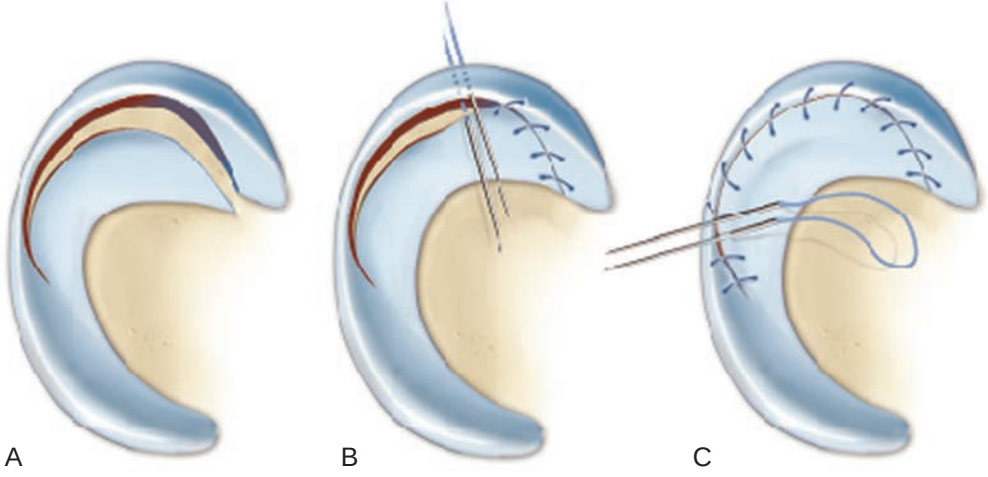

FIGURE 30-6. Repair technique for flap tears. **A,** the tear is identified and reduced. **B,** Horizontal tension sutures are placed to anchor the radial component of the tear. **C,** The longitudinal component is sutured using the double-stacked suture technique. *(Redrawn with permission from Noyes FR, Barber-Westin SD. Meniscus tears: Diagnosis, repair techniques, and clinical outcomes. In Noyes' Knee Disorders: Surgery, Rehabilitation, Clinical Outcomes, Saunders, Philadelphia, 2009, pp. 733–771. Fig. 28-17.)*

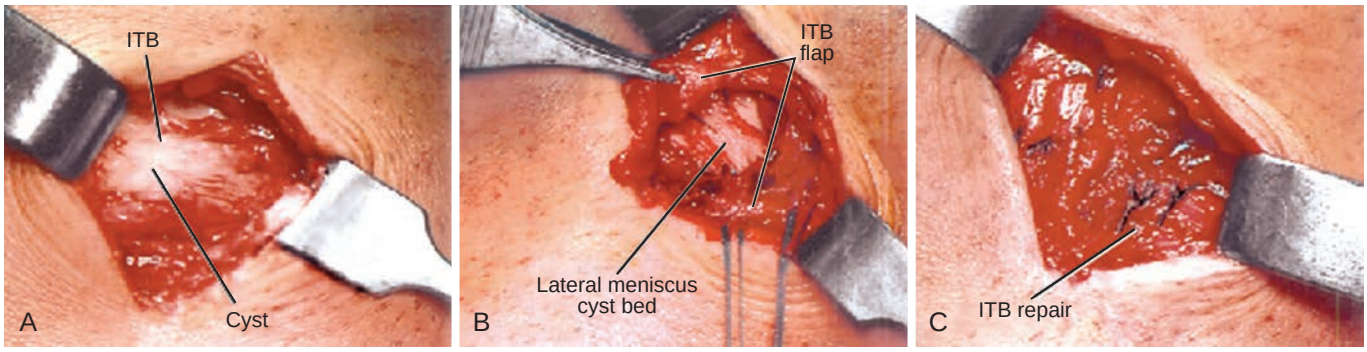

FIGURE 30-7. Demonstration of repair of lateral meniscus horizontal tear with a meniscal cyst. **A,** A 3-cm lateral joint incision placed directly over cyst shows the iliotibial band and an obvious protruding cyst. **B,** Iliotibial band is split in a line of fibers over the cyst and retracted, the cyst is removed, and repair is performed of the remaining meniscus to the attachments. **C,** Closure of the iliotibial band over the meniscus. Vertical sutures placed through the peripheral meniscus and iliotibial band help stabilize the repair. Then the arthroscopic inside-out repair of the meniscus body tear is performed. *(Reprinted with permission from Noyes FR, Barber-Westin SD. Meniscus tears: Diagnosis, repair techniques, and clinical outcomes. In Noyes' knee disorders: surgery, rehabilitation, clinical outcomes, Philadelphia, 2009, Saunders, pp. 733–771. Fig. 28-15.)*

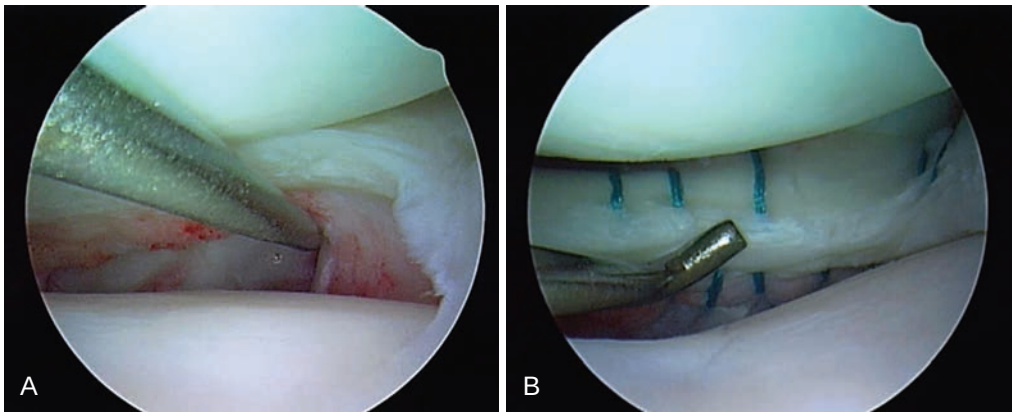

FIGURE 30-8. An athlete who had a prior negative arthroscopic examination and MRI and continued posterolateral joint pain shows a posterior horn popliteomeniscal attachment tear that required suture repair. **A,** Enlarged popliteal hiatus and laxity of the meniscotibial attachments is shown. **B,** Multiple vertical divergent superior and inferior inside-out sutures. *(Reprinted with permission from Noyes FR, Barber-Westin SD. Meniscus tears: Diagnosis, repair techniques, and clinical outcomes. In Noyes' knee disorders: surgery, rehabilitation, clinical outcomes, Philadelphia, 2009, Saunders, pp. 733–771. Fig. 28-4.)*

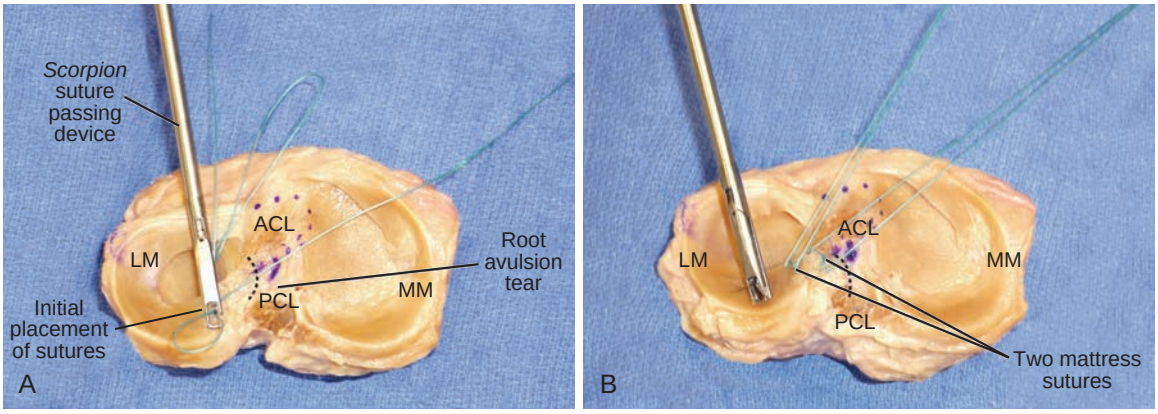

FIGURE 30-9. Posterior meniscus root attachment tear. **A,** Placement of two mattress sutures; the meniscus suture-passing device (Arthrex, Naples, FL) may be passed in and out of the portal to place higher-holding strength mattress sutures over a single suture. **B,** Final placement of sutures brought out through a 4-mm transtibial tunnel and tied over a post to restore the meniscus attachment. *(Reprinted with permission from Noyes FR, Barber-Westin SD. Meniscus tears: Diagnosis, repair techniques, and clinical outcomes. In Noyes' knee disorders: surgery, rehabilitation, clinical outcomes, Philadelphia, 2009, Saunders, pp. 733–771. Fig. 28-16.)*

- Inner third region and chronic degenerative tears resected
- Use vertical divergent sutures to anatomically appose the tear site. This suture technique has superior tensile strength compared with horizontal sutures and meniscus fixators.
  - Complex tears are usually repaired with the vertical divergent suture technique. The other option, all-inside suture devices, is not preferred because only 2 to 4 sutures are placed, which does not provide an adequate repair for sufficient healing, especially with immediate range of motion programs.

Evidence

Crawford R, Walley G, Bridgman S, et al: Magnetic resonance imaging versus arthroscopy in the diagnosis of knee pathology, concentrating on meniscal lesions and ACL tears: a systematic review. *Br Med Bull* 84:5–23, 2007.

This systematic review studies differences between MRI and arthroscopy in the diagnosis of knee pathology. A total of 59 articles met the study criteria. Ages of the patients ranged from 3 to 87 years. MRI had accuracy rates in detecting medial and lateral meniscus tears of 86.3% and 88.8%, respectively. The study concluded that MRI was an appropriate screening tool before arthroscopy. (Level II evidence)

Fithian DC, Paxton EW, Stone ML, Luetzoq WF, et al: Prospective trial of a treatment algorithm for the management of the anterior cruciate ligament-injured knee. *Am J Sports Med* 33:335–346, 2005.

A prospective study was performed on 108 female and 101 male patients to determine if certain risk factors could be used to indicate whether ACL reconstruction or conservative management should be used for managing this injury. Patients were classified as high, moderate, or low-risk using preinjury sports participation and knee laxity measurements. Early ACL reconstruction was recommended for high-risk patients, conservative management for low-risk patients, and either treatment method for moderate-risk patients. Patients were followed a mean of 6.6 years after their injury. The results found that early phase conservative management resulted in more late phase meniscus surgery than did early phase ACL reconstruction at all risk levels. Early reconstruction reduced late phase knee laxity, risk of symptomatic instability, and late meniscus tear and surgery. (Level II evidence)

Levy IM, Torzilli PA, Warren RF: The effect of medial meniscectomy on anterior-posterior motion of the knee. *J Bone Joint Surg* 64:883–888, 1982.

An in vitro knee testing apparatus was used to measure anterior displacement of the tibia on the femur and tibial rotations in response to an applied AP force in nine intact knees, five medial-meniscectomized knees, three ACL-resected knees, and eight medial-meniscectomized and ACL-resected knees. Excision of the medial meniscus in knees with sectioned ACLs resulted in significantly greater increases in anterior tibial displacement compared to those with ACL section only. The significant differences were observed at all knee flexion angles, with the greatest increase (58%) at 60° of knee flexion and the smallest increase (18%) at 0°. The authors concluded that it seemed likely that the posterior horn of the medial meniscus served as a secondary restraint to anterior tibial translation. Removal of the medial meniscus after ACL rupture could further compromise these knees. (Controlled laboratory study)

Majewski M, Susanne H, Klaus S: Epidemiology of athletic knee injuries: a 10-year study. *Knee* 13:184–188, 2006.

This prospective study analyzed the type and frequency of knee injuries that presented in a clinic in Switzerland over a 10-year period. There were 17,397 patients with 19,530 sports injuries analyzed. The ACL was injured the most frequently in knees that underwent surgery, followed by the MCL, medial meniscus, and lateral meniscus. Data on meniscus injuries (284 lateral and 836 medial) showed no difference in incidence rates between gender, and approximately 60% occurred in patients aged 20 to 39. (Level IV evidence)

Mohan BR, Gosal HS: Reliability of clinical diagnosis in meniscal tears. *Int Orthop* 31:57–60, 2008.

This retrospective study determined the clinical diagnostic test characteristics of 130 patients diagnosed with a meniscus tear. The clinical examination findings were compared to those documented at arthroscopy. The tibiofemoral joint line test and McMurray test had accuracy rates of 88% for medial meniscus tears and 92% for lateral meniscus tears. (Level III Evidence)

Musahl V, Jordan SS, Colvin AC, et al: Practice patterns for combined anterior cruciate ligament and meniscal surgery in the United States. *Am J Sports Med* 38:918–923, 2010.

The frequency of meniscal repair to meniscectomy in patients undergoing ACL reconstruction using the American Board of Orthopaedic Surgeons database was performed form 2003–2007. There were 8,342 patients identified, 4.088 of whom underwent concomitant meniscus surgery with an ACL reconstruction. Of these, 34% underwent partial meniscectomy and 15% underwent meniscal repair. Meniscal repair was significantly more likely to be performed when the ACL surgery was done by a sports medicine fellowship-trained surgeon (16.6%) compared with a general orthopaedic surgeon (11.7%) or other fellowship-trained surgeon (12%). Concomitant partial meniscectomy was performed twice as frequently as meniscal repair by sports medicine fellowship-trained surgeons and three times as frequently by other surgeons. The authors concluded that concomitant meniscal repair was performed by fellowship-trained surgeons in only 18% of the reported cases, approximately half that of meniscectomy, warranting further investigation. (Level III Evidence)

Noyes FR, Chen RC, Barber-Westin SD, et al: Greater than 10-year results of red-white longitudinal meniscal repairs in patients 20 years of age or younger. *Am J Sports Med* 39:1008–1017, 2011.

A prospective longitudinal study was performed in 33 meniscus repairs performed for single longitudinal tears that extended into the central avascular region. Twenty-nine repairs were done in patients aged 20 years or younger who were followed a mean of 16.8 years (range, 10.1 to 21.9 years) postoperatively. The results were ascertained from two validated knee rating systems, MRI with 3T scanner and T2 mapping, and weightbearing posteroanterior radiographs. The data showed that 62% had normal or nearly normal characteristics, 21% required partial arthroscopic resection, 10% failed according to MRI criteria, and 7% had loss of tibiofemoral joint space on radiographs. A chondroprotective effect was demonstrated in the healed repairs, warranting the procedure in select patients. (Level IV Evidence)

Rubman MH, Noyes FR, Barber-Westin SD: Arthroscopic repair of meniscal tears that extend into the avascular zone. A review of 198 single and complex tears. *Am J Sports Med* 26:87–95, 1998.

The results of 198 meniscus repairs for complex tears that extended into the central third region were evaluated by clinical examination (mean, 42 months postoperative) or follow-up arthroscopy (mean, 18 months postoperative). The data showed that 80% of the repairs were asymptomatic for tibiofemoral joint symptoms. Patients who had joint symptoms underwent repeat arthroscopic surgery. The findings allowed recommendation of repair of these types of meniscus tears, especially for patients under the age of 30 and highly competitive athletes. The authors recommended inside-out repair techniques with vertical divergent sutures in contrast to all-inside repair. (Level IV Evidence)

Tandogan RN, Taser O, Kayaalp A, et al: Analysis of meniscal and chondral lesions accompanying anterior cruciate ligament tears: Relationship with age, time from injury, and level of sport. *Knee Surg Sports Traumatol Arthrosc* 12:262–270, 2004.

The cases of 764 patients with ACL tears were analyzed to determine the relationships between meniscus tears and chondral lesions and patient age, time from injury, and sports level. The patients were assessed a mean of 20 + 33 months (range, 0.2 to 360 months) after their injury. A total of 73% of the patients had one or more meniscus tears. The odds of the patient sustaining a medial meniscus tear were 2.2 times higher at 2 to 5 years postinjury compared with the first year, and 5.9 times higher after 5 years compared with the first year. A total of 86% of patients who were greater than 5 years postinjury had a medial meniscus tear and 48% had a lateral meniscus tear. (Level IV Evidence)

Multiple-Choice Questions

QUESTION 1. Meniscus tears frequently accompany which other knee injury?

A. Patellar subluxation
B. Saphenous neuritis
C. Anterior cruciate ligament rupture
D. Tibial stress fracture

QUESTION 2. Which of the following findings may be misdiagnosed as a meniscus tear?

A. Pain with full flexion
B. Pain anterior to superficial medial collateral ligament
C. Lack of pain-free full extension
D. Tibiofemoral compartment clicking

QUESTION 3. Full standing radiographs should be performed under which circumstances?

A. Positive Lachman test
B. Patient walks with severe limp
C. Older patient with potential for arthritis
D. Knee with varus or valgus malalignment

QUESTION 4. Which type of meniscus tear should always be treated by resection and not by repair?

A. Longitudinal tears less than 10 mm in length
B. Posterior root attachment
C. Flap
D. Triple longitudinal

QUESTION 5. One of the factors that significantly increases healing rates and the ability to repair complex meniscus tears is:

A. Horizontal suture technique
B. All-inside suture technique
C. Vertical divergent suture technique
D. Meniscus fixators

Answer Key

QUESTION 1. Correct answer: **C** (see Clinical Presentation)

QUESTION 2. Correct answer: **B** (see Differential Diagnosis)

QUESTION 3. Correct answer: **D** (see Imaging Studies)

QUESTION 4. Correct answer: **A** (see Aspects of Clinical Decision Making When Surgery Is Indicated)

QUESTION 5. Correct answer: **C** (see Aspects of Clinical Decision Making When Surgery Is Indicated)

NONOPERATIVE REHABILITATION OF MENISCUS INJURIES

K. Donald Shelbourne, MD, and Heather E. Freeman, PT, DHS

GUIDING PRINCIPLES OF NONOPERATIVE REHABILITATION

- When any type of degenerative meniscus tear is accompanied by an effusion and/or any loss of range of motion or strength compared with the opposite knee, rehabilitation to address these impairments is usually effective for reducing or eliminating the patient's symptoms.
- Steroid injections, oral steroids, or nonsteroidal antiinflammatory medications may be used as an adjunct to rehabilitation by decreasing the effusion and pain.
- Rehabilitation should be structured into phases based on the following goals:
  - Reduce the effusion and restore normal knee extension (symmetric to the noninvolved knee).
  - Restore normal, symmetric knee flexion.
  - Restore symmetric lower extremity strength.
  - Gradually re-introduce impact activities/athletics.
  - Progression of rehabilitation to the next phase is determined by meeting the goals of each phase rather than based on a timeline.

Introduction

- Selecting an appropriate course of treatment for meniscus tears needs to be based on an understanding of the type and location of the meniscus tear as well as an assessment of concomitant impairments such as loss of range of motion (ROM), strength, and the presence of an effusion.
- It is important for clinicians to recognize that meniscal pathology seen on a magnetic resonance imaging (MRI) scan of a middle-aged patient is frequently an incidental finding.[1–3]
- Clinical correlation of symptoms, physical examination findings, and diagnostic imaging studies is needed to determine whether the patient's symptoms are related to the meniscal pathology, early osteoarthritis, or other associated impairments.[3,4]
- Even in the presence of a degenerative meniscus tear, a patient with a loss of ROM and/or a knee joint effusion may improve with a well-directed rehabilitation program designed to resolve these deficits.
- The knee pain may be a new occurrence, but it is important to consider that the degenerative meniscus tear may have been present for quite some time without causing pain.[1–3] If the tear is not new, then the pain may be related to stiffness, deconditioning, or a joint effusion.
- The overall goal of treatment is to regain symmetry. By restoring full, symmetric knee extension first, then knee flexion, and finally strength, the patient often experiences a significant improvement or resolution of symptoms.
- The progression of this rehabilitation process should be based on meeting specific goals, rather than based on a timeline.
- Patients with tibiofemoral joint space narrowing typically have meniscal abnormalities that are amenable to rehabilitation rather than surgical treatment.[1,4]
- One common type of meniscus tear in the osteoarthritic patient is a posterior horn radial tear that extrudes beyond the tibiofemoral articulation. This occurs when narrowing of the joint space places a compressive force on the meniscus, creating "hoop stress" that eventually causes the meniscus to tear and the peripheral part of the meniscus gets extruded.
- The patient often gives a history of feeling a painful "pop," followed by a joint effusion and decreased ROM. Although this type of tear is very painful initially, a combined treatment approach of medication and rehabilitation is often very effective.
- An initial course of nonoperative treatment is most appropriate for degenerative meniscus tears because many patients will improve to a functional level without surgery.[5]
- Meniscus tears that are degenerative in nature are not amenable to repair owing to the characteristic

TIMELINE 30-1: **Nonoperative Rehabilitation of Meniscus Injuries**

PHASE I	PHASE II

• Cold-compression device and elevation to decrease effusion
• Gait training
• Knee extension ROM- regain symmetry
  • Heel prop
  • Towel stretch
  • Passive knee extension device
• Active heel lifts for quadriceps muscle neuromuscular control
	• Maintain full knee extension
	• Knee flexion ROM—regain symmetry
	  • Wall slide
	  • Heel slide
	• Low impact exercise progression (bike, elliptical, stair climber)
	• Cold-compression and elevation as needed

horizontal cleavage seen with a degenerative tear, the poor blood supply, and the frayed, degenerative quality of the meniscus at the tear location.[6] These tears often occur in patients who are middle aged or older and are most common in the medial meniscus.[7]
- Most meniscus tears in young, competitive athletes are not degenerative in nature and therefore, would not respond as well to nonsurgical intervention.
- Hence, the focus on this chapter is on nonsurgical treatment of degenerative meniscus tears in the older, recreational athlete.

Phase I[1]

Goal

- To eliminate effusion and restore normal, symmetric knee extension

Protection

- No protection required. Encourage the patient to fully weight bear on the affected leg and use the knee normally as soon as possible.
- Provide gait training to restore normal gait pattern. By teaching the patient to stop favoring the leg, there will be less strength and range of motion loss owing to disuse.

Management of Pain and Swelling

- Over-the-counter nonsteroidal antiinflammatory medications and acetaminophen may be used as needed to help with swelling control and pain.
- If additional pain control is needed to allow the patient to tolerate rehabilitation during the early phase, injected or oral steroids may be used.
- If a moderate or severe effusion is present, significant relief may also be achieved by draining the knee.

Techniques for Progressive Increase in Range of Motion

- First determine what amount of ROM is normal for the patient.

[1]The timeframes of each phase of the rehabilitation will vary widely between patients. Progression to the next phase of rehabilitation is criteria based rather than time based.

FIGURE 30-10. Patient positioning for measurement of knee extension. Patient is lying supine with both heels propped up on a bolster high enough to allow the knees to fall into hyperextension.

- If the opposite knee is normal, use the ROM of that knee as a baseline for determining how much knee extension and flexion is normal for that patient.
- Most people have some degree of knee hyperextension,[6] so the goal is not to achieve 0° of extension; rather, the goal is to restore normal knee extension, which may include hyperextension.
- In some instances the opposite knee may not be normal and may also have limited ROM, which makes determining the goals for ROM more difficult. When both knees have limited ROM attempts should be made to achieve knee hyperextension, and although the end goal may not be as clearly defined, maximize ROM of both knees until the patient reaches a plateau and do not stop simply because 0° of extension is achieved.
- Measure knee extension by having the patient lie supine and prop both heels up on a bolster high enough to allow the knees to fall into hyperextension (Figure 30-10).
- Perform a low-load, long duration stretch for knee extension/hyperextension three to five times per day.
  - Instruct the patient to perform a 10-minute heel prop with an ankle weight placed above and below the knee joint, AND/OR
  - Use a passive knee extension device for 10 to 15 minutes (Figure 30-11).
- Perform towel stretches into maximal extension. Stabilize the thigh with one hand while using a towel to pull the heel upwards (Figure 30-12). Hold for 5 seconds and perform ten repetitions.

TIMELINE 30-1: Nonoperative Rehabilitation of Meniscus Injuries (Continued)

PHASE III	PHASE IV

• Maintain full knee extension and flexion
• Regain symmetric lower extremity strength
  • Single leg press
  • Single knee extension
  • Step downs
• Continue low impact exercise progression
• Return to low impact sports-related activities (nonrunning/jumping)
	• Return to sport progression
	• Functional progression
	• Sport-specific drills
	• Scrimmage
	• Competition
	• Monitor ROM and swelling, adjust activity level as needed

FIGURE 30-11. A passive knee extension device is used for a low-load, long duration stretch. The patient controls the intensity of the stretch through a hand-held crank.

Activation of Primary Muscles Involved

- Ensure that good neuromuscular control of the quadriceps is achieved.
  - Perform active heel lifts. Have the patient sit with the leg extended, contract the quadriceps muscle group, and actively lift the heel up off of the table (Figure 30-13).
  - If the patient cannot achieve an active heel lift, add a short-arc quad exercise to help facilitate activation of the quadriceps muscle group.

Techniques to Reduce Effusion

- Instruct patient in use of a cold-compression device.
- Advise patient to elevate the knee above the level of the heart while using the cold-compression device and whenever possible.
- Advise patient to avoid high impact activities such as running, jumping, and prolonged walking.

Functional Exercises

- Teach the patient standing and sitting extension habits.

FIGURE 30-12. The towel stretch exercise is used to stretch the knee into maximal extension, including hyperextension.

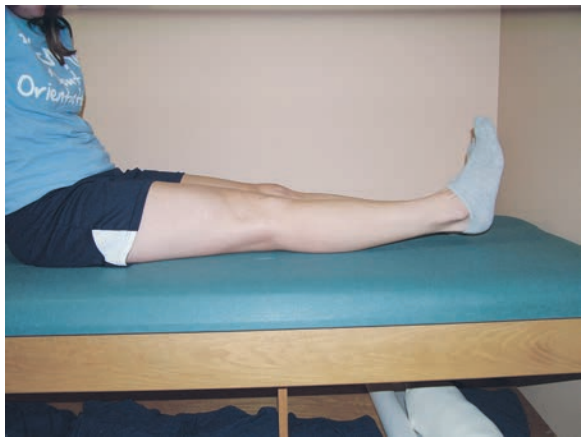

FIGURE 30-13. The active heel lift is performed in a long-sitting position. The patient contracts the quadriceps and dorsiflexes the ankle, elevating the heel above the supporting surface.

  - Stand with body weight shifted onto the involved leg and lock the knee out straight.
  - Sit with the heel propped and knee straight, allowing the knee to fall into hyperextension.

Milestones for Progression to the Next Phase

- Little to no effusion present in the knee
- Full, symmetric knee extension equal to the opposite normal knee

Phase II

Goals

- To restore normal, symmetric knee flexion and maintain symmetric knee extension

Management of Pain and Swelling

- Over-the-counter nonsteroidal antiinflammatory medications and acetaminophen may be used as needed to help with swelling control and pain.

Techniques for Progressive Increase in Range of Motion

- First determine what amount of knee flexion is normal for the patient.
- If the opposite knee is normal, use the range of motion of that knee as a baseline for determining how much knee flexion is normal for that patient.
- Measure knee flexion by having the patient perform a heel slide. Ask the patient to slide the heel toward the buttocks, pulling the knee into as much flexion as possible while in a long-sitting position (Figure 30-14). Compare the involved knee to the non-involved knee.
- Perform a heel slide exercise. Hold the stretch for 5 seconds, then pull the knee into slightly more flexion and hold for an additional 5 seconds.
- If knee flexion is more severely limited, begin with a wall slide exercise (Figure 30-15)

FIGURE 30-14. A heel slide is performed by having the patient use the hands or a towel to slide the heel toward the buttocks as far as possible.

Other Therapeutic Exercises

- Perform towel stretches to monitor knee extension (see Figure 30-12).
- If any loss of knee extension is detected, back off from flexion exercises and return to focusing on knee extension.
- Begin a low impact exercise program using a bike, elliptical, or stair climber. Begin with light resistance and gradually increase time from 5 minutes to 30 minutes. Then slowly increase the resistance.

Functional Exercises

- Continue with standing and sitting extension habits to encourage full knee extension and normal use of the involved leg.

FIGURE 30-15. In cases of more severe knee flexion loss, the wall slide is an effective exercise to improve knee flexion. The patient uses the foot of the noninvolved leg to apply gentle, downward pressure on the foot of the involved leg, increasing the knee flexion of the involved leg.

Milestones for Progression to the Next Phase

- Full, symmetric knee range of motion compared to the opposite, normal knee
- No effusion
- Good neuromuscular control of the quadriceps muscle group

Phase III

Goals

- To restore symmetric lower extremity strength

Management of Pain and Swelling

- Although some activity-related soreness and swelling may occur, pain and swelling should mostly be under control during this phase.
- Patients are advised to use a cold-compression device as needed for swelling and pain control.
- Over-the-counter nonsteroidal antiinflammatory medications and acetaminophen may also be used as needed.

Techniques for Progressive Increase in Range of Motion

- Range of motion should be maximized prior to the beginning of Phase III. Monitor range of motion by performing towel stretch and heel slide and comparing with the opposite, normal knee.
- If any loss of range of motion occurs as the strengthening program is underway, discontinue strengthening exercises and focus on Phase I and II exercises until symmetric range of motion is restored.

Other Therapeutic Exercises

- Objectively measure strength of the quadriceps and hamstring muscle groups for both the involved and noninvolved legs (Cybex, Biodex, etc.)
- If a side-to-side deficit is detected (greater than or equal to 10%), begin single-leg strengthening program 5 to 7 times per week. Reevaluate strength testing on a regular basis and transition to bilateral strengthening exercises once full strength symmetry has been restored.
  - Single leg press
  - Single knee extension
  - Step-down
- Continue to progress the low impact exercise program (bike, elliptical, or stair climber) by increasing resistance and/or increasing workout time.

Sport-Specific Exercises

- Patients involved in low impact sports (nonrunning or jumping) activities may gradually return to these activities at this time.
- Participation in sports requiring running or jumping should be delayed until full strength and range of motion symmetry has been regained.

Milestones for Progression to the Next Phase

- Quadriceps and hamstring muscle group strength at least 90% (involved knee/non-involved knee)
- Full, symmetric knee range of motion compared to the opposite, normal knee.
- No effusion

Phase IV

Goal

- Return to sports

Management of Pain and Swelling

- Some soreness and swelling may occur during this phase as the patient's activity level is increased and should be treated with use of a cold-compression device as needed.

Techniques for Progressive Increase in Range of Motion

- Range of motion should be maximized prior to the beginning of Phase IV. Monitor range of motion by performing towel stretch and heel slide and comparing with the opposite, normal knee.
- If any loss of range of motion occurs during the return to sport phase, discontinue impact activities and focus on Phase I and II exercises until symmetric range of motion is restored.

Other Therapeutic Exercises

- Continue with the low impact exercise program for cardiovascular conditioning and as a form of cross-training.
- Once symmetric strength has been achieved, begin doing lower extremity strengthening program for both legs.

Functional Exercises

- For patients returning to sports requiring change of direction, gradually progress through a functional progression to introduce jumping, planting, and pivoting.
- Add increased speed and multidirectional components to the movement patterns throughout the progression.

Sport-Specific Exercises

- When introducing impact activities (running, jumping, etc.) begin with an every-other-day schedule to allow the knee to adjust to the new level of activity without increasing amounts of soreness or swelling.
- Begin with structured drills to allow the patient to work through each component skill of the sport individually.
- Progress into "scrimmage" situations where skills are combined together in a non-competitive situation.
- Finally, progress to full competition.

Milestones for Progression to Advanced Sport-Specific Training and Conditioning

- Symmetric ROM, symmetric strength, no effusion
- Completion of functional progression

Criteria for Abandoning Nonoperative Treatment and Proceeding to Surgery or More Intensive Intervention

- Continued pain that is isolated to the medial or lateral joint line and limits activity despite attempts to regain symmetry
- Patient is unable to tolerate rehabilitation because of pain that is not controlled with the pain control measures described previously.

Specific Criteria for Return to Sports Participation: Tests and Measurements

- Full, symmetric knee range of motion compared with the opposite, normal knee
- No effusion
- Quadriceps and hamstring muscle group strength at least 90% (involved knee/noninvolved knee)
- Completion of functional progression

Evidence

DeCarlo MS, Sell KE: Normative data for range of motion and single-leg hop in high school athletes. *J Sport Rehab* 6:246–255, 1997.

The authors performed a study to determine normative values of range of motion and single-leg hop tests in high school athletes. This study shows that in normal, healthy subjects, hyperextension of the knee is a normal finding. The mean amount of hyperextension was 5° for males and 6° for females. Furthermore, some degree of hyperextension was found in 95% of the males and 96% of the females. The authors discuss that in light of these findings, the goal for rehabilitation programs should not just be to achieve 0° of extension, rather some degree of hyperextension is normal for most people. (Level III evidence)

Englund M, Guermazi A, Lohmander SL: The role of the meniscus in knee osteoarthritis: A cause or consequence? *Radiol Clin N Am* 47:703–712, 2009.

The authors provide a clinical review of the role of the meniscus and meniscus pathology in osteoarthritis. The difference between acute, traumatic meniscus tears and degenerative meniscus tears is clearly explained and the authors discuss the prevalence of incidental findings of degenerative changes

in the meniscus on MRI, particularly in the middle-aged or older adult age groups. The authors acknowledge that meniscus tears can lead to osteoarthritis, but osteoarthritis can also lead to meniscus tears. They conclude that arthroscopic resection of nonobstructive degenerative lesions may be unnecessary. (Level V evidence)

Fukuta S, Kuge A, Korai F: Clinical significance of meniscal abnormalities on magnetic resonance imaging in an older population. *The Knee* 16:187–190, 2009.

Using MRI, this study evaluated 85 knees of asymptomatic subjects over the age of 40 for meniscal abnormalities. The subjects were divided into two groups based on whether or not they had radiographic evidence of osteoarthritis. The posterior segment of the medial meniscus was the most common location of meniscal abnormalities in both groups. Meniscal abnormalities were found in 63.4% of subjects without osteoarthritis and 80.4% of subjects with osteoarthritis. The authors concluded that there is a high prevalence of asymptomatic meniscus tears in this age group and MRI alone should not be used to evaluate meniscus tears in this age group. (Level III evidence)

Kornick J, Trefelner E, McCarthy S, et al: Meniscal abnormalities in the asymptomatic population at MR imaging. *Radiology* 177:463–465, 1990.

This study evaluated the prevalence of meniscal abnormalities of 70 knees in 64 symptomatic subjects (33 males and 31 females) using MRI. Subjects ranged in age from the second to eighth decade of life. The prevalence of meniscal abnormalities was at least 25% as early as the second decade. The prevalence increased with age, with a prevalence of nearly 60% in the sixth and seventh decades. The most common location for signal abnormalities was in the posterior horn of the medial meniscus. (Level III evidence)

LaPrade RF, Burnett QM, Veenstra MA, et al: The prevalence of abnormal magnetic resonance imaging findings in asymptomatic knees. With correlation of magnetic resonance imaging to arthroscopic findings in symptomatic knees. *Am J Sports Med* 22:739–745, 1994.

This prospective study was done to evaluate the prevalence of abnormal MRI scans of the knee in 54 asymptomatic subjects, ranging in age from 19 to 39 years. A comparison of MRI findings to arthroscopic findings was also done in a separate group of 72 symptomatic subjects to determine the specificity and sensitivity of MRI of the knee joint. The prevalence of meniscal tears in asymptomatic knees was 5.6%, although 24.1% had grade II changes (linear signal not extending to the meniscal surface) in the medial meniscus. The authors caution against using MRI without correlating physical examination findings to determine if surgery is necessary. (Level II and III evidence)

Rimington T, Mallik K, Evans D, et al: A prospective study of the nonoperative treatment of degenerative meniscus tears. *Orthopedics* 32(8):pii, 2009.

The authors performed a prospective study of 26 subjects who were clinically diagnosed with a degenerative meniscus tear. The subjects were followed for 37 months and completed both subjective and objective follow-up testing. All subjects were initially treated with non-steroidal anti-inflammatory drugs for 4 weeks, then they were offered arthroscopic partial meniscectomy or continued nonoperative treatment. Forty-six percent of patients declined surgical treatment and improved to a functional level. The operative group demonstrated significantly higher Modified Lysholm Knee Scores ($p = .04$); however, all other measures showed no difference. The authors concluded that an initial course of nonoperative treatment should be recommended for all patients with degenerative medial meniscus tears. (Level II evidence)

Shelbourne KD, Gray T: Meniscus tears to leave in situ, with or without trephination or synovial abrasion to stimulate healing. *Sports Med Arthros Rev* 20:62–67, 2012.

The authors provide a review of the treatment options based on the type of tear, location of the tear, and whether the tear is in a stable (ACL-intact) or unstable knee. The difference between degenerative and nondegenerative tears is described and their respective treatment options are outlined. Much of the article is based on the decision making for meniscus tears encountered at the time of ACL surgery. (Level V evidence)

Multiple-Choice Questions

QUESTION 1. The first phase of rehabilitation should focus on swelling control and regaining symmetric _____.

A. strength
B. knee extension
C. thigh girth
D. knee flexion

QUESTION 2. Nonoperative treatment of meniscus tears is most appropriate for which type of tear?

A. Medial meniscus
B. Nondisplaced bucket handle
C. Degenerative
D. Meniscus tears associated with ACL tears

QUESTION 3. Normal knee range of motion is defined as:

A. whatever the range of motion of the opposite, normal knee is.
B. 0° of extension to 135° of flexion.
C. 0° of extension to 145° of flexion.
D. 5° of hyperextension to 145° of flexion.

QUESTION 4. When measured objectively, symmetric strength is defined as being within ___% of the opposite knee.

A. 5
B. 10
C. 15
D. 20

QUESTION 5. Forms of lower impact exercise are:

A. Bike
B. Stair climber
C. Elliptical
D. All of the above

Answer Key

QUESTION 1. Correct answer: **B** (see Phase I)

QUESTION 2. Correct answer: **C** (see Introduction)

QUESTION 3. Correct answer: **A** (see Phase I)

QUESTION 4. Correct answer: **B** (see phase III)

QUESTION 5. Correct answer: **D** (see Phase III)

POSTOPERATIVE REHABILITATION AFTER MENISCUS REPAIR

Frank R. Noyes, MD, Timothy P. Heckmann, PT, ATC, and Sue D. Barber-Westin, BS

Indications for Surgical Treatment

- Meniscus tear with unresolved tibiofemoral joint pain
- Patient less than 50 years of age or in 50s and physically active
- Meniscus tear reducible with good tissue integrity affirmed at surgery
- Meniscus tear classified at surgery according to location, type, size, integrity of tissue, and remaining meniscus bed
- Peripheral single longitudinal tears (red-red, one plane)—repairable in all cases, high success rates
- Middle third region (red-white or white-white—often repairable with reasonable success rates
- Outer-third and middle-third regions (red-white, one plane) longitudinal, radial horizontal tears—decision on repair versus excision made at surgery
- Patients willing to comply with postoperative rehabilitation program

Brief Summary of Surgical Treatment

Major Surgical Steps[1]

- Diagnostic arthroscopy
- Meniscus tissue and synovial junction rasped, loose unstable meniscus fragments removed
- Preferred procedure uses multiple vertical divergent sutures
- Neurovascular structures protected throughout procedure with posterolateral or posteromedial exposure and Henning retractor (Figure 30-16)
- Placement of sutures depends on tear pattern.
- Single longitudinal tears: vertical divergent sutures placed 3- to 4-mm intervals along the length of the tear

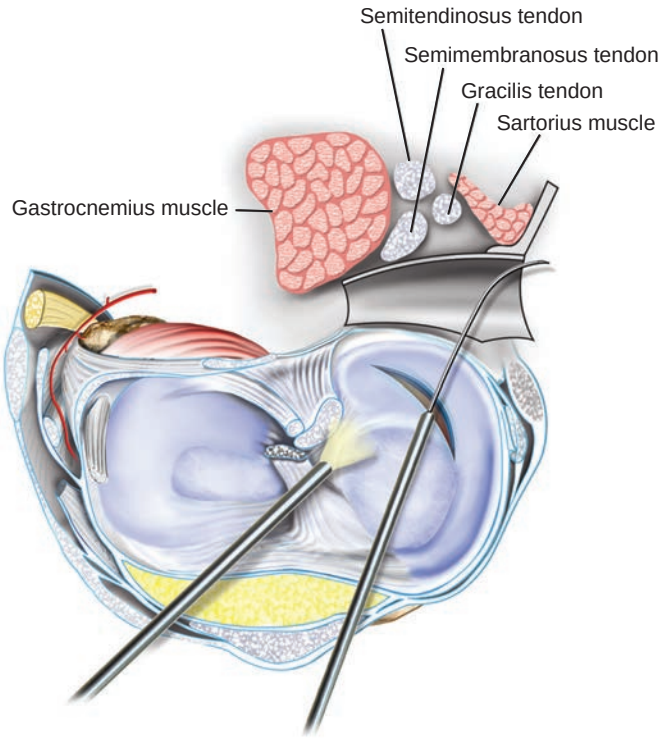

FIGURE 30-16. Cross-section showing popliteal retractor between the posterior capsule and the medial gastrocnemius for a medial meniscus repair. The suture cannula is placed through the lateral or medial portal with care taken to angle the needle away from the neurovascular structures. *(Reprinted with permission from Noyes FR, Barber-Westin SD: Meniscus tears: Diagnosis, repair techniques, and clinical outcomes. In Noyes FR, Barber-Westin SD, editors: Noyes' knee disorders: surgery, rehabilitation, clinical outcomes, Philadelphia, 2009, Saunders, pp. 733–771. Fig. 28-7.)*

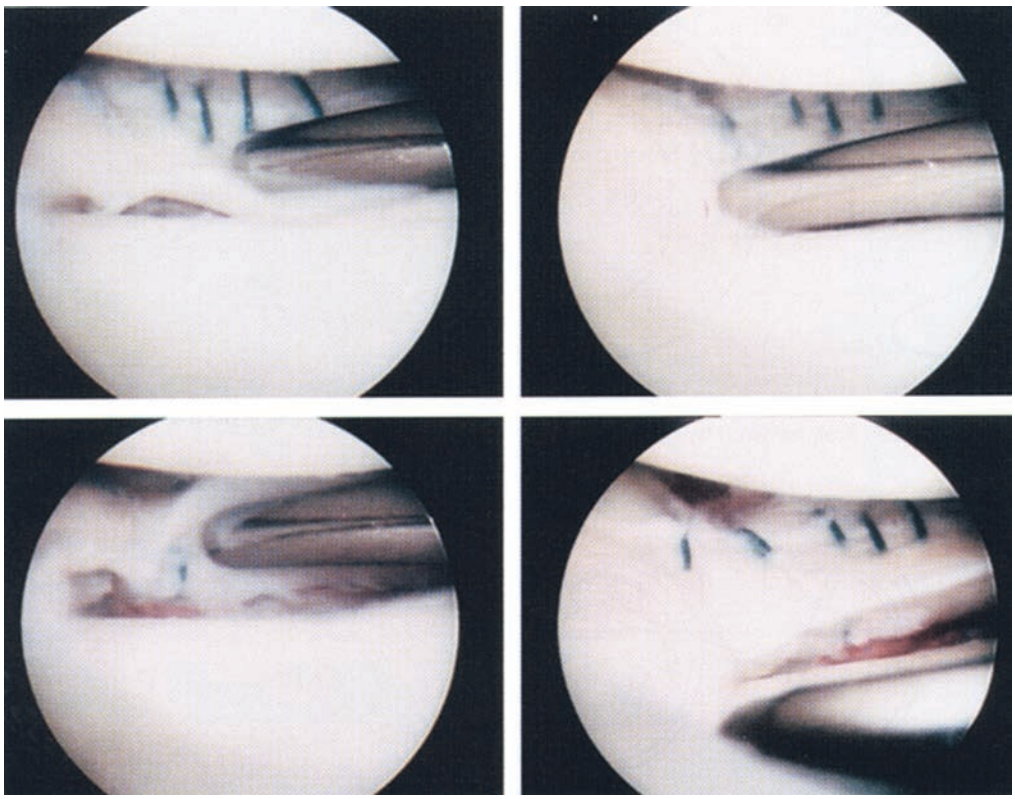

FIGURE 30-17. A longitudinal meniscal tear site demonstrating some fragmentation inferiorly. This tear required multiple superior and inferior vertical divergent sutures to achieve an anatomic reduction. *(Reprinted with permission from Noyes FR, Barber-Westin SD: Arthroscopic repair of meniscal tears extending into the avascular zone in patients younger than twenty years of age. Am J Sports Med 30:589–600, 2002.)*

in alternating fashion; first on the superior surface to reduce the meniscus and then on the inferior surface to close the inferior tear (see Figure 30-3)
- Sutures are brought out through posterolateral or posteromedial accessory incision and tied directly over the posterior meniscal attachment and capsule.
- Tension in each suture is confirmed arthroscopically after the knot is tied
- Double-longitudinal meniscus tears require an additional set of sutures (Figure 30-17; see also Figure 30-4)
- Radial tears are repaired with horizontal sutures placed at 2- to 4-mm intervals along the tear site (see Figure 30-5).
- Flap tears require two sets of sutures (see Figure 30-6).

Factors That May Affect Rehabilitation

- Classification of meniscus tear according to location, type and size of tear, and integrity of meniscal tissue[2]
- Meniscus repairs located in the periphery (outer one-third region) heal rapidly, complex multiplanar repairs that extend into central one-third region require greater caution with rehabilitation
- Type of repair: inside-out multiple vertical sutures versus all-inside
- All-inside repairs use only a few sutures, require delay in full weight bearing and added protection
- Presence of articular cartilage damage, 2-B or 3-A, B (Cincinnati Knee Rating classification)
- Concurrent procedures such as knee ligament reconstruction, high tibial osteotomy, articular cartilage restorative procedures

GUIDING PRINCIPLES OF POSTOPERATIVE REHABILITATION

- Understand type and location of meniscus tear and repair technique.
- Knowledge of concurrent operative procedures and condition of articular cartilage throughout knee joint
- Early return (within 4 to 6 months) to strenuous activities, high impact loading, deep knee flexion, sudden pivoting or twisting carries definite risk of repeat meniscus tear.
- Supervised rehabilitation program is supplemented with home exercises performed daily.
- Be aware of potential complications, signs, symptoms requiring prompt treatment
  - Continued pain in involved tibiofemoral compartment
  - Failure to achieve knee extension and flexion goals according to protocol
  - Decreased patellar mobility (early arthrofibrosis)
  - Decreased voluntary quadriceps contraction and muscle tone
  - Persistent joint effusion, inflammation

Phase I (days 0–14):[2] Immediate Postoperative Period

Clinical Pearls

Important early postoperative signs for the therapist to monitor are effusion, pain, gait, knee flexion and extension, patellar mobility, strength and control of the lower extremity, lower extremity flexibility, and tibiofemoral compartment symptoms. Use modalities such as electrical muscle stimulation, biofeedback, and cryotherapy as required. The patient's response to surgery and progression during the first 14 days sets the tone for the initial phases of rehabilitation. Monitor for posteromedial or infrapatellar burning, posteromedial tenderness along the distal pes anserine tendons, tenderness of Hunter's canal along the medial thigh, hypersensitivity to light pressure or temperature change, abnormal pain response, quadriceps shutdown, and inability to achieve knee motion goals as designated by protocol.

Goals

- Range of motion (ROM) minimum: 0° to 90° first 2 weeks postop
- Weight bearing: toe-touch to half body weight (BW) for peripheral repairs; toe-touch to quarter BW for complex or all-inside repairs; none to toe-touch for radial repairs
- Pain, hemarthrosis controlled
- Good patellar mobility
- Adequate quadriceps contraction

Protection

- Long-leg postoperative brace for complex or all-inside meniscus repairs. Brace is opened from 0° to 90°, but is locked at 0° at night. Brace not routinely used for peripheral repairs.
- Crutches. Toe-touch to half BW for peripheral repairs. Toe-touch to quarter BW for complex and all-inside repairs. None to toe-touch weight bearing for radial repairs. "Sponge (very light) pressure" allowed during toe-touch weight bearing.

Management of Pain and Swelling

- Oral medications as required
- Therapeutic modalities: electrical muscle stimulation, cryotherapy
- Elevate lower limb as frequently as possible.

Techniques for Progressive Increase in Range of Motion

- Begin first day postoperative
  - Passive knee flexion and passive and active/active-assisted knee extension exercises
  - Seated position, 0° to 90°, three to four times a day in 10-minute sessions
  - Active knee flexion is limited to avoid hamstring strain to the posteromedial joint.
  - Hyperextension avoided in anterior horn meniscus repairs.
- Patellar mobilization in superior, inferior, medial, and lateral directions
- Hamstring and gastrocnemius-soleus flexibility

TIMELINE 30-2: **Postoperative Rehabilitation After Meniscus Repair**

PHASE I (weeks 1 to 2)	PHASE II (weeks 3 to 6)
• Brace • Toe-touch to ½ BW for peripheral repairs • Toe-touch to ¼ BW for complex and all-inside repairs • None to toe-touch weight bearing for radial repairs • ROM 0°–90°, begin first day postoperative • Patellar mobilization • Flexibility: hamstrings, gastrocnemius-soleus • Weight shifting side-side, forward-backward • Cup walking • Quadriceps isometrics • Straight leg raises, flexion only • Active-assisted knee extension 90°-30°	• Brace • Full weight bearing peripheral repairs weeks 3–4 • Weight bearing ½ to ¾ BW complex, all-inside repairs (increase by approximately 25% per week) • ROM 0°–135° by week 6 • Patellar mobilization • Flexibility: hamstrings, gastrocnemius-soleus • Double-leg balance exercises • Balance board • Minitrampoline for balance exercises • Multi-angle quadriceps isometrics • Straight leg raises flexion, extension, abduction, adduction • Knee extension, active-assisted, 90°–0° • Toe raises, heel raises • Wall sits (above 60°) • Minisquats (0°–40°) • Hamstring curls, peripheral repairs (0°–90°) • Leg press, peripheral repairs (70°–10°) • Knee extension (90°–30°) • Multihip • Upper body ergometer

FIGURE 30-18. Extension overpressure hanging-weight exercise. *(Reprinted with permission from Heckmann TP, Noyes FR, Barber-Westin SD: Rehabilitation of meniscus repair and transplantation procedures. In Noyes FR, Barber-Westin SD, editors: Noyes' knee disorders: surgery, rehabilitation, clinical outcomes, Philadelphia, 2009, Saunders, pp. 806–817, Figure 30-3.)*

- If 0° to 90° not achieved by seventh day postoperative, begin overpressure exercises.
  - Hanging weights for extension (Figure 30-18)
  - Rolling stool, wall-sliding for flexion (Figures 30-19, 30-20)
  - Commercially available ROM devices

Activation of Primary Muscles Involved in Injury Area or Surgical Structures

- Activation of the quadriceps, hamstrings, gastrocnemius-soleus, and hip musculature is accomplished immediately postoperatively with the exercises described in this time frame.

Electrical muscle stimulation and/or biofeedback may be used to enhance quadriceps contraction.

FIGURE 30-19. Rolling stool overpressure exercise for knee flexion. *(Reprinted with permission from Heckmann TP, Noyes FR, Barber-Westin SD: Rehabilitation of primary and revision anterior cruciate ligament reconstructions. In Noyes FR, Barber-Westin SD, editors: Noyes' knee disorders: surgery, rehabilitation, clinical outcomes, Philadelphia, 2009, Saunders, pp. 306–336, Figure 13-7A.)*

Sensorimotor Exercises

- Begin first week postoperative during partial weight-bearing period.
  - Weight shifting side-to-side and front-to-back with crutch support
  - Cup walking to develop symmetry between limbs, hip and knee flexion, quadriceps control during

TIMELINE 30-2: Postoperative Rehabilitation After Meniscus Repair (Continued)

PHASE III (weeks 7 to 12)	PHASE IV (weeks 13 to 26)	PHASE V (weeks 27+)
• DC brace, crutches • Full weight bearing • Flexibility: hamstrings, gastrocnemius-soleus, quadriceps, iliotibial band • Balance board • Lateral step-ups (5–10 cm) • Stationary bicycling (high seat/ low resistance) • Swimming, straight leg kicking (light, from hip) • Walking (level) • Stair climbing machine (short stroke/ decreased resistance) • Ski machine (decreased resistance) • Elliptical cross-trainer (decreased resistance) • Straight leg raises: flexion, extension, abduction, adduction (up to 10% BW) • Knee extension, active-assisted, 90°-0° • Toe raises, heel raises • Wall sits (above 60°) • Minisquats, rubber tubing (0°–40°) • Hamstring curls (0°–90°) • Leg press, start weeks 9–12 for complex repairs • Knee extension • Multihip	• Stationary bicycling • Swimming, straight leg kicking • Water walking • Stair climbing machine • Ski machine • Elliptical cross-trainer • Balance board • Single-leg stance, unstable platform • Perturbation training • Ball toss on plyoback, single-leg stance • Straight leg raises, rubber tubing • Minisquats, rubber tubing • Hamstring curls • Leg press, start weeks 9–12 for complex repairs • Knee extension • Multihip • Running program week 16–20 peripheral repairs, based on criteria provided • Running program week 24 complex repairs, based on criteria provided • Cutting, carioca, agility drills week 24 peripheral repairs • Plyometrics week 24 peripheral repairs, based on criteria provided • Sport-specific exercises week 20–24 peripheral repairs • Return to sports, peripheral repairs: based on criteria provided	• Stationary bicycling • Swimming, straight leg kicking • Water walking • Stair climbing machine • Ski machine • Elliptical cross-trainer • Balance board • Single-leg stance, unstable platform • Perturbation training • Ball toss on plyoback, single-leg stance • Straight leg raises, rubber tubing • Minisquats, rubber tubing • Hamstring curls • Leg press • Knee extension • Multi-hip • Cutting, carioca, agility drills week 30 complex repairs • Plyometrics week 30 peripheral repairs, based on criteria provided • Sport-specific exercises week 30 peripheral repairs • Return to sports, complex repairs: based on criteria provided

FIGURE 30-20. Wall slide overpressure exercise for knee flexion. *(Reprinted with permission from Heckmann TP, Noyes FR, Barber-Westin SD: Rehabilitation of primary and revision anterior cruciate ligament reconstructions. In Noyes FR, Barber-Westin SD, editors: Noyes' knee disorders: surgery, rehabilitation, clinical outcomes, Philadelphia, 2009, Saunders, pp. 306–336, Fig. 13-7C.)*

midstance, hip and pelvic control during midstance, and gastrocnemius-soleus control during pushoff (Figure 30-21).

Open and Closed Kinetic Chain Exercises

- Begin first day postoperative.
  - Quadriceps isometrics: one set × 10 repetitions every hour patient is awake
  - Straight leg raises, flexion plane only initially: three sets × 10 repetitions
    - Add leg raises in extension, abduction, adduction planes when patient has sufficient quadriceps control to prevent an extensor lag during flexion plane leg raises.

FIGURE 30-21. Cup walking. *(Reprinted with permission from Heckmann TP, Noyes FR, Barber-Westin SD: Rehabilitation of meniscus repair and transplantation procedures. In Noyes FR, Barber-Westin SD, editors: Noyes' knee disorders: surgery, rehabilitation, clinical outcomes, Philadelphia, 2009, Saunders, pp. 806–817, Figure 30-6A.)*

  - Active-assisted knee extension 90° to 0°: three sets × 10 repetitions. Limit to 90° to 30° for anterior horn repairs.

Milestones for Progression to the Next Phase

- ROM 0° to 90°
- Adequate quadriceps contraction, exhibited by no extensor lag on supine straight leg raise
- Pain, inflammation controlled
- Good patellar mobility: patient or therapist is able to move the patella medial-lateral and inferior-superior directions without problems.

Phase II (weeks 3 to 6)

Clinical Pearl

By 6 weeks postoperative, the patient should have at least 0° to 135° of knee motion and a normal gait pattern.

Goals

- ROM 0° to 135°
- Gradually resume full weight bearing with a normal gait pattern.
- Begin closed-chain exercises.
- Progress balance, proprioceptive training.
- Progress lower extremity strength exercises.

Protection

- Brace discontinued week 6 for complex and all-inside meniscus repairs; 6 to 8 weeks for radial repairs.
- Crutches discontinued week 4 for peripheral repairs.
- Half to full weight bearing for complex and all-inside repairs

Management of Pain and Swelling

- Continue cryotherapy following all exercise sessions.
- Oral medications if required

Techniques for Progressive Increase in Range of Motion

- ROM is increased to 120° by weeks 3 to 4 and 135° by weeks 5 to 6.
  - Patients who fail to achieve these goals are placed into the overpressure program and should be evaluated by the surgeon.
  - Gentle manipulation under anesthesia may be indicated for noteworthy limitations of knee motion by week 6.

Other Therapeutic Exercises

- Upper body ergometer at 3 to 4 weeks if available

Activation of Primary Muscles Involved in Injury Area or Surgical Structures

- Activation of the quadriceps, hamstrings, gastrocnemius-soleus, and hip musculature is accomplished with the exercises described in this time frame.

Sensorimotor Exercises

- Double-leg balance exercises: The patient should point the feet straight ahead in tandem (heel/toe), flex the knee 20° to 30°, extend the arms outward to horizontal, and position the torso upright with the shoulders above the hips and the hips above the ankles. Stand in this position until balance is disturbed.
  - Balance exercises may be done on a minitrampoline for greater challenge.
- Walk on Styrofoam half rolls and whole rolls
- Balance board

Open and Closed Kinetic Chain Exercises

- Multiangle quadriceps isometrics (active), 0°, 30°, 60°, 90°: 1 set × 10 repetitions each
- Straight leg raises in flexion, extension, abduction, and adduction: 3 sets × 10 repetitions. Add ankle weights at 5 to 6 weeks of less than 10% of body weight.
- Knee extension (active/ active-assisted) 90 to 0°: three sets × 10 repetitions. Limit to 90° to 30° for anterior horn repairs
- Toe raises: three sets × 20 repetitions
- Heel raises begin at 5 to 6 weeks: three sets × 10 repetitions
- Wall sits (above 60°) to fatigue: three sets
- Minisquats: 3 sets
- At 5 to 6 weeks, peripheral meniscus repairs, hamstring curls, 0° to 90°: three sets × 10 repetitions
- At 5 to 6 weeks, peripheral meniscus repairs, leg press, 70 to 10°: three sets × 10 repetitions
- At 5 to 6 weeks, all repairs, multi-hip machine (flexion, extension, abduction, adduction): three sets × 10 repetitions
- 5 to 6 weeks, all repairs, knee extension (resisted), 90° to 30°: three sets × 10 repetitions

Milestones for Progression to the Next Phase

- ROM 0° to 135°
- Normal gait
- Normal patellar mobility: patient or therapist able to move the patella in all directions without resistance
- Pain, effusion controlled
- Muscle control throughout ROM as observed by therapist as patient performs exercises

Phase III (weeks 7 to 12)

Clinical Pearl

Full return to activities of daily living by 8 to 12 weeks postoperative. Precautions include no impact loading, no pivoting or twisting, no deep squatting.

Goals

- Progress lower extremity strength
- Progress balance, proprioception
- Increase endurance

Protection

- Crutches discontinued weeks 8 to 12 for complex, all-inside, and radial repairs
- Weight bearing advanced per gait pattern and change in knee symptoms

Management of Pain and Swelling

- Cryotherapy as required

Techniques for Progressive Increase in Range of Motion

- If knee motion is still limited during this time period, a gentle manipulation under anesthesia may be indicated. Severe limitations may be treated with arthroscopic debridement. The program for treatment of knee motion problems has been described in detail.[3]
- Flexibility: hamstring, gastrocnemius-soleus, quadriceps, iliotibial band

Other Therapeutic Exercises

- Weeks 7 to 8: stationary bicycling, 15 minutes, one to two times a day
- Weeks 9 to 12 (select one activity a day for 15 minutes)
  - Stationary bicycling
  - Water walking
  - Swimming with straight leg kicking
  - Walking
  - Stair climbing machine, low resistance, low stroke
  - Ski machine, short stride, level, low resistance
  - Elliptical cross-trainer

Activation of Primary Muscles Involved in Injury Area or Surgical Structures

- Activation of the quadriceps, hamstrings, gastrocnemius-soleus, and hip musculature is accomplished with the exercises described in this time frame.

Sensorimotor Exercises

- Balance board: two-legged, three times per day for 5 minutes
- Lateral step-ups: 5- to 10-cm block, three times per day, three sets × 10 repetitions
- Resisted gait training: resisted band marching and elastic band resistance to terminal single leg standing balance

Open and Closed Kinetic Chain Exercises

- Straight leg raises flexion, extension, adduction, abduction: three sets × 10 repetitions
  - Add rubber tubing, three sets × 30 repetitions

- Toe and heel raises: three sets × 10 repetitions
- Wall sits, to fatigue: three sets
- Minisquats: three sets
  - Weeks 9 to 12: add rubber tubing, 0° to 40°: three sets × 20 repetitions
- Hamstring curls all meniscus repairs, active: three sets × 10 repetitions
- Knee extension, active, 90° to 30°: three sets × 10 repetitions
- Multihip: three sets × 10 repetitions
- Leg press, 70° to 10°: three sets × 10 repetitions
  - Start weeks 9 to 12 for complex repairs.

Techniques to Increase Muscle Strength, Power, and Endurance

- See Open and Closed Kinetic Chain Exercises described above.

Neuromuscular Dynamic Stability Exercises

- See Sensorimotor Exercises described above.

Milestones for Progression to the Next Phase

- No effusion, painless ROM
- Performs daily activities without problems
- Can walk 20 minutes without pain
- Normal range of motion

Phase IV (weeks 13 to 26)

Clinical Pearl

Primary focus during this phase is developing lower extremity muscle strength and cross-training for cardiovascular endurance.

Goals

- Increase strength and endurance.
- Peripheral repairs may begin running program 20 weeks postoperative if tolerated (Box 30-1)

Management of Pain and Swelling

- Cryotherapy as required

Therapeutic Exercises

- Patients encouraged to perform upper body and core strengthening according to future desired activity level.
- Aerobic conditioning, three times a week for 20 minutes; select one activity per session
  - Stationary bicycle
  - Water walking
  - Swimming, straight-leg kicking
  - Walking
  - Stair climbing machine
  - Ski machine
  - Elliptical cross-trainer

BOX 30-1 Running Program for Rehabilitation of Meniscus Injuries

A running program is begun at approximately 20 weeks postoperative in patients who had peripheral meniscus repairs and who have no more than a 30% deficit in average peak torque for the quadriceps and hamstrings on isometric testing performed on a Biodex dynamometer (Biodex Corp., Shirley, NY). This program is delayed until approximately 30 weeks postoperative in patients who had complex meniscus repairs and until at least 1 year postoperative in patients who had a meniscus transplant.

Isometric muscle testing is initially performed at an angle of 60° of knee flexion, which places the knee in a protected position for both the meniscus and the patella. Progression to isokinetic testing at high speeds is important, but the initial goal is to test the integrity of the quadriceps and hamstring musculatures. Other testing parameters worth evaluating include peak torque to bodyweight ratios, agonist-to-antagonist ratios, and time to peak torque values.

Patients begin with a walk/run combination program, using running distances of 18, 37, 55, and 91 meters. Initially, patients run at 25% to 50% of their normal speed. Once patients can run straight ahead at full speed, lateral and crossover maneuvers are added. Short distances (such as 18 m) are used to work on speed and agility. Side-to-side running over cups may be used to facilitate agility and proprioception. Figure-eight and carioca running drills are also useful.

Running, Begin

- 20 wk postoperative peripheral meniscus repairs
- 30 wk postoperative complex meniscus repairs
- Minimum 1 yr postoperative meniscus transplants

Patient must demonstrate no more than 30% deficit in quadriceps and hamstrings peak torque on isometric testing.

Use Walk/Run Program Initially

- 18, 37, 55, 91 m
- 25%–50% normal running speed, straight
- Progress to 100% speed

Add lateral, crossover, side-to-side, figure eights, carioca drills for agility

(From Heckmann TP, Noyes FR, Barber-Westin SD: Rehabilitation of meniscus repair and transplantation procedures. In Noyes FR, Barber-Westin SD, editors: *Noyes' knee disorders: surgery, rehabilitation, clinical outcomes*, Philadelphia, 2009, Saunders, *pp. 806–817*.)

Activation of Primary Muscles Involved in Injury Area or Surgical Structures

- Activation of the quadriceps, hamstrings, gastrocnemius-soleus, and hip musculature is accomplished with the exercises described in this time frame.

Sensorimotor Exercises

- Balance board, two-legged, three times a day for 5 minutes

- Single-leg stance, unstable platform, three times a day for 5 minutes
- Perturbation training
- Ball toss on plyoback, single-leg stance

Open and Closed Kinetic Chain Exercises

- Straight leg raises with rubber tubing, high speed: three sets × 30 repetitions
- Minisquats, rubber tubing, 0° to 40°: three sets × 20 repetitions
- Hamstring curls, with resistance, 0° to 90°: three sets × 10 repetitions
- Knee extension, active with resistance, 90° to 30°: three sets × 10 repetitions
- Multi-hip: three sets × 10 repetitions
- Leg press, 70° to 10°: three sets × 10 repetitions

Techniques to Increase Muscle Strength, Power, and Endurance

- See Open and Closed Kinetic Chain Exercises.

Neuromuscular Dynamic Stability Exercises

- See Sensorimotor Exercises.

Plyometrics

- Week 24 for peripheral meniscus repairs only. Must have completed running program.
- Level surface box hops on 4-square grid. Double-legged hops, land in knee flexion. 4 levels.
- Single-leg hops
- Vertical box hops

Functional Exercises

- Week 16 to 20: peripheral meniscus repairs allowed to begin running program if tolerated. Patient must have less than 30% deficit in quadriceps and hamstrings peak torque on isometric and/or isokinetic testing to begin running.
- Week 24: peripheral meniscus repairs allowed to begin cutting, carioca, figure 8 agility, plyometrics (box hops, level, double-leg) if tolerated. Must have less than 20% deficit for quadriceps/hamstrings peak torque on isometric and/or isokinetic testing to begin plyometrics.

Sport-Specific Exercises

- Begin week 20 to 24 for peripheral meniscus repairs.

Milestones for Progression to the Next Phase

- No pain, effusion
- Can perform ADL, walk for 20 minutes without pain

Phase V (weeks 27 and beyond)

Clinical Pearls

Return to activity at 6 to 9 months for peripheral repairs, 9 to 12 months for complex, all-inside and radial repairs.

Condition of the articular cartilage may also be a determining factor for functional progressions.

Goals

- Increase strength, endurance, lower extremity function.
- Return to previous or desired activity level.

Management of Pain and Swelling

- Cryotherapy as required

Therapeutic Exercises

- Patients encouraged to perform upper body and core strengthening according to future desired activity level.
- Aerobic conditioning, three times a week for 20 to 30 minutes; select one activity per session
  - Stationary bicycle
  - Water walking
  - Swimming, straight-leg kicking
  - Walking
  - Stair climbing machine
  - Ski machine
  - Elliptical cross-trainer

Sensorimotor Exercises

- Balance board, two-legged, three times a day for 5 minutes
- Single-leg stance, unstable platform, three times a day for 5 minutes. Progress from 2-legged to 1-legged activity.
- Perturbation training
- Ball toss on plyoback, single-leg stance

Open and Closed Kinetic Chain Exercises

- Straight-leg raises with rubber tubing, high speed: 3 sets × 30 repetitions
- Minisquats, rubber tubing, 0° to 40°: three sets × 20 repetitions
- Knee extension, active with resistance, 90° to 30°: three sets × 10 repetitions
- Hamstring curls, with resistance, 0° to 90°: three sets × 10 repetitions
- Multihip: three sets × 10 repetitions
- Leg press, 70° to 10°: three sets × 10 repetitions

Techniques to Increase Muscle Strength, Power, and Endurance

- See Open and Closed Kinetic Chain Exercises.

Neuromuscular Dynamic Stability Exercises

- See Sensorimotor Exercises.

Plyometrics

- Week 30 for complex meniscus repairs. Must have completed running program.
- Level surface box hops on 4-square grid. Double-legged hops, land in knee flexion. 4 levels.
- Single-leg hops
- Vertical box hops

Functional Exercises

- Week 24: complex meniscus repairs allowed to begin running program if tolerated. Patient must have less than 30% deficit in quadriceps and hamstrings peak torque on isometric and/or isokinetic testing to begin running.
- Week 30: complex meniscus repairs allowed to begin cutting, carioca, figure 8 agility, plyometrics (box hops, level, double-leg) if tolerated. Patient must have less than 20% deficit in quadriceps and hamstrings peak torque on isometric and/or isokinetic testing to advance to cutting.

Sport-Specific Exercises

- Begin week 30 for complex meniscus repairs.

Criteria for Return to Sport

- No knee joint pain or swelling
- Full range of knee motion
- Less than or equal to 10% deficit quadriceps and hamstrings strength isokinetic testing
- Less than or equal to 15% deficit lower limb symmetry single-leg hop testing
- Successful completion running and functional training
- Complete trial of function by returning to sport, monitor for overuse symptoms
- Patient education for re-evaluation if any future knee problems occur

After Return to Sport

Continuing Fitness or Rehabilitation Exercises

- Aerobic conditioning recommended according to patient activity levels.
- Lower extremity strengthening to be advanced or maintained as required.

Evidence

The authors' postoperative rehabilitation program following meniscus repairs (performed with inside-out multiple vertical divergent suture techniques) in both the peripheral and central avascular regions has been used in the following clinical studies.

Buseck MS, Noyes FR: Arthroscopic evaluation of meniscal repairs after anterior cruciate ligament reconstruction and immediate motion. *Am J Sports Med* 19:489–494, 1991.

The healing rate of 79 meniscus tears that underwent follow-up arthroscopy an average of 12 months postoperative was determined in 66 patients. Fifty-one repairs were done for tears located in the periphery or outer third region and 28 for tears that extended into the central avascular region. The healing rates for tears in the periphery or outer third region were 94% complete, 4% partial, and 2% failed. The healing rates for tears in the central avascular region were 54% healed, 32% partially healed, and 14% failed. The results allowed recommendation for routine repair of meniscus tears located in the periphery as well as those that extend into the central region, including flap and double longitudinal tears. (Level IV evidence)

Noyes FR, Barber-Westin SD: Arthroscopic repair of meniscus tears extending into the avascular zone with or without anterior cruciate ligament reconstruction in patients 40 years of age and older. *Arthroscopy* 17:822–829, 2000.

A prospective study was performed to determine the outcome of meniscus repairs for tears that extended into the central avascular region in a case series of patients 40 years of age or older. A total of 30 meniscus repairs in 29 patients were evaluated by a clinical examination a mean of 34 months postoperative, by follow-up arthroscopy a mean of 24 months postoperative, or both. The mean age of the patients was 45 years (range, 40 to 58 years). We found that 87% of the meniscus repairs were asymptomatic for tibiofemoral symptoms and had not required subsequent surgery. Three repairs failed and required partial meniscectomy and one with tibiofemoral symptoms related to the repair had been treated conservatively. There were no infections, knee motion limitations, or other complications. In athletically active patients, the recommendation was made to preserve meniscal tissue whenever possible regardless of age. Indications should be based on current and future activity levels and the condition of the meniscal tissue determined at surgery. (Level IV evidence)

Noyes FR, Barber-Westin SD: Arthroscopic repair of meniscal tears extending into the avascular zone in patients younger than twenty years of age. *Am J Sports Med* 30:589–600, 2002.

A prospective study was conducted on 71 meniscal repairs in 64 knees for tears extending into the central third avascular region in patients less than 20 years of age. We followed 67 repairs with a clinical examination a mean of 51 months after surgery and 36 by follow-up arthroscopy a mean of 18 months postoperative. The meniscus tears included single longitudinal, double longitudinal, triple longitudinal, horizontal, radial, and flap. We found that 75% of the patients had no tibiofemoral compartment symptoms at follow-up. In 25%, patients had tibiofemoral symptoms that lead to arthroscopy or were deemed clinical failures on examination. There were no complications or limitations of knee motion. Repair of these meniscus tears was recommended in young active patients. (Level IV evidence)

Noyes FR, Chen RC, Barber-Westin SD, et al: Greater than 10-year results of red-white longitudinal meniscal repairs in patients 20 years of age or younger. *Am J Sports Med* 39:1008–1017, 2011.

A prospective longitudinal investigation was conducted to determine the long-term outcome of single longitudinal

meniscal repairs that extended into the central third avascular region in patients aged 20 years or younger. Thirty-three repairs were performed; the long-term success rate was determined in 29 repairs using 2 validated knee rating systems, advanced 3T MRI using T2 mapping, weight-bearing posteroanterior radiographs, a comprehensive knee examination, and follow-up arthroscopy when required. The mean follow-up was 16.8 years (range, 10.1–21.9 years). The data showed that 18 (62%) of the meniscus repairs had normal or nearly normal characteristics. Six required partial arthroscopic resection, two had loss of joint space on radiographs, and three failed according to MRI criteria. There were no limitations of knee motion or other complications. A chondroprotective joint effect was demonstrated in the healed meniscus repairs, warranting the procedure in young active patients. (Level IV evidence)

Rubman MH, Noyes FR, Barber-Westin SD: Arthroscopic repair of meniscal tears that extend into the avascular zone. A review of 198 single and complex tears. *Am J Sports Med* 26: 87–95, 1998.

We determined the results of 198 meniscus tears that extended into the central avascular region in 177 patients. The repairs were evaluated by clinical examination a mean of 42 months postoperative, by follow-up arthroscopy a mean of 18 months postoperative, or both. We found that 80% of the 198 tears were asymptomatic for tibiofemoral joint symptoms and had not failed clinically. The remaining 20% had tibiofemoral symptoms related to the repair that required follow-up arthroscopy. There were statistically significant differences in the rates of healing for tibiofemoral compartment of the repair, time from repair to follow-up arthroscopy, and the presence of tibiofemoral joint symptoms. There were no limitations of knee motion or complications other than one infection which resolved with treatment. The results allowed recommendation of repair of these meniscal tears in young active patients. (Level IV evidence)

Multiple-Choice Questions

QUESTION 1. Which of the following is not considered as part of the criteria for classifying meniscus tears?

A. Type of tear
B. Location of tear
C. Degree of articular cartilage damage
D. Size of tear

QUESTION 2. Which of the following meniscal repairs requires the greatest degree of protection in the postoperative recovery phase?

A. Peripheral repair
B. Radial repair
C. Complex repair
D. All inside repair

QUESTION 3. Which of the following is not considered an important precaution during the postoperative rehabilitation when attempting to minimize risk for reinjury?

A. High impact loading
B. Sudden pivoting or twisting
C. Deep weight bearing knee flexion
D. Resisted knee extension

QUESTION 4. Which of the following is not considered to be a possible early postsurgical complication of meniscus repair?

A. Delayed return to running
B. Limitation of knee motion
C. Quadriceps inhibition
D. Hypersensitivity and/or burning

QUESTION 5. Return to activity after a meniscus repair requires careful consideration of both subjective and objective measurements. Which of the following factors would not be considered acceptable in allowing the patient to return to full activity?

A. Successful completion of running/functional training
B. No knee pain and/or swelling
C. Greater than 30% deficit of quadriceps and hamstrings on an isokinetic strength test
D. Full range of motion

Answer Key

Question 1. Correct answer: **C** (see Indications for Surgery)

Question 2. Correct answer: **B** (see Immediate Postop Period):

Question 3. Correct answer: **D** (see Principles of Postop Rehab Box)

Question 4. Correct answer: **A** (see Clinical Pearls section, Phase 1)

Question 5. Correct answer: **C** (see criteria for Return to Sport, Week 27)

POSTOPERATIVE REHABILITATION AFTER MENISCUS REPAIR AND PRIMARY ANTERIOR CRUCIATE LIGAMENT RECONSTRUCTION

Frank R. Noyes, MD, Timothy P. Heckmann, PT, ATC,
and Sue D. Barber-Westin, BS

Indications for Surgical Treatment

- Meniscus tear with unresolved tibiofemoral joint pain
- Complete anterior cruciate ligament (ACL) tear (grade 2 to 3 pivot shift, Lachman)
  - This chapter discusses primary ACL reconstruction only.
- Patients less than 50 years of age or in their fifties and physically active
- Meniscus tear reducible with good tissue integrity affirmed at surgery
- Meniscus tear classified at surgery according to location, type, size, integrity of tissue, and remaining meniscus bed
- Peripheral single longitudinal tears (red-red, one plane)—repairable in all cases, high success rates
- Middle third region (red-white or white-white)—often repairable with reasonable success rates
- Outer-third and middle-third regions (red-white, one plane) longitudinal, radial horizontal tears—decision repair versus excision made at surgery
- Patients willing to comply with postoperative rehabilitation program

Brief Summary of Surgical Treatment

Major Surgical Steps

- Diagnostic arthroscopy
- Description of meniscus repair provided in previous section of this chapter
- ACL reconstruction operative techniques described in detail elsewhere[1]
- Prefer bone-patellar tendon-bone (B-PT-B) autograft for athletes, semitendinosus-gracilis (STG) autograft in recreational or more sedentary patients or those with patellofemoral problems
- B-PT-B graft harvested (Figure 30-22), placed in central anatomic tibial and femoral attachment sites (Figure 30-23).
- Avoid proximal ACL femoral attachment and posterior ACL tibial attachment locations, as these result in a vertically oriented graft that does not resist rotational coupled motions (Figure 30-24).
- B-PT-B graft passed, femoral fixation secured with interference screw, graft conditioned at 44 N for 40 cycles, graft position verified arthroscopically, tibial fixation with interference screw
- Perform Lachman test, and ensure the knee is not overconstrained.
- STG graft femoral fixation: endobutton. Tibial fixation: interference screw plus suture post.

Factors That May Affect Rehabilitation

- Classification of meniscus tear according to location, type and size of tear, and integrity of meniscal tissue[2]
- Meniscus repairs located in the periphery (outer ⅓ region) heal rapidly, complex multiplanar repairs that extend into central one-third region require greater caution with rehabilitation
- Type of repair: inside-out multiple vertical sutures versus all-inside
- All-inside repairs use only a few sutures, require delay in full weight bearing and added protection
- Presence of articular cartilage damage, 2-B or 3-A, B (Cincinnati Knee Rating classification)

GUIDING PRINCIPLES OF POSTOPERATIVE REHABILITATION[2]

- Understand type and location of meniscus tear and repair technique.
- Know type of ACL graft and fixation used.
- Know concurrent operative procedures and condition of articular cartilage throughout knee joint.
- Early return (within 4 to 6 months) to strenuous activities, high impact loading, and deep knee flexion carry a definite risk of repeat meniscus tear or reinjury to the knee.
- A supervised rehabilitation program is supplemented with home exercises performed daily.[3,4]
- Be aware of potential complications, signs, and symptoms requiring prompt treatment:
  - Continued pain in involved tibiofemoral compartment
  - Failure to achieve knee extension and flexion goals according to protocol[5]
  - Decreased patellar mobility (early arthrofibrosis)
  - Decreased voluntary quadriceps contraction and muscle tone
  - Persistent joint effusion, inflammation

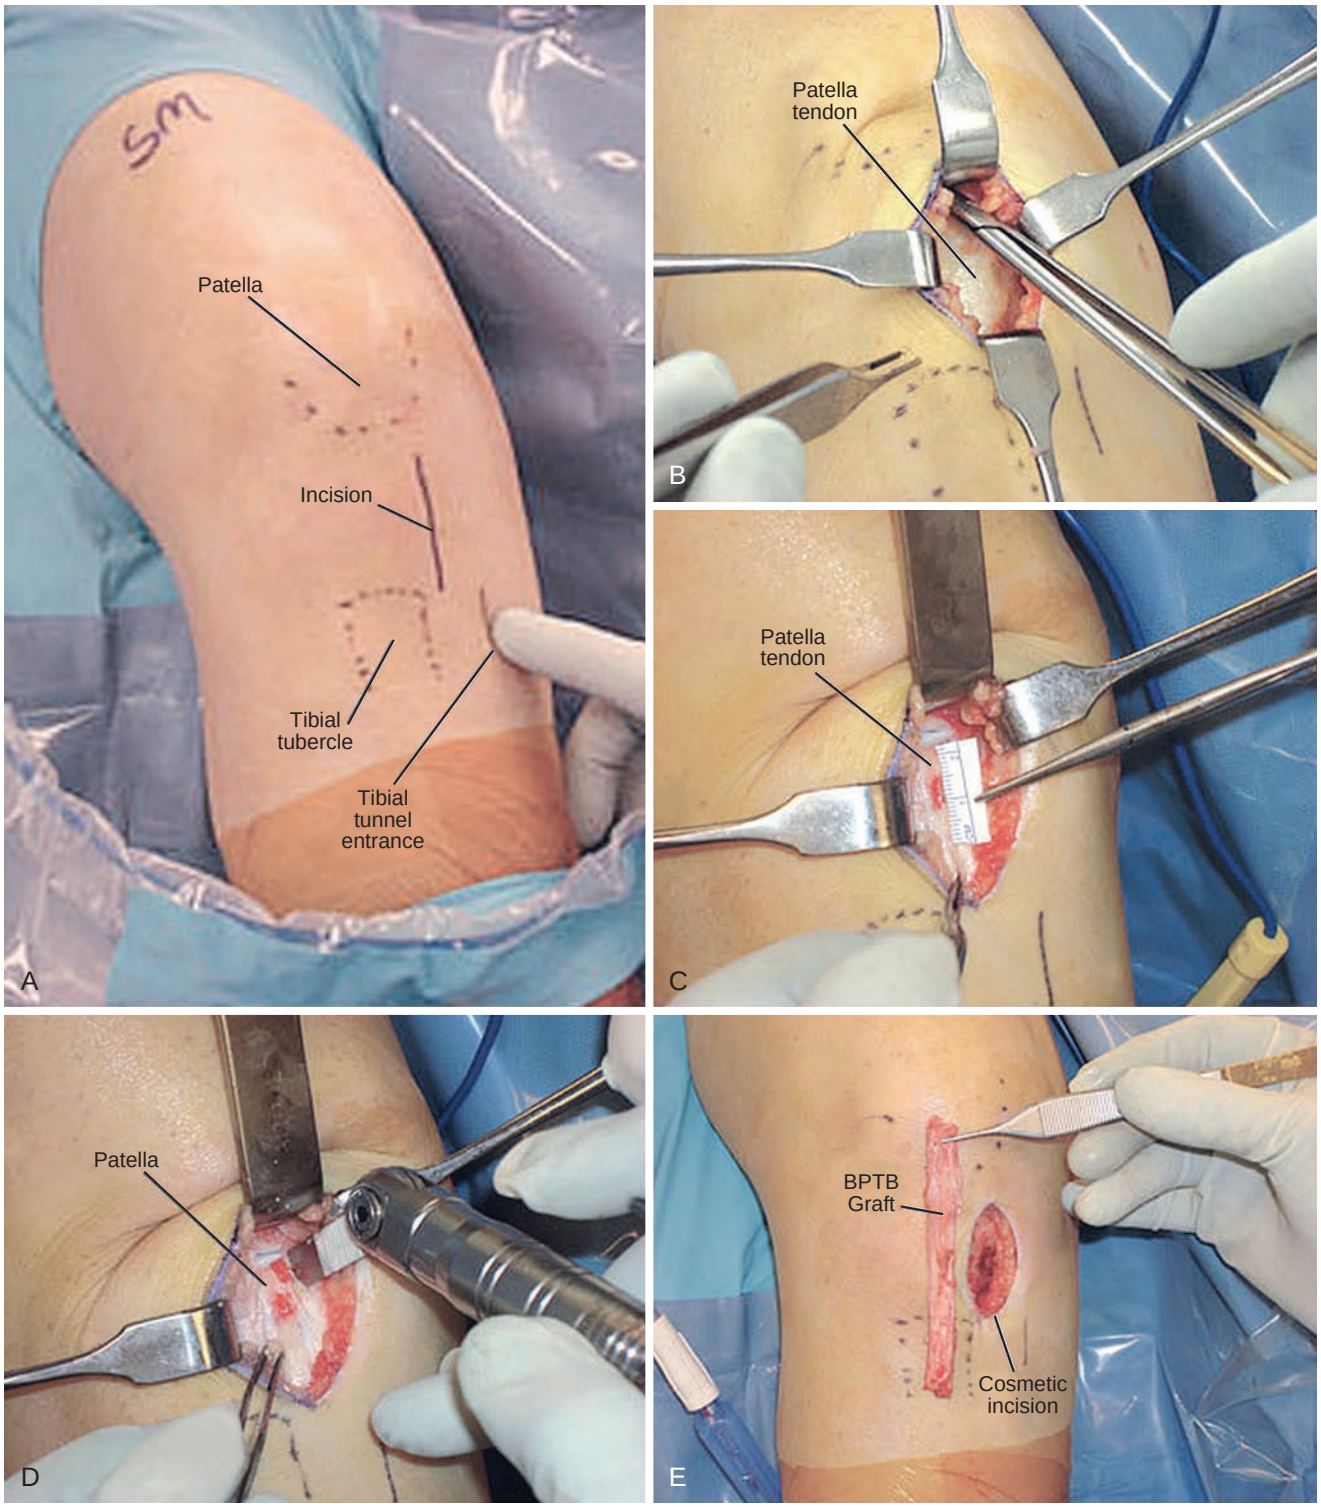

FIGURE 30-22. **A,** A 3- to 4-cm skin incision, just medial to the patellar tendon, is made to avoid the bony prominence of the patella and tibial tubercle. The index finger points to the planned tibial tunnel, which can be reached through this cosmetic incision. **B,** Mobilization of subcutaneous tissues to allow the cosmetically placed incision to be moved in a proximal-distal and medial fashion. **C,** A ruler measures the length of the patellar tendon and a 10-mm wide patellar tendon graft is marked by two to three ink dots. **D,** The patella is displaced distally and the patellar bone block removed. The saw has a tape marking a 9-mm depth to prevent from cutting too deep into the patella. The saw is angled 10° to 15° to produce a trapezoidal bone block. The saw carefully cuts the medial and lateral borders, making sure the bone beneath the tendon insertion has been cut to prevent a fracture of the graft. **E,** Appearance of the graft after harvest. *(Reprinted with permission from Noyes FR, Barber-Westin SD: Anterior cruciate ligament primary and revision reconstruction: Diagnosis, operative techniques, and clinical outcomes. In Noyes' Knee Disorders: Surgery, Rehabilitation, Clinical Outcomes. Saunders, 2009, Philadelphia, pp. 140–228.)*

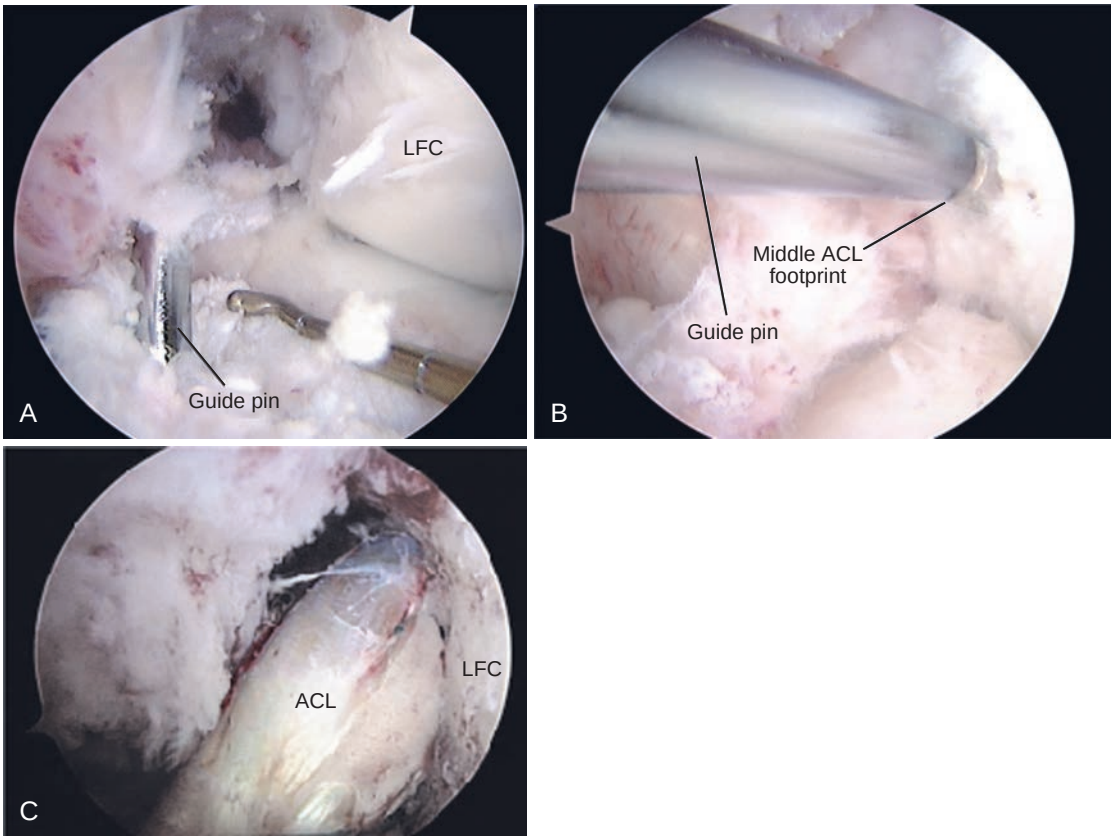

FIGURE 30-23. A, Guide pin placement is shown into the center of the ACL tibial attachment and adjacent, but not behind, the lateral meniscus attachment. **B,** ACL femoral central point is reached with knee hyperflexion and anteromedial portal or with a two-incision rear-entry technique. **C,** Final ACL graft appearance on the lateral femoral wall. *(Reprinted with permission from Noyes FR, Barber-Westin SD: Anterior cruciate ligament primary and revision reconstruction: Diagnosis, operative techniques, and clinical outcomes. In Noyes' Knee Disorders: Surgery, Rehabilitation, Clinical Outcomes. Saunders, 2009, Philadelphia, pp. 140–228.)*

TIMELINE 30-3: **Postoperative Rehabilitation After Meniscus Repair and Primary ACL Reconstruction**

PHASE I (weeks 1 to 2)

- Brace
- Toe-touch to ½ WB for peripheral meniscus repairs
- Toe-touch to ¼ WB for complex and all-inside meniscus repairs
- None-toe touch WB for radial meniscus repairs
- ROM 0° to 90°, begin first postoperative day
- Patellar mobilization
- Flexibility: hamstrings, gastrocnemius-soleus
- Weight shifting side-side, forward-backward
- Cup walking
- Quadriceps isometrics
- Straight leg raises, flexion only
- Active-assisted knee extension 90° to 30°

PHASE II (weeks 3 to 6)

- Brace
- Full WB peripheral meniscus repairs weeks 3–4
- ½ to ¾ BW complex, all-inside meniscus repairs (increase by approximately 25% per week)
- ¼ WB for radial repairs (increase by approximately 25% per week)
- ROM 0° to 135° by week 6
- Patellar mobilization
- Flexibility: hamstrings, gastrocnemius-soleus
- Double-leg balance exercises
- Balance board
- Mini-trampoline for balance exercises
- Multi-angle quadriceps isometrics
- Straight leg raises flexion, extension, abduction, adduction
- Knee extension, active-assisted ROM, 90° to 0°
- Toe raises, heel raises
- Wall sits (above 60°)
- Mini-squats (0° to 40°)
- Hamstring curls, peripheral meniscus repairs (0° to 90°)
- Leg press, peripheral meniscus repairs (70° to 10°)
- Knee extension PRE (90° to 30°)
- Multi-hip
- Upper body ergometer

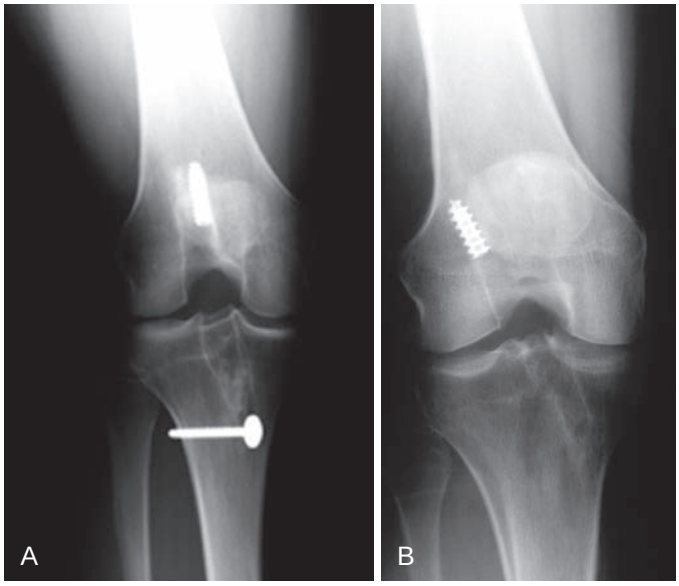

FIGURE 30-24. A, Anteroposterior radiograph shows a vertically oriented ACL graft with enlarged tibial and femoral tunnels. This graft placement should be avoided at all times, as it will not be effective in restoring normal ACL function. **B,** Correct ACL graft placement is shown. *(Reprinted with permission from Noyes FR, Barber-Westin SD: Anterior cruciate ligament primary and revision reconstruction: Diagnosis, operative techniques, and clinical outcomes. In Noyes' Knee Disorders: Surgery, Rehabilitation, Clinical Outcomes. Saunders, 2009, Philadelphia, pp. 140–228.)*

Phase I (days 0 to 14): Immediate Postoperative Period[1]

Clinical Pearl

Important early postoperative signs for the therapist to monitor are effusion, pain, gait, knee flexion and extension, patellar mobility, strength and control of the lower extremity, lower extremity flexibility, and tibiofemoral compartment symptoms. Use modalities such as electrical muscle stimulation, biofeedback, and cryotherapy as required. The patient's response to surgery and progression during the first 14 days sets the tone for the initial phases of rehabilitation. Monitor for posteromedial or infrapatellar burning, posteromedial tenderness along the distal pes anserine tendons, tenderness of Hunter's canal along the medial thigh, hypersensitivity to light pressure or temperature change, abnormal pain response, quadriceps shutdown, and inability to achieve knee motion goals as designated by protocol.

[1]*Prehabilitation, if appropriate, is described in the Nonoperative Rehabilitation section of this chapter.*

TIMELINE 30-3: **Postoperative Rehabilitation After Meniscus Repair and Primary ACL Reconstruction** (Continued)

PHASE III (weeks 7 to 12)	PHASE V (weeks 13 to 26)	PHASE VI (weeks 27+)
• DC brace, crutches • Full weight bearing • Flexibility: hamstrings, gastrocnemius-soleus, quadriceps, iliotibial band • Balance board • Lateral step-ups (5–10 cm) • Stationary bicycling (high seat/ low resistance) • Swimming, straight leg kicking (light, from hip) • Walking (level) • Stair climbing machine (short stroke/ decreased resistance) • Ski machine (decreased resistance) • Elliptical cross-trainer (decreased resistance) • Straight leg raises: flexion, extension, abduction, adduction (up to 10% BW) • Knee extension, active-assisted ROM, 90° to 0° • Toe raises, heel raises • Wall sits (>60°) • Mini-squats, rubber tubing (0° to 40°) • Hamstring curls (0° to 90°) • Leg press, start weeks 9–12 for complex meniscus repairs • Knee extension, PRE (90° to 30°) • Multi-hip	• Stationary bicycling • Swimming, straight leg kicking • Water walking • Stair climbing machine • Ski machine • Elliptical cross-trainer • Balance board • Single-leg stance, unstable platform • Perturbation training • Ball toss on plyoback, single-leg stance • Straight leg raises, rubber tubing • Mini-squats, rubber tubing • Hamstring curls • Leg press, start weeks 9–12 for complex meniscus repairs • Knee extension • Multi-hip • Running program week 16–20 peripheral meniscus repairs, based on criteria provided • Running program week 24 complex meniscus repairs, based on criteria provided • Cutting, carioca, agility drills week 24 peripheral meniscus repairs • Plyometrics week 24 peripheral meniscus repairs, based on criteria provided • Sport-specific exercises week 20–24 peripheral meniscus repairs • Return to sports, peripheral meniscus repairs: based on criteria provided	• Stationary bicycling • Swimming, straight leg kicking • Water walking • Stair climbing machine • Ski machine • Elliptical cross-trainer • Balance board • Single-leg stance, unstable platform • Perturbation training • Ball toss on plyoback, single-leg stance • Straight leg raises, rubber tubing • Mini-squats, rubber tubing • Hamstring curls • Leg press • Knee extension • Multi-hip • Cutting, carioca, agility drills week 30 complex meniscus repairs • Plyometrics week 30 peripheral meniscus repairs, based on criteria provided • Sport-specific exercises week 30 peripheral meniscus repairs Return to sports, complex meniscus repairs: based on criteria provided

Goals

- Range of motion (ROM) minimum: 0° to 90°
- Weight bearing depends on type of meniscus repair: toe touch, ½ body weight (BW) for peripheral repairs; toe touch, ¼ BW for complex or all-inside repairs; none, toe touch for radial repairs
- Pain, hemarthrosis controlled
- Good patellar mobility
- Adequate quadriceps contraction

Protection

- Long-leg postoperative brace for complex or all-inside meniscus repairs. Brace is opened from 0° to 90°, but is locked at 0° at night. Brace not routinely used for peripheral repairs, but an immobilizer may be used for patient comfort.
- Crutches. Toe-touch to ½ WB for peripheral repairs. Toe-touch to ¼ WB for complex and all-inside repairs. None to toe touch WB for radial repairs. "Sponge (very light) pressure" allowed during toe-touch WB.

Management of Pain and Swelling

- Oral medications as required.
- Therapeutic modalities: electrical muscle stimulation, cryotherapy.
- Elevate lower limb as frequently as possible.

Techniques for Progressive Increase in Range of Motion

- Begin on first postoperative day.
  - Passive knee flexion and passive and active/active-assisted knee extension exercises
  - Seated position, 0° to 90°, three to four times a day in 10-minute sessions
  - Active knee flexion is limited to avoid hamstring strain to the posteromedial joint.
  - Hyperextension avoided in anterior horn meniscus repairs
- Patellar mobilization in superior, inferior, medial, and lateral directions
- Hamstring and gastrocnemius-soleus flexibility
- If 0° to 90° not achieved by seventh postoperative day, begin overpressure exercises.
  - Hanging weights for extension
  - Rolling stool, wall-sliding for flexion
  - Commercially available ROM devices

Activation of Primary Muscles Involved in Injury Area or Surgical Structures

- Activation of the quadriceps, hamstrings, gastrocnemius-soleus, and hip musculature is accomplished immediately postoperatively with the exercises described in this time frame.
- Electrical muscle stimulation and/or biofeedback may be used to enhance quadriceps contraction (Figure 30-25).

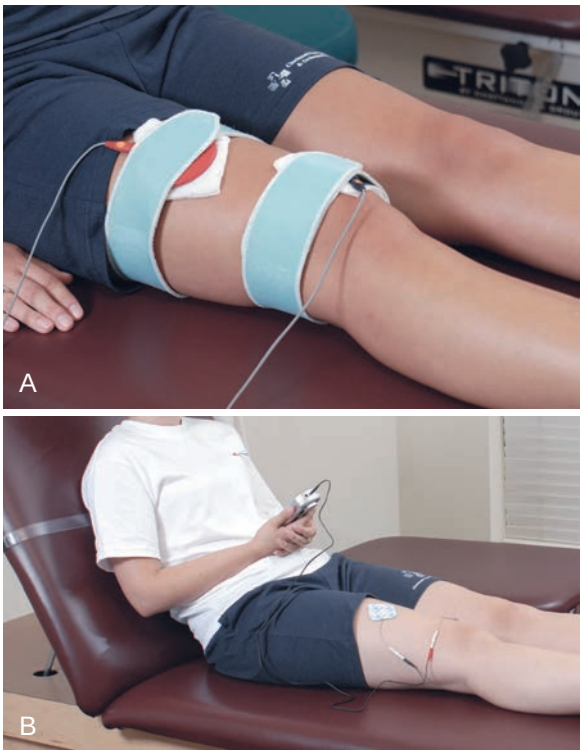

FIGURE 30-25. A, Electrical muscle stimulation. **B,** Biofeedback. *(Reprinted with permission from Noyes FR, Barber-Westin SD: Anterior cruciate ligament primary and revision reconstruction: Diagnosis, operative techniques, and clinical outcomes. In Noyes' Knee Disorders: Surgery, Rehabilitation, Clinical Outcomes. Saunders, 2009, Philadelphia, pp. 306–336.)*

Sensorimotor Exercises

- Begin first postoperative week during partial weight-bearing period.
  - Weight shifting side-to-side and front-to-back with crutch support
  - Cup walking to develop symmetry among limbs, hip and knee flexion, quadriceps control during mid-stance, hip and pelvic control during midstance, and gastrocnemius-soleus control during push-off

Open and Closed Kinetic Chain Exercises

- Begin first postoperative day
  - Quadriceps isometrics: one set × 10 repetitions every hour patient is awake
  - Straight leg raises, flexion plane only initially: three sets × 10 repetitions
    - Add leg raises in extension, abduction, adduction planes when patient has sufficient quadriceps control to prevent an extensor lag during flexion plane leg raises.
  - Active-assisted knee extension 90° to 0°: three sets × 10 repetitions. Limit to 90° to 30° for anterior horn repairs.

Milestones for Progression to the Next Phase

- ROM 0° to 90°
- Adequate quadriceps contraction, exhibited by no extensor lag on supine straight leg raise

- Pain, inflammation controlled
- Good patellar mobility

Phase II (weeks 3 to 6)

Clinical Pearl

By 6 weeks postoperative, the patient should have at least 0° to 135° of knee motion and a normal gait pattern. The KT-2000 arthrometer or Lachman test should be normal, with less than 3 mm increased anterior tibial displacement compared to the opposite knee.

Goals

- ROM 0° to 135°
- Gradually resume full WB with a normal gait pattern.
- Begin closed-chain exercises.
- Progress balance, proprioceptive training
- Progress lower extremity strength exercises

Protection

- Brace discontinued week 6 for complex and all-inside meniscus repairs; 6 to 8 weeks for radial repairs.
- Crutches discontinued week 4 for peripheral repairs.
- ½ to full WB for complex and all-inside repairs.

Management of Pain and Swelling

- Continue cryotherapy following all exercise sessions.
- Oral medications if required

Techniques for Progressive Increase in Range of Motion

- ROM is increased to 120° by weeks 3 to 4 and 135° by weeks 5 to 6.
  - Patients who fail to achieve these goals are placed into the overpressure program and should be evaluated by the surgeon.
  - Gentle manipulation under anesthesia may be indicated for noteworthy limitations of knee motion by week 6.

Other Therapeutic Exercises

- Upper body ergometer at 3 to 4 weeks if available

Activation of Primary Muscles Involved in Injury Area or Surgical Structures

- Activation of the quadriceps, hamstrings, gastrocnemius-soleus, and hip musculature is accomplished with the exercises described in this time frame.

Sensorimotor Exercises

- Double-leg balance exercises. The patient should point the feet straight ahead in tandem (heel/toe), flex the knee 20° to 30°, extend the arms outward to horizontal, and position the torso upright with the shoulders above the hips and the hips above the ankles. Stand in this position until balance is disturbed.
  - Balance exercises may be done on a mini-trampoline for greater challenge.
- Walk on Styrofoam half rolls.
- Balance board

Open and Closed Kinetic Chain Exercises

- Multi-angle quadriceps isometrics (active), 0°, 30°, 60°, 90°: one set × 10 repetitions each
- Straight leg raises in flexion, extension, abduction, and adduction: three sets × 10 repetitions. Add ankle weights at 3 to 4 weeks of less than 10% of body weight.
- Knee extension (active/active-assisted) 90° to 0°: three sets × 10 repetitions. Limit to 90° to 30° for anterior horn repairs.
- Toe raises: three sets × 20 repetitions
- Heel raises begin at 5 to 6 weeks: three sets × 10 repetitions.
- Wall sits (above 60°) to fatigue: three repetitions with at least eight repetitions per day.
- Mini-squats: 3 sets × 10 repetitions 90-40)
- At 5 to 6 weeks, peripheral meniscus repairs, hamstring curls, 0° to 90°: three sets × 10 repetitions
- At 5 to 6 weeks, peripheral meniscus repairs, leg press, 70° to 10°: three sets × 10 repetitions
- At 5 to 6 weeks, all repairs, multi-hip machine (flexion, extension, abduction, adduction): three sets × 10 repetitions
- 5 to 6 weeks, all repairs, knee extension (resisted), 90° to 30°: three sets × 10 repetitions

Neuromuscular Dynamic Stability Exercises

- See Sensorimotor Exercises in the preceding

Milestones for Progression to the Next Phase

- ROM 0° to 135°
- Normal gait
- Normal patellar mobility
- Pain, effusion controlled
- Muscle control throughout ROM
- Lachman less than 3 mm increase

Phase III (weeks 7 to 12)

Clinical Pearl

Full return to activities of daily living by postoperative weeks 8 to 12.

Precautions include no impact loading, no pivoting or twisting, no deep squatting.

Goals

- Progress lower extremity strength
- Progress balance, proprioception
- Increase endurance

Protection

- Crutches discontinued weeks 8 to 12 for complex, all-inside, and radial meniscus repairs.
- Weight bearing advanced per gait pattern and change in knee symptoms.

Management of Pain and Swelling

- Cryotherapy as required

Techniques for Progressive Increase in Range of Motion

- If knee motion is still limited during this time period, gentle manipulation under anesthesia may be indicated. Severe limitations may be treated with arthroscopic debridement. The program for treatment of knee motion problems has been described in detail.[7]
- Flexibility: hamstring, gastrocnemius-soleus, quadriceps, iliotibial band

Other Therapeutic Exercises

- Weeks 7 to 8: stationary bicycling, 15 minutes, one to two times a day
- Weeks 9 to 12 (select one activity a day for 15 minutes), with a goal of increasing duration by 10% per week.
  - Stationary bicycling
  - Water walking
  - Swimming with straight leg kicking
  - Walking
  - Stair climbing machine, low resistance, low stroke
  - Ski machine, short stride, level, low resistance
  - Elliptical cross-trainer

Activation of Primary Muscles Involved in Injury Area or Surgical Structures

- Activation of the quadriceps, hamstrings, gastrocnemius-soleus, and hip musculature is accomplished with the exercises described in this time frame.

Sensorimotor Exercises

- Balance board: two-legged, three times per day for 5 minutes
- Lateral step-ups: 5- to 10-cm block, three times per day, three sets × 10 repetitions (Figure 30-26)
- Resisted gait training: resistance band marching and elastic band resistance to terminal single leg standing balance.

FIGURE 30-26. Lateral step-up exercise. *(Reprinted with permission from Noyes FR, Barber-Westin SD: Anterior cruciate ligament primary and revision reconstruction: Diagnosis, operative techniques, and clinical outcomes. In Noyes' Knee Disorders: Surgery, Rehabilitation, Clinical Outcomes. Saunders, 2009, Philadelphia, pp. 306–336.)*

Open and Closed Kinetic Chain Exercises

- Straight leg raises flexion, extension, adduction, abduction: three sets × 10 repetitions
  - Add rubber tubing, three sets × 30 repetitions
- Toe and heel raises: three sets × 20 repetitions
- Wall sits, to fatigue: three repetitions
- Mini-squats: three sets × 10 repetitions
  - Weeks 9 to 12: add rubber tubing, 0° to 40°: three sets × 20 repetitions
- Hamstring curls all meniscus repairs, active: three sets × 10 repetitions
- Knee extension, active, 90° to 30°: three sets × 10 repetitions
- Multi-hip: three sets × 10 repetitions
- Leg press, 70° to 10°: three sets × 10 repetitions
  - Start weeks 9 to 12 weeks for complex repairs.

Techniques to Increase Muscle Strength, Power, and Endurance

- See the preceding

Neuromuscular Dynamic Stability Exercises

- See the preceding

Functional Exercises

- See the preceding

Milestones for Progression to the Next Phase

- No effusion, painless ROM
- Performs daily activities without problems

- Can walk 20 minutes without pain
- Normal range of motion
- Lachman less than 3 mm

Phase IV (weeks 13 to 26)

Clinical Pearl

Primary focus during this phase is developing lower extremity muscle strength and cross-training for cardiovascular endurance.

Early phases of a functional progression are implemented.

Goals

- Increase strength and endurance.
- Peripheral repairs may begin running program 20 weeks postoperative if tolerated.

Management of Pain and Swelling

- Cryotherapy as required

Therapeutic Exercises

- Patients encouraged to perform upper body and core strengthening according to future desired activity level
- Aerobic conditioning, three times per week for 20 minutes, select one activity per session
  - Stationary bicycle
  - Water walking
  - Swimming, straight leg kicking
  - Walking
  - Stair climbing machine
  - Ski machine
  - Elliptical cross-trainer

Activation of Primary Muscles Involved in Injury Area or Surgical Structures

- Activation of the quadriceps, hamstrings, gastrocnemius-soleus, and hip musculature is accomplished with the exercises described in this time frame.

Sensorimotor Exercises

- Balance board, two-legged, three times per day for 5 minutes
- Single-leg stance, unstable platform, three times per day for 5 minutes
- Perturbation training
- Ball toss on plyoback, single-leg stance

Open and Closed Kinetic Chain Exercises

- Straight leg raises with rubber tubing, high speed: three sets × 30 repetitions
- Mini-squats, rubber tubing, 0° to 40°: three sets × 20 repetitions
- Hamstring curls, with resistance, 0° to 90°: three sets × 10 repetitions
- Knee extension, active with resistance, 90° to 30°: three sets × 10 repetitions
- Multi-hip: three sets × 10 repetitions
- Leg press, 70° to 10°: three sets × 10 repetitions

Techniques to Increase Muscle Strength, Power, and Endurance

- See the preceding

Neuromuscular Dynamic Stability Exercises

- See the preceding

Plyometrics

- Week 24 for peripheral meniscus repairs only. Must have completed running program.
- Level surface box hops on four-square grid. Double-legged hops, land in knee flexion; four levels.
- Single-leg hops
- Vertical box hops

Functional Exercises

- Week 16 to 20: peripheral meniscus repairs allowed to begin running program if tolerated. Patient must have less than 30% deficit in quadriceps and hamstrings peak torque on isometric and/or isokinetic testing to begin running.
- Week 24: peripheral meniscus repairs allowed to begin cutting, carioca, figure-eight agility, plyometrics (box hops, level, double-leg) if tolerated. Must have less than 20% deficit for quadriceps/hamstrings peak torque on isometric and/or isokinetic testing to begin plyometrics.

Sport-Specific Exercises

- Begin week 20 to 24 for peripheral meniscus repairs

Milestones for Progression to the Next Phase

- No pain, effusion
- Can perform ADL, walk for 20 minutes without pain
- Lachman less than 3 mm

Phase V (weeks 27 and beyond)

Clinical Pearl

Return to activity at 6 to 9 months for peripheral repairs, 9 to 12 months for complex, all inside and radial repairs.

Condition of the articular cartilage may also be a determining factor for functional progressions.

Goals

- Increase strength, endurance, lower extremity function
- Return to previous or desired activity level

Management of Pain and Swelling

- Cryotherapy as required

Therapeutic Exercises

- Patients encouraged to perform upper body and core strengthening according to future desired activity level
- Aerobic conditioning, three times per week for 20 to 30 minutes; select one activity per session.
  - Stationary bicycle
  - Water walking
  - Swimming, straight leg kicking
  - Walking
  - Stair climbing machine
  - Ski machine
  - Elliptical cross-trainer

Sensorimotor Exercises

- Balance board, two-legged, three times per day for 5 minutes
- Single-leg stance, unstable platform, three times per day for 5 minutes. Progress from two-legged to one-legged activity.
- Perturbation training
- Ball toss on plyoback, single-leg stance

Open and Closed Kinetic Chain Exercises

- Straight leg raises with rubber tubing, high speed: three sets × 30 repetitions
- Mini-squats, rubber tubing, 0° to 40°: three sets × 20 repetitions
- Knee extension, active with resistance, 90° to 30°: three sets × 10 repetitions
- Hamstring curls, with resistance, 0° to 90°: three sets × 10 repetitions
- Multi-hip: three sets × 10 repetitions
- Leg press, 70° to 10°: three sets × 10 repetitions

Techniques to Increase Muscle Strength, Power, and Endurance

- See the preceding

Neuromuscular Dynamic Stability Exercises

- See the preceding

Plyometrics

- Week 30 for complex meniscus repairs. Must have completed running program.
- Level surface box hops on four-square grid. Double-legged hops, land in knee flexion. Four levels.
- Single-leg hops
- Vertical box hops

Functional Exercises

- Week 24: complex meniscus repairs: allowed to begin running program if tolerated. Patient must have less than 30% deficit in quadriceps and hamstrings peak torque on isometric and/or isokinetic testing to begin running.
- Week 30: complex meniscus repairs: allowed to begin cutting, carioca, figure-eight agility, plyometrics (box hops, level, double-leg) if tolerated. Patient must have less than 20% deficit in quadriceps and hamstrings peak torque on isometric and/or isokinetic testing to advance to cutting.

Sport-Specific Exercises

- Begin week 30 for complex meniscus repairs

Criteria for Return to Sport

- No knee joint pain or swelling
- Full range of knee motion
- Less than 3 mm increase on Lachman test
- Less than or equal to 10% deficit quadriceps and hamstrings strength isokinetic testing
- Less than or equal to 15% deficit lower limb symmetry single-leg hop testing
- Successful completion running and functional training
- Complete trial of function, monitor for overuse symptoms
- Patient education for re-evaluation if any future knee problems occur

After Return to Sport

Continuing Fitness or Rehabilitation Exercises

- Aerobic conditioning is recommended according to patient activity levels.
- Lower extremity strengthening to be advanced or maintained as required.

Exercises and Other Techniques for Prevention of Recurrent Injury

- For patients returning to high-risk athletic activities, completion of at least 6 weeks of additional plyometrics, jump retraining, agility, strengthening (Sportsmetrics, Cincinnati Sportsmedicine Research and Education) Foundation strongly advised.[6]

Evidence

The authors' postoperative rehabilitation program following combined ACL reconstruction and meniscus repairs has been used in the following clinical studies.

Buseck MS, Noyes FR: Arthroscopic evaluation of meniscal repairs after anterior cruciate ligament reconstruction and immediate motion. *Am J Sports Med* 19:489–494, 1991.

The healing rate of 79 meniscus tears that underwent follow-up arthroscopy an average of 12 months postoperatively was determined in 66 patients. All had also undergone ACL allograft reconstruction. Fifty-one meniscus repairs were done for tears located in the periphery or outer third region and 28 for tears that extended into the central avascular region. The healing rates for tears in the periphery or outer third region were 94% complete, 4% partial, and 2% failed. The healing rates for tears in the central avascular region were 54% healed, 32% partially healed, and 14% failed. The ACL reconstruction restored normal stability in 68%, nearly normal stability in 28%, and failed in 4%. The results allowed recommendation for routine repair of meniscus tears located in the periphery as well as those that extend into the central region, including flap and double longitudinal tears. The use of immediate motion and early weight bearing did not adversely affect the healing of either the ACL reconstructions or meniscus repairs. (Level III evidence)

Noyes FR, Barber-Westin SD: A comparison of results in acute and chronic anterior cruciate ligament ruptures of arthroscopically assisted autogenous patellar tendon reconstruction. *Am J Sports Med* 25:460–471, 1997.

A prospective study was done in 94 consecutive patients who underwent B-PT-B autograft ACL reconstruction. Forty-six meniscus tears were also concurrently repaired. At a mean of 28 months postoperatively, normal knee stability was restored in 85% of knees with chronic ACL ruptures and 92% of knees with acute ruptures. We found that 89% of the menisci repaired had no evidence of failure or tibiofemoral joint symptoms. One patient had a knee motion complication. The study showed that patients who had early ACL reconstruction had superior results in regard to symptoms and activity levels. (Evidence levels are given for each reference)

Noyes FR, Barber-Westin SD: Arthroscopic repair of meniscus tears extending into the avascular zone with or without anterior cruciate ligament reconstruction in patients 40 years of age and older. *Arthroscopy* 17:822–829, 2000.

A prospective study was performed in 27 patients aged 40 to 58 years who underwent ACL B-PT-B autograft reconstruction and meniscus repair. At a mean of 34 months postoperatively, none of the ACL grafts had failed. We found that 87% of the meniscus repairs were asymptomatic for tibiofemoral symptoms and had not required subsequent surgery. Three repairs failed and required partial meniscectomy and one with tibiofemoral symptoms related to the repair had been treated conservatively. There were no infections, knee motion limitations, or other complications. In athletically active patients, the recommendation was made to preserve meniscal tissue whenever possible and restore knee joint stability regardless of age, but based on current and future activity levels. (Level IV evidence)

Noyes FR, Barber-Westin SD: Arthroscopic repair of meniscal tears extending into the avascular zone in patients younger than twenty years of age. *Am J Sports Med* 30:589–600, 2002.

A prospective study was conducted on 71 meniscal repairs in 64 knees for tears extending into the central third avascular region in patients less than 20 years of age. Forty-seven had a concurrent ACL reconstruction with either a B-PT-B autograft (n = 27) or allograft (n = 20). At a mean of 51 months postoperatively, none of the ACL autografts had failed, whereas five of the allografts had failed. We found that 75% of the patients had no tibiofemoral compartment symptoms at follow-up. In 25%, patients had tibiofemoral symptoms that led to arthroscopy or were deemed clinical failures for the meniscus repair on examination. There were no complications or limitations of knee motion. (Level IV evidence)

Rubman MH, Noyes FR, Barber-Westin SD: Arthroscopic repair of meniscal tears that extend into the avascular zone. A review of 198 single and complex tears. *Am J Sports Med* 26:87–95, 1998.

A study was performed in 177 patients who underwent 198 meniscus tears that extended into the central avascular region. A total of 126 knees also had ACL reconstruction using either allografts (72 knees) or B-PT-B autografts (54 knees). At a mean of 42 months postoperatively, 80% of meniscus repairs were asymptomatic for tibiofemoral joint symptoms and had not failed clinically. The remaining 20% had tibiofemoral symptoms related to the repair that required follow-up arthroscopy. The ACL graft failure rates were 4% for the autografts and 15% for the allografts. There were statistically significant differences in the rates of meniscus repair healing for tibiofemoral compartment of the repair, time from repair to follow-up arthroscopy, and the presence of tibiofemoral joint symptoms. There were no limitations of knee motion or complications other than one infection, which resolved with treatment. (Level IV evidence)

Multiple Choice Questions

QUESTION 1. Which of the following details of the operative procedure do not affect the rehabilitation program?

A. Location of meniscus tear
B. Condition of the articular cartilage
C. ACL semitendinosus-gracilis versus patellar tendon autograft
D. Use of all-inside meniscus repair technique

QUESTION 2. Which procedure does not routinely require a postoperative brace?

A. Complex meniscus repair
B. Peripheral meniscus repair
C. Radial meniscus repair
D. All-inside meniscus repair

QUESTION 3. What major goal is expected to be achieved by postoperative week 6?

A. No problems with activities of daily living
B. Initiation of light jogging
C. At least 0° to 135° of knee motion
D. May swim with straight leg kicking

QUESTION 4. What milestone is not required for patients to progress to Phase IV?

A. No problems with daily activities
B. Full range of knee motion
C. Walking tolerance: 20 minutes
D. Able to do light jogging without problems

QUESTION 5. What is the first exercise in the beginning plyometric program?

A. Vertical box hops
B. Single-leg box hops
C. Level surface box hops, 4-square grid, double-legged
D. Level surface hops, single-leg

Answer Key

QUESTION 1. Correct answer: **C** (see Summary Surgical Technique)

QUESTION 2. Correct answer: **B** (see Phase I)

QUESTION 3. Correct answer: **C** (see Phase II)

QUESTION 4. Correct answer: **D** (see Phase III)

QUESTION 5. Correct answer: **C** (see Phase IV)

BEYOND BASIC REHABILITATION: RETURN TO CATCHING AFTER MENISCAL REPAIR

Kenny Patterson, MPT, and William Raasch, MD

ASPECTS OF CATCHING THAT REQUIRE SPECIAL ATTENTION IN REHABILITATION

- A baseball catcher requires full knee range of motion (ROM) and strength in order to successfully perform the necessary baseball skills.
- Baseball is highly repetitive in nature necessitating immense muscular activation, muscular endurance, and power while the knee is under axial and rotational loads.
- Catching/Receiving/Blocking—A majority of time the knee is weight bearing and subject to extremes of flexion and rotation when receiving or blocking the pitch (Figures 30-27 to 30-30).
- Throwing—The strength of the throw relies on power generated from the entire body through the kinetic chain (Figure 30-31).
- Hitting—Hitting for power, like throwing, requires coordinated lower body movement with the knee subject to significant rotational stress (Figure 30-32).
- Base Running/Sliding—Rounding a base or sliding into one may create significant axial loads while the knee is undergoing rotation (Figure 30-33).

FIGURE 30-27. Primary stance, no one on base.

FIGURE 30-28. Signal stance.

FIGURE 30-29. Secondary stance, block/throw stance.

Introduction

- Meniscal tears are common injuries seen in orthopaedic and sports medicine clinics.
- Arthroscopic treatment is the standard of care for the symptomatic knee and meniscal repair the treatment of choice.[1–12]
- The meniscus plays an important role in joint surface preservation and knee function. The meniscus provides stress reduction, shock absorption, lubrication, nutrition, and joint congruency.[13,14]
- In addition, the literature supports the role of the meniscus in neuromuscular control by providing proprioceptive input for joint position, direction, velocity, and acceleration.[15–17]
- This specific injury is being reviewed in the context of returning a catcher to baseball activities owing to the high demands placed on the knee joint in a position that places the meniscus at risk for reinjury.
- With deep squatting (Figure 30-34) and heel sitting (Figure 30-35), the knee, while in extreme flexion is subject to high rotational loads.
- Under these conditions, the risk of reinjury following meniscal repair must be considered carefully when allowing the athlete to return to play.
- Minimal evidence exists in the current literature on healing time frames, strength capacity, or the effect of weight bearing to a healing or repaired meniscus.[18]
- Rehabilitation following meniscal repair is controversial, with a wide spectrum of proposed rehabilitation protocols.[15,19–23] Currently, treatment options following meniscal repair can be roughly divided between a conservative and an accelerated approach.
- The conservative approach includes partial to nonweight bearing for the first 4 to 6 weeks with a postoperative brace limiting flexion.
- Passive ROM is restricted from 0° to 90° degrees for the first 4 weeks.[24,25]
- During the first 6 weeks, the knee joint axial loads and shear forces are minimized by limiting ROM, hamstring activation, and weight bearing. The imposed restrictions are based on the literature reporting an increase in compressive loads to the posterior horn of the meniscus, with 85% of the axial load transmitted through the meniscus in 90° of flexion and only 50% in full extension.[18,26,27]
- Limiting hamstring activation is based on evidence that resisted knee flexion results in displacement and excessive loading of the posterior horn.[17,24,26]
- Subsequently, weight bearing with deep knee flexion is restricted for 4 months resulting in a typical return to play at the 6-month mark.[24,25]
- In the accelerated approach, knee ROM, hamstring activation and weight bearing are unrestricted and progressed to individual tolerance in the early stages of rehabilitation.
- Authors have shown similar success rates with meniscal repair under these conditions and have reported return to play in as little as 10 weeks.[19,20]
- Various modifications to the aggressive approach including limiting weight bearing in flexion greater than 90° and holding off on any impact loading until the 3-month mark.
- With either approach, rehabilitation guidelines emphasize neuromuscular rehabilitation and sport specific training for safe return to play.[15,18,32,33]
- It is evident that restoring function and regaining sport specific skills are critical for successful return to competition.
- The athlete must be educated and cautioned on the early return to strenuous activity, impact loading, deep knee flexion, and cutting/pivoting to lower the incidence of reinjury.
- Any rehabilitative approach must at some level, be individually tailored to the injury, demands, and goals of the athlete.

Literature

- Currently, to the authors' knowledge, there is no specific literature on returning a catcher following meniscal repair. The authors found a similar case report

FIGURE 30-34. Deep squat.

FIGURE 30-35. Heel sitting.

presented in JOSPT (Feb 2006) involving a professional ice hockey goaltender return to sport following lateral meniscal repair.[32]

- Axe et al.[34,35] designed and provided clinical commentary on a complete set of data-based interval throwing programs including simulated game and progression instructions for the baseball athlete to include the specialized position of catcher. These programs can also be utilized following injuries to body regions other than upper extremities to gradually increase the stresses and loads to injured area.
- Barrett and Burton[36] provide an analysis of a quantitative breakdown of the number and type of throws as well as distances required of individual fielders. The vast majority of throws were made between 46 and 60 feet principally by pitchers and catchers. Catchers accounted for 29% of throws made by positions from data compiled.[37]
- Baseball is a sport abundant with personal experiences and testimonials. Odgers and Axe[38] state "In an unpublished study, Mick Smith from the University of Miami found that during a collegiate game, a catcher throws 221 times with 131 from the squatting position. Furthermore, the catcher can expect to perform 238 squat repetitions and sprint 30 yards for an average of 15 times during each outing." The authors contribute that catchers throw from mechanically disadvantageous positions and maintain a squatting position for more than 1 hour over the course of a game.[10]
- The authors include material to provide a brief snapshot of what a catcher might encounter during a typical game and to encourage those professionals involved with the care of athletes to understand the mechanics, movements, and skills required of the athlete and sport.
- Specificity of training is the foundation for resistance and functional training programs.[39]

Advanced Rehabilitation Program

- Isokinetic training (Figure 30-36) for knee flexion and extension are employed during the latter stage of moderate protection phase to offer accommodative resistance at various speeds and progressed until the athlete is given full clearance to return to sport.
- Isokinetic testing is initiated in the advanced strengthening phase and performed at periodic intervals (approximately every 4 to 6 weeks) in the stages of rehabilitation progression and standardized to enhance the reliability of data acquired. Comparisons of bilateral strength variables of torque, total work, and unilateral muscle ratios (ham/quad) are collected.
- Published normative values for unilateral hamstrings to quadriceps ratios have been defined.
- The isokinetic testing protocol is utilized on the Biodex Multi Joint System 3 (Biodex Medical Systems, Shirley, NY) at speeds of 180°/second and 300°/second advocated by Wilk et al.[40]
- Clinically, isokinetic rehabilitation and training are based on Davies' VSRP (velocity spectrum rehabilitation protocol).[40–42]
- Plyometric and agility exercises are an effective and necessary component integrated into the advanced stages of rehabilitation to ensure neuromuscular training and functional progression to return to sport.
- Following medical clearance from the physician and criteria achieved for readiness and advancement, discussed later in this chapter, plyometrics are initiated.
- The prescription starts with exercises plyometric in nature (submaximal, low intensity, low impact, decreased weight) that encompasses agility and foot work drills.
- In conjunction, core and upper extremity plyometrics are introduced and prescribed to facilitate transfer of energy through the kinetic chain and integration of total body movement patterns required of the baseball athlete.
- As the athlete becomes proficient and masters these treatment strategies, plyometrics are advanced accordingly, ultimately to high-intensity sport-specific drills in preparation to return to sport.
- The Shuttle MVP (Figure 30-37) is used extensively throughout this author's program design owing to its versatility, variable resistance, and unloading features of body weight. The Shuttle MVP provides a safe, controlled environment for closed kinetic chain

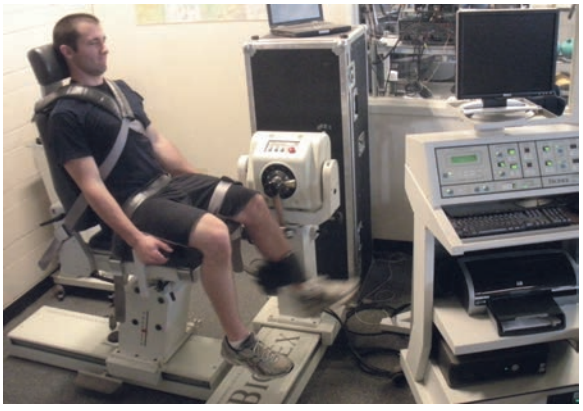

FIGURE 30-36. Biodex Isokinetic.

TIMELINE 30-4: **Beyond Basic Rehabilitation: Return to Catching after Meniscal Repair**

PHASE I: Maximal Protection/Immediate Rehabilitation (weeks 0 to 6)

- Goals
  - Protect anatomic repair
  - Minimize knee joint effusion
  - Gently increase ROM per guidelines, emphasis on extension
  - Encourage/Regain quadriceps control
  - Prevent negative effects of immobilization

Stage 1: Immediately post-op to week 2

- Cryotherapy, compression, elevation
- IFC for pain/effusion
- NMES/Biofeedback for quad activation and control
- Brace locked at 0° for ambulation and sleeping only (brace may or may not be prescribed by MD)
- Brace may be unlocked while sitting, ROM, etc.
- ROM (passive 0°-90° (gradual increase in flexion ROM based on symptoms)
- PROM / AAROM, CPM (continuous passive motion, LLLD for ext)
- Patellar mobilizations
- Flexibility exercise for hamstrings and gastroc/soleus complex
- Ankle pumps, ankle circles, alphabet
- Strengthening exercises:
- Quad sets
- SLR flexion
- Hip abduction/adduction
  - Knee extension 60°-0°
  - Weight bearing: 25%-50% WB as tolerated with 2 crutches. Avoid active knee flexion

Stage 2: Weeks 2–4

- Continue use of cryotherapy and compression
- Brace locked for ambulation (if prescribed)
- Patellar mobilization/scar massage
- Manual Therapy—soft tissue/joint mobilization peri-articular knee structures
- IFC for pain/effusion
- NMES/Biofeedback for quad activation and control
- ROM guidelines (no forced flexion, CPM, LLLD for ext)
- Gradually increase PROM
  - Week 2: 0–100/105°
  - Week 3: 0–115/120°
  - Week 4: 0–125/135°
- Weight bearing guidelines—continue to lock brace (if prescribed)
  - Week 2: 50% WB
  - Week 3: FWB as tolerated
- Discontinue crutches when safe and proper gait (usually 3–4 weeks)
- Continue PROM to AAROM to AROM (no posterior knee pain exercises) and LE flexibility exercises (hamstrings, gastroc/soleus complex)
- Strengthening exercises
  - Ankle/foot strengthening—gastroc/soleus, invertors/evertors, foot intrinsics
  - Multiangle quad isometrics
  - SLR (all 4 planes)
  - Knee extension 90°–0°
  - CKC minisquats 0°–45°
  - CKC wall squats
  - CKC weight shifts (diagonal)
- Balance/proprioception training—cup walking, weight shifting; double leg progressing to single leg activities; UE supported to UE unsupported; stable to less stable surfaces; eyes open/closed; avoid rotation
- Stationary bicycle for ROM stimulus (once ROM appropriate)
- Avoid twisting, loaded/WB CKC squatting >90° flexion, and pivoting for 10–12 weeks to minimize shear forces.
- No deep squatting for 5–6 months
- Avoid isolated resistance to knee flexion for 6 weeks
- Core stability and upper body exercises implemented at 4 weeks modified and dosed to protect meniscal repair
- Cardiovascular training—upper body ergometer (UBE)
- Home ex program (HEP to include ROM, quad facilitation, symptom reduction, and gait training)

Stage 3: Weeks 4–6

- Continue use of cryotherapy and compression as needed
- Continue PROM to AAROM to AROM (no posterior knee pain exercises and LE flexibility exercises (hamstrings, gastroc/soleus complex)
- Maintain 0°-135° ROM; goal full ROM by 8 weeks unloaded/WB if not achieved
- Manual Therapy—soft tissue/joint mobilization as needed peri-articular knee structure for pain/effusion as needed
- NMES/Biofeedback for quad activation and control as needed
- Progress strengthening exercises
- Ankle/Foot strengthening—gastroc/soleus, invertors/evertors, foot intrinsics
- Leg press 60°–0°; Shuttle MVP
- Knee extension 90°–40°
- Hip Abduction/adduction
- Wall squats 0°–60°
- Wall sits 30°–45°
- Vertical squats 0°–60°
- Lateral stepups
- Balance/proprioception training (nonimpact, perturbations, oscillatory)
- Wobble/tilt/rocker board (i.e., squats)
- BAPS
- Mini tramp
- Shuttle MVP (wobble board, air-ex pad, half foam roll, DynaDisc)
- Power Plate (vibration)
- Stationary Bicycle (if ROM permits)
- Pool program (if accessible, ROM, nonimpact, gait, balance/proprioception, flexibility, and gentle OKC/CKC strengthening aquatic exercises)
- Discontinue brace at weeks 4–5 (if applicable)
- Core stability and upper body exercises implemented at 4 weeks modified and dosed to protect meniscal repair
- Cardiovascular training—upper body ergometer (UBE)
- Home ex program (HEP to include ROM, quad facilitation, symptom reduction, and gait training if needed)
- Avoid twisting, pivoting, running, and loaded/WB CKC squatting >90° flexion

(Adapted with permission from previously established protocols: Meniscus Repair Rehabilitation Protocol. La Crosse, WI: 2008. [Accessed March 4, 2008 at http://www.gundluth.org/upload/docs/Services/SportsMedicine/knee-meniscus%20repair-2008.pdf]; Meniscus Repair Rehabilitation. Advanced Continuing Education Institute, 2004. TIMELINE 30-4: Beyond Basic Rehabilitation: Return to Catching after Meniscal Repair (Continued)

PHASE II: Moderate Protection/Intermediate Rehabilitation (weeks 6 to 12)

- Goals
  - Normalize ROM of knee
  - Normalize weight bearing and gait
  - Minimize joint effusion
  - Gradual progression of therapeutic and functional exercise for strength, endurance, neuromuscular control, balance/proprioception, and flexibility
  - Prepare for advanced and sport-specific activities
- Continue use of ice and compression as needed
- Maintain 0°-135° ROM if achieved
- Continue ROM if not achieved; goal full ROM by 8 weeks unloaded/WB
- No forceful WB stretching into flexion until 8 weeks (initiate progressive loaded WB stretch beyond 90° at 10 weeks)
- Avoid twisting, pivoting, and loaded/WB CKC squatting >90° for 10–12 weeks to minimize shear forces
- No deep squatting for 5–6 months
- Manual therapy—soft tissue/joint mobilization as needed periarticular knee structures
- IFC for pain/effusion if needed
- NMES/Biofeedback for quad activation and control if needed
- Flexibility exercises for hamstrings, gastroc/soleus, quadriceps, ITB, iliopsoas, adductors if indicated
- Closed kinetic chain exercises progress from 0°-60° to 0°-90°: leg press, stepups, partial lunges, varied squats, etc. as tolerated
- Pool program (if accessible, ROM, flexibility, OKC/CKC strengthening, CV conditioning, balance/proprioception)
- Treadmill walking program (forward, lateral, retro; no incline)
- Initiate Hamstring strengthening 0°–90° (light resistance initially)
- Incorporate total leg strengthening, balance/proprioception, and neuromuscular control in functional activities
- Continue/progress strengthening exercises listed above
  - Machine weights (multihip x 4 way, leg curl, leg ext, leg press, calf raise)
  - Shuttle MVP
  - Inertial Exercise Trainer (Impulse)
  - Power Plate
- Continue/progress balance/proprioception training/exercises listed above
  - Static to dynamic activities
  - Supported to unsupported
  - Isolated to multiple functional movement patterns
  - Add BOSU
  - Core stability and upper body exercises as recommended and tolerated
- Week 7:
  - Precor EFX Elliptical Trainer
  - Stationary bike at resistance/intensities for CV training
- Week 8:
  - Isokinetic quadriceps/hamstrings VSRP 150°–300°/sec, submax to max, progressing to 90°/sec
  - Treadmill walking program (forward, lateral, retro) progressing inclination at this time incrementally by 5% as tolerated (max 10–12%)
  - Manual stretch into increasing knee flexion (>90° to end range flexion utilizing static to PNF stretching techniques) contract-relax, agonist contract-relax, hold relax in durations ranging from 10 sec to 30 sec. Self-stretch with use of strap in prone, supine, and side lying postures with various degrees of hip flex/ext taught to improve/maintain quadriceps flexibility and knee flexion end ranges in unloaded WB status.
- Week 9:
  - Stepper/stairmaster
- Week 10:
  - Weight-bearing stretch with increasing knee flexion activities
  - Shuttle MVP weight-bearing/loaded stretch into increasing knee flexion (bilaterally until full, symmetrical, and zero symptoms of pain/swelling)
  - Resistance increased in increments of 5% of body weight starting with no resistance progressing to 100%. Consider utilizing Knee Saver, firm wedged pad, bilaterally between buttocks and lower leg.
  - Kneeling squat exercise (sit back to heels utilizing Knee Savers in full kneeling progressing to half kneeling until full, symmetrical and zero symptoms of pain/swelling)
  - Slide board

PHASE III: Controlled Advanced (weeks 12 to 18)

- Goals
  - Progress strength, endurance, power, balance/proprioception, neuromuscular control, and flexibility
  - Maintain full ROM
  - Emphasize advanced and sport specific activities/skills on MD approval
  - Prepare to return to full unrestricted sport/activities
- Continue and progress all strengthening and endurance exercises listed in Phase II
- Continue and progress balance/proprioception and neuromuscular training listed in Phase II
- Continue with stretching and flexibility exercises listed in Phase II
- Emphasize advancement of exercise in terms of functional demands and sport-specific drills/activities
- Pool program (if accessible, ROM, flexibility, OKC/CKC strengthening, CV conditioning, balance/proprioception, impact loading, jogging/running, kicking, plyometrics)
- Week 12:
  - Isokinetic Test (180°/sec & 300°/sec)
  - Interval throwing program (Nonshoulder/elbow injury—catcher/position player)
  - Interval hitting program
  - Exercises plyometric in nature (low impact, low intensity); Shuttle MVP
  - Agility/Foot work drills (low impact, low intensity), cones, agility ladder, jump rope
  - Functional Grid (Figure 30-50)
  - TRX (suspension training, Figure 30-51)
- Week 13:
  - Hurdle Activities—over/under dynamic mobility (Figure 30-52)
- Week 14:
  - Interval treadmill jogging/walking program (return to running program)
  - Supported catching drills (receiving, blocking, physio ball, stool, plyo boxes [Figure 30-53])
  - Ball pick ups
- Week 16:
  - Isokinetic Test (180°/sec & 300°/sec)
  - Plyometric exercises (moderate impact, moderate intensity)
  - Agility/foot work drills (cutting/pivoting)
  - Functional grid (lunges, balance, bounding, plyometrics)
  - Team on-field controlled/limited activities (i.e., team stretch, conditioning, batting practice, throwing, jogging/running)

PHASE IV: Return to Sport/Activity (weeks 18 to 24)

- Criteria for return to sport activity
  - MD approval
  - Full nonpainful ROM, no joint effusion
  - Satisfactory clinical exam
  - Satisfactory isokinetic testing 90% compared to uninvolved
  - Satisfactory functional testing 90% compared to uninvolved
  - Successful completion of sport-specific drills
- Week 18:
  - Sprint work/base running
  - Unsupported catching drills (receiving/blocking/throwing; see Box 30-5)
  - Reaction ball (z ball)
  - Functional tests at 50% intensity
- Week 19:
  - Functional tests at 75% intensity
- Week 20:
  - Functional testing (LE functional testing, Shuttle, Pro Agility 5/10/5)
  - Biodex test (180 deg/sec & 300 deg/sec)
  - Sliding drills (slide mat to base path/on-field)
  - Catching pens

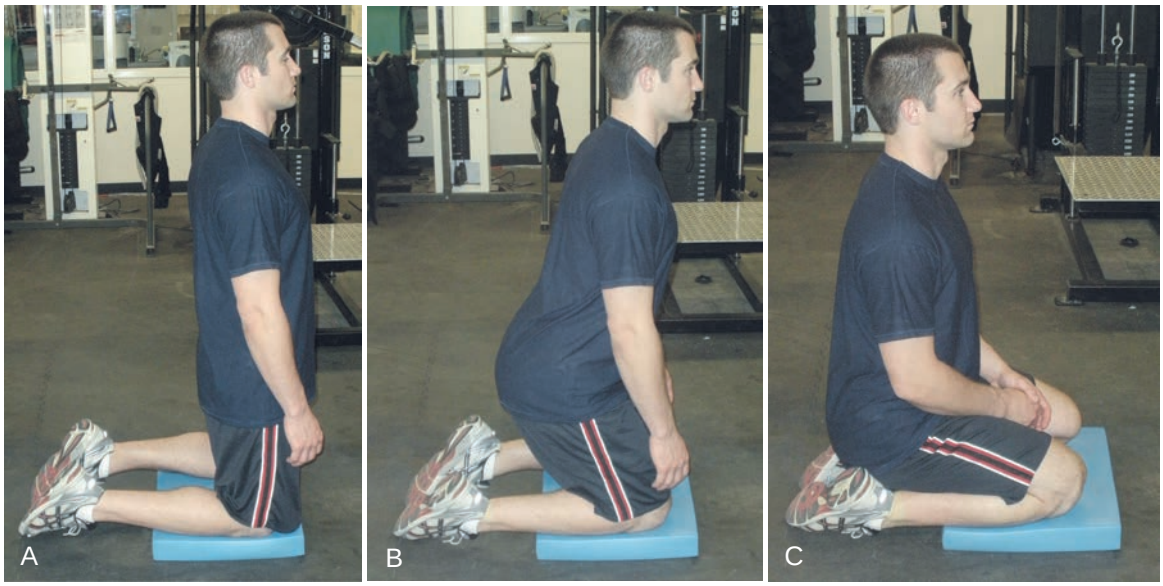

FIGURE 30-38. Kneeling squat. **A,** Start position. **B,** Middle position. **C,** End position.

activities and plyometrics. The Shuttle MVP is used in the early rehab phase within physician guidelines and throughout the rehabilitation phases until return to sport is achieved.

- The athlete is advanced by a criteria-based progression and rehabilitation timeline noted later in the chapter.
- At 10 weeks a progressive weight-bearing stretch into increasing knee flexion is initiated using the Shuttle MVP. Weight-bearing/loaded stretch into increasing knee flexion is progressed (bilaterally) until full, symmetrical, and zero symptoms of pain/swelling.
- Resistance is increased in increments of 5% of body weight, starting with no resistance and progressing to 100% body weight. Time under tension ranges from 3 to 5 seconds to 60 seconds to approximate varied time spent in squatting position for catcher. This is performed daily until criteria are met.
- Once the athlete achieves criteria bilaterally, single leg is progressed in a similar manner to approximately two-thirds body weight until full, symmetrical, and zero symptoms on the Shuttle MVP.
- At the time the athlete progresses to single leg on the Shuttle MVP, a kneeling squat exercise (Figure 30-38), sitting back on the heels and returning to full kneeling, is instructed and executed following the same parameters as before until criteria are met of full, symmetrical, and zero symptoms.
- Full kneeling is progressed to half kneeling (Figure 30-39) as tolerated.
- In this author's clinical experiences application of a neoprene sleeve and Knee Saver (Figure 30-40), firm wedged pad, during this progressive loading of end-range knee flexion expedites and minimizes setbacks. The authors speculate a strong psychological

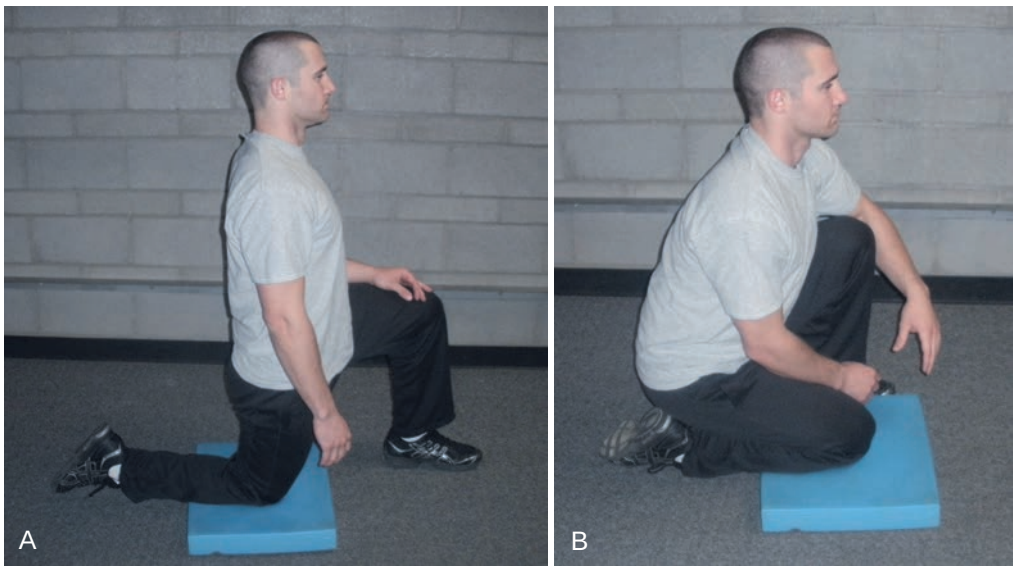

FIGURE 30-39. Half kneeling squat. **A,** Start position. **B,** End position.

FIGURE 30-40. Knee savers.

component giving a sense of security, improved performance, and favorable subjective responses. The literature suggests neoprene sleeves can enhance/provide proprioceptive stimuli.[43–46]

- The authors are unaware of any known literature on the efficacy or scientific data of the Knee Saver. Based on our clinical observation, the Knee Saver does provide sensorimotor (tactile feedback/reminder), mechanical support, and psychological benefit to the rehabbing athlete during this phase of achieving fully loaded positions/movements in extreme knee flexion. The Knee Saver is utilized bilaterally as well as unilaterally between the buttocks and lower leg for the treatment strategies listed previously and throughout program design. The potential benefits, inherent limitations, and dependence of the neoprene sleeve and Knee Saver are strongly communicated to the athlete.
- The combination of weight bearing and increasing knee flexion must be carefully balanced, monitored, and progressed throughout the athlete's rehabilitation.
- Regaining end-range flexion in fully loaded/weight-bearing positions is imperative for this athlete to return to catching after meniscal repair. The reader is reminded that the goal is symmetrical knee ROM bilaterally not only in supine position but also in weight-bearing positions required of athlete.
- The Inertial Exercise Trainer (Impulse Training Systems; Newnan, GA) (Figure 30-41) is incorporated early as a treatment strategy and progressed to high-performance sport-specific movement.

FIGURE 30-41. Impulse inertial training.

FIGURE 30-42. Power plate.

- Inertial exercise offers a unique form of exercise/training from the traditional methods. Tonic and phasic applications are utilized with varying weight progressing to no weight (gravity-free and low friction) to isolate single joints and/or involve multiple joints.[47] Evidence supports implementation of inertial exercise for neuromuscular training.[47–49]
- Vibration training or whole body vibration on the Power Plate Pro 5 (Power Plate^{R})[50] is implemented at 6 weeks in combination with conventional resistance.
- The vibration platform produces triplanar vertical vibration at a frequency between 25 and 50 Hz. Training variables are manipulated just as traditional methods with use of the Power Plate (Figure 30-42) generally three times per week utilizing 3 to 5 therapeutic exercises in a single vibration session. The authors prescribe frequency varying between 30 and 50 Hz consisting of short bouts of 30 to 90 seconds.
- The athlete is systematically progressed from static positions to dynamic movements or performed encompassing a mixture of the two.
- The literature suggests that vibration training should be viewed as a potential mode of training and intervention.[51–57]

Advanced Strength and Conditioning Program

Periodization

- Undulating

Program Design/Performance Training Program

Sport-Specific Concepts of Integrated Training

- Training continuum
- Flexibility/joint mobility for joint stability
- Training with optimum posture
- Sensorimotor and balance training
- Core training
- Cardiorespiratory training
- Multiplanar training activities
- Training for optimum muscle balance
- Training for optimum muscle functional strength
- Training for optimum muscle functional power
- Neuromuscular dynamic stability exercises
- Training for speed, agility, quickness (SAQ)
- Plyometric training
- Functional training
- Sport-specific training

Training Principles Used in the Design of the Program

- Principle of progression
- Principle of overload
- Principle of variation
- Principle of individualization
- Principles of specificity—specific adaptation to imposed demands (SAID)

Application of Acute Training Variables

- To properly design the athlete's program following meniscal repair, a "needs analysis"[58] is performed comprised of physiological and biomechanical requirements of the rehabilitating athlete, sport, and catcher position. This comprehensive analysis is utilized to address specific strength, flexibility, range of motion, power, endurance, and speed in order to maximize performance and successful return to sport.
- It is the author's opinion that exercise selection incorporates mixed modes and various forms of exercise/resistance separate or in combination of traditional forms to provide optimal acute and chronic physiological adaptations (i.e., vibration training, inertial exercise, TRX, aquatics, etc.).
- This author advocates undulating (nonlinear) periodization for program design. It allows multiple variables to be manipulated and prescribed during the phases of rehabilitation program. A general outline[59] that established and described utilizing undulating periodization in the different phases of rehabilitation provides the premise and groundwork (Table 30-1).
- Collectively, the acute training variables are the basic components of the program design. The acute variables determine the amount of stress placed on the athlete and concomitantly what adaption the body will undergo and gain.
- All acute variables are interdependent of one another and manipulated accordingly to achieve desired result. Initially the bulk of therapeutic exercises and drills are two to three sets of 15 repetitions or bouts of 25- to 30-second intervals to foster development of muscular endurance and joint stabilization.
- Rest intervals typically are 30 to 90 seconds depending on load to promote endurance and stability adaptations.
- Essential to the success of the rehab/training sessions, and ultimately the return to sport, is training intensity. Effort level must be regulated and monitored accordingly to construct the desired physiological responses.
- The customary repetition maximum loading schemes are used on occasion when the athlete's loading capabilities can safely and effectively handle the progressive increase to determine their repetition maximum. The authors' preference to determine load of rehabilitating athlete is guided by clinical observation of movement, function, and muscle performance without compensation during prescribed therapeutic exercises and drills.
- In addition, the athlete's feedback and perceived exertion are monitored diligently using the OMNI-RES scale between 4 and 7.
- Repetition tempo is generally slow to moderate to achieve the objective of endurance, stability, and strength (i.e., slow: 2 to 3 sec/2 sec/4 to 5 sec concentric/isometric/eccentric to moderate: 2 sec/0 sec/2 sec concentric/isometric/eccentric).
- Volume of training is inversely proportional to intensity of training.
- Training is cumulative and must avoid/prevent overtraining.
- Training frequency consists of 3 to 5 days per week with active recovery days between.
- Rehab/training sessions are approximately 60 to 90 minutes in length over a 4 to 6 (peripheral tears) to 6 to 8 (complex tears) -month period with 6 to 8 weeks generally dedicated to return to sport and sport-specific activities/phases as discussed in this chapter.

Sport-Specific Training (Interval Sport Program)

Table 30-1 Utilization of Nonlinear Undulating Periodization in Different Phases of Rehabilitation

Phase	Training Emphasis	Nonlinear Periodization Phase	Parameter Trained	Training with Team
Phase I: Immediate Rehabilitation	Low intensity endurance of stabilizing muscles Training of joint above and/or below for stability and endurance	I. Setting foundation with emphasis on muscle endurance	I. Monday: Endurance Wednesday: Hypertrophy Friday: Strength	I. Cardiovascular (CV) endurance training (e.g., stationary bike for injured UE or trunk. Upper body ergometer [UBE] for injured LE or trunk) II. Weight room training of noninjured areas with protection of injured area III. Lower-level sport related skills of noninjured areas (e.g., free throws or ball tossing for injured LE; ball passing drills for soccer player with injured [UE])
Phase II: Intermediate Rehabilitation	Low to high intensity endurance of stabilizing muscles (dependent on their specific function) Progression from low to high intensity strength for muscles responsible for movement of affected area (dependent on contraindications and precautions, etc.)	I. Emphasis on increasing muscle size and continued strength training II. Strength gain emphasis prior to transition to power training	I. Monday: Hypertrophy Wednesday: Strength Friday: Hypertrophy II. Monday: Strength Wednesday: Endurance Friday: Strength	I. Weight room training of noninjured areas; continue CV endurance, progressing to long duration lower intensity interval CV activity (bike, UBE, etc.) II. Interval CV activity increasing in intensity (decreasing duration) with emphasis on energy system most relevant to athlete's sport. III. Sport related skills as prior; initiation of sport related skills of injured area (patterns of movement, low-intensity drills, etc.)
Phase III: Advanced Rehabilitation	Continued endurance emphasis for stabilizing muscles High intensity strengthening progressing Low to high intensity power progression of movement muscles (dependent on prevention, etc.)	I. Strength gain emphasis prior to transition to power training (short duration emphasis) II. Begin transition to power	I. Monday: Strength Wednesday: Endurance Friday: Strength II. Monday: Strength Wednesday: Power Friday: Strength	I. Interval training emphasis on proper energy system and incorporating total body movement patterns II. Sport related skills—Progressed to game intensity as per athlete readiness and tolerance
Phase IV: Return to Function	Continued as in phase III; with increased emphasis on clients functional requirements (i.e., power for jumping athletes; endurance for long distance running athletes, etc.)	I. Continued progression of strength and power phase	I. Monday: Power Wednesday: Strength/Hypertrophy Friday: Power	I. Sport related skills at game intensity progressed to normal practice and eventually return to game competition

Training Principles Used in the Design of the Program

- Principle of progression
- Principle of overload
- Principle of variation
- Principle of individualization
- Principles of specificity—SAID

Application of Acute Training Variables

The interval sport programs are designed to return the athlete from surgery/injury by progressing through graduated sport-specific activities. Progressive exposure to the demands of the sport are monitored and afford individual variability based on the athlete's injury, skill level, and goals.

The interval sport programs are integrated into the rehabilitation sessions on an every other day basis to allow for rest and recovery. Alternate days incorporate upper body, core/stability, and cardiovascular training. Core lower extremity exercises (strength, plyometrics, neuromuscular drills) are performed on the same day of interval sport programs. This cycle is repeated throughout the week with designated rest/off days.

- Interval sport programs are performed first (priority) after adequate warmup followed by dosed/prescribed rehabilitation for that day.
- To progress to the next step of the interval sport program, the athlete must be able to perform a set number of consecutive sessions without pain/dysfunction. If pain or difficulty, the athlete returns to the previous level.
- In addition, the athlete is closely monitored for appropriate mechanics and fatigue which can affect progression.
- The authors recommend commencing interval sport programs (i.e., hitting, throwing, running) separately over a period of time to acclimate and monitor for signs and symptoms prior to initiating another interval

sport program. The authors assert that the interval sports programs presented are only guidelines that can be modified to address the situational needs of the individual performing them. There is no set timetable for completing the interval sport programs.

- The hitting program is divided into five phases (Box 30-2). The step-wise progression provides the gradual tissue load required for the dynamic forces of the bat swing.
- Phase I begins with dry swinging both from the right and left sides to provide biomechanical force production in the kinetic chain. The athlete's tibiofemoral joints have the opportunity to act in the lead/front leg or back leg manner in swinging a bat. This is only done in phase I unless the athlete is a switch hitter. Swing intensity and volume are progressed through a series of steps. The athlete progresses through each step only if pain free and demonstrates good quality movement and execution.
- Phase II is hitting off tee with increasing intensity and number of swings.
- Phase III integrates soft toss.
- Phase IV batting practice usually off coach or machine.
- To prepare for game hitting, Phase V incorporates hitting against live pitching and simulation of an at bat.
- The interval throwing program (Box 30-3) has two phases.
- The long toss program, Phase I, consists of 17 progressive steps.
- The athlete typically performs each step twice before progressing and should successfully complete Phase I prior to initiating Phase II.
- Distance is sequentially progressed by 15-foot increments starting at 45 feet and concluding at 180 feet.
- The number of throws is progressive in nature, culminating at 75 throws at the 90-foot phase in a single session.
- Commencing at the 105-foot phase, the number of throws are reduced with increasing distances.[60]
- The author warns not to neglect the number of throws for warmup and/or "nonrecorded" throws such as in catching drills or catching bullpens.
- A "crow hop" method is taught and instituted during the interval throwing program. Although there is general consensus to teach and use the "crow hop" method for proper body mechanics of throwing, varied opinions exist on the footwork sequence and the author is unaware of any published literature on the "crow hop" method.
- Phase II is initiated on successful completion of the long toss program.
- It is position specific for the catcher and incorporates the unique throwing demands required to bases and mound from the squat, kneeling, and standing positions.
- Four steps are included in Phase II with step four participating in a simulated game.
- Each step is performed a minimum of twice before advancing.
- The "pop time" for a catcher, time from receiving pitch and throwing to second base, is a measure often taken to gauge quickness and strength of catcher's arm. The general consensus among baseball scouts and coaches for a catcher's "pop time" is 1.85 seconds or less (excellent), 1.95 to 2.0 seconds (average), and 2.05 seconds or above (low).
- The return to running program (Box 30-4) has four phases that increase loads and require progressive adaptations for the athlete to achieve prior to advancing to the next level.
- Phase I, the walking program, is formally introduced on the treadmill and performed three to five times per week until successfully completed.
- The walking program is a precursor and criterion to be achieved prior to Phase II, walk/jog. It is worth noting that the design of the return to running program, initially, does not facilitate cardiovascular fitness and must be supplemented with appropriate cross-training strategies.
- Step 2 progresses treadmill inclination in 2% to 5% increments as tolerated.
- Step 3 incorporates various surfaces/terrain outdoors to be negotiated (i.e., grass, dirt, sand, etc.). The goal is to walk briskly for 1 mile and/or 30 minutes without symptoms of pain, effusion, or antalgic gait.
- Phase II is comprised of a straight-line walk/jog combination. For discussion, running speed is a quarter to

BOX 30-2 Interval Hitting Program

Phase I: Dry Swings

Step 1: 50% effort (1 set 25 swings R/L)
Step 2: 50% effort (2 sets 25 swings R/L)
Step 3: 75% effort (2 sets 25 swings R/L)
Step 4: 80% to 90% effort (2 sets 25 swings R/L)

Phase II: Off a Tee

Step 5: 50% effort (1 set 25 swings R/L)
Step 6: 50% effort (2 sets of 25 swings R/L)
Step 7: 75% effort (2 sets of 25 swings R/L)
Step 8: 80% to 90% effort (2 sets 25 swings R/L)
Step 9: 80% to 90% effort (2 sets 25 swings R/L)

Phase III: Soft Toss Swings (Front/Side Toss)

Warm up using a tee
Step 10: 50% to 60% effort (1 set 25 swings R/L)
Step 11: 65% to 75% effort (2 sets 25 swings R/L)
Step 12: 80% to 90% effort (2 sets 25 swings R/L)
Step 13: 80% to 90% effort (2 sets 25 swings R/L)

Phase IV: Batting Practice Swings (Coach/Machine BP)

Warm up using a tee
Warm up with soft toss swings
Step 14: 50–65% effort (2 sets 25 swings)
Step 15: 70–75% effort (2 sets 30 swings)
Step 16: 80–90% effort (2 sets 30–35 swings)
Step 17: 80–90% effort (2 sets 30–35 swings)

Phase V: "Live" Batting Practice (Off Pitcher)

Step 18: 80–90% effort (10–15 pitches)
Step 19: 80–90% effort (10–15 pitches)
Step 20: 80–90% effort (10–15 pitches)
Hit 3–4 times per week with a day off in-between

BOX 30-3 Interval Throwing Program

Phase I: Long Toss

STEP 1

45-ft Phase
A. Warm-up
B. 25 throws
C. Rest 5–10 min
D. Warm-up
E. 25 throws

STEP 2

45-ft Phase
A. Warm-up
B. 25 throws
C. Rest 5–10 min
D. Warm-up
E. 25 throws
F. Rest 5–10 min
G. 25 throws

STEP 3

Initiate Phase II: Catcher

Phase II: Catcher

STEP 1

A. Warm-up to 130–150 ft
B. 15 throws from 60 ft
C. 10 throws from 90 ft
D. 10 throws from 120 ft
E. Rest 5–10 minutes
F. 10 throws from squat at 60 ft
G. 10 throws from squat at 90 ft'
H. 5 throws from squat at 120 ft

STEP 2

A. Warm-up to 130–150 ft
B. 15 throws to mound from squat after pitch
C. 5 throws to each base from squat after pitch
D. Rest 5–10 minutes
E. 15 throws to mound from squat after pitch
F. 5 throws to each base from squat after pitch

STEP 3

A. Warm-up to 130–150 ft
B. 15 throws to mound from squat after pitch
C. 10 throws to each base from squat after pitch
D. Rest 5–10 minutes
E. 5 throws to each base after bunt
F. 15 throws to mound standing (pitch out)

STEP 4

Simulated game

BOX 30-4 Return to Running Program

Phase I: Walking Program

STEP 1: NO INCLINE

Treadmill walking program: forward, lateral, retro at a comfortable pace progressing to aggressive/brisk walk without pain/effusion

A. Warm-up
B. Forward walking x 4 min
C. Lateral side stepping left x 2 min
D. Lateral side stepping right x 2 min
E. Retro walking x 2 min
F. Cool-down

STEP 2: PROGRESSIVE INCLINE (INCREMENTS OF 2% TO 5% AS TOLERATED, MAX 10% TO 12% INCLINATION)

Treadmill walking program: forward, lateral, retro at a comfortable pace progressing to aggressive/brisk walk without pain/effusion

A. Warm-up
B. Forward walking x 4 min
C. Lateral side stepping left x 2 min
D. Lateral side stepping right x 2 min
E. Retro walking x 2 min
F. Cool-down

STEP 3: VARIOUS SURFACES/TERRAIN (ON-FIELD/OUTSIDE)

Walking program: forward, lateral, retro at a comfortable pace progressing to aggressive/brisk walk without pain/effusion (total time 30 minutes)

A. Warm-up
B. Forward walking
C. Lateral side stepping
D. Lateral side stepping
E. Retro walking
F. Cool-down

Phase II: Walk/Jog

STEP 1

Jog ¼ mile, Walk ¾ mile, comfortable pace (¼ – ½ speed)

STEP 2

Jog ½ mile, Walk ½ mile, comfortable pace (¼ – ½ speed)

STEP 3

Jog ¾ mile, Walk ¼ mile, comfortable pace (¼ – ½ speed)

STEP 4

Jog 1 mile, comfortable pace (¼ – ½ speed)

STEP 5

Jog 1 mile, comfortable pace (¾ speed; Goal 7.5- to 8-minute mile)

Phase III: Sprint/Straight Ahead Running

STEP 1

Run ½ speed 180 ft x 10 reps

STEP 2

Run ½ speed first 45 ft; ¾ speed middle 90 ft; last 45 ft ½ speed x 10 reps

STEP 3

Run ½ speed first 45 ft; full speed middle 90 ft; last 45 ft ½ speed x 10 reps

STEP 4

Lead off position (start)—run ¾ speed 90 ft x 10 reps

STEP 5

Lead off position (start)—run full speed 90 ft x 10 reps

Phase IV: Base Running/Sliding

STEP 1

Incorporate base running and sliding

- Single
- Double
- Triple
- Homerun
- Home to first thru the bag
- First to third with lead
- Tag and score from third
- Score from second
- Sliding (feet first—single leg bent knee)

half (jog) the athlete's normal speed progressing to three-quarter (half speed sprint) to full speed (sprint). The purpose of this phase is to provide a general cardiovascular fitness (aerobic baseline, normalize mechanics, and gradually increase the loads imparted on the knee with jogging/running.

- The goal is to jog a 7.5 to 8 minute mile at conclusion of Phase II.
- Phase III initiates the sprint program and is designed based on the requirements of the sport. Consequently, short duration and high intensity sprinting are the desired task of this phase.
- The standing position is assumed initially for the start position of sprinting. A distance of 180 feet is used and broken into 45-foot segments. This allows for jogging the first 45 ft, manipulated intensity (half, three-quarter, full speed) of sprint the middle 90 ft, and the last 45 ft for deceleration.
- Typically each step is performed 2 to 3 times before advancing to an every-other-day basis.
- Once full sprinting is accomplished at the middle 90 ft, the starting position is altered to the "lead off" position to stress the acceleration aspect of base running and distance is decreased to 90 feet (base to base).
- Full-speed sprinting is allowed from start to finish. Readers are reminded that progressive sport-specific agility drills and foot work are concomitantly being administered to address changes in direction (cutting, pivoting) but are not included specifically in the return to running program.

- The final component, Phase IV, focuses on base running and sliding. Simplistically, the athlete performs the various scenarios encountered in base running, which can be viewed/treated as simulated games and/or conditioning.
- There is limited published literature on running speeds for professional baseball players. The average MLB player ran 4.33 ± 0.15 seconds from home to first reported by Coleman.[61]
- Of note, the author included catchers with a time of 4.48 ± 0.11 seconds. Subsequently the goal desired with the return to running program's latter stage is for the catcher to run from home to first ranging from 4.37 to 4.59 seconds.
- Sliding is a necessary and often neglected aspect of base running. It has been recognized as a significant cause of injuries in softball and an important source of lost participation time in collegiate baseball and softball.[62]
- Corzatt et al.[63] describes sliding as the ability to sprint along a base path and suddenly convert a vertical body to a nearly horizontal one. This study also identified four distinct phases of sliding mechanics: sprint, attainment of sliding position, airborne position, and landing.
- The two basic sliding techniques used are head-first and feet-first.
- A third type, the diveback, is used to return to a base as opposed to running from one base to the next. The diveback is typically performed head-first and of lower velocity secondary to the sprint phase being absent.
- Although there is potential for injury with each technique, the head-first slide is discouraged because of the potential to be more dangerous, with upper extremities, head, and cervical spine at risk. Head-first sliding offers no speed advantage compared with feet-first sliding.[64] The single bent-leg (feet-first) sliding technique (see Figure 30-33) is advocated and taught until the athlete has mastered it.
- The catching drills (Box 30-5) are an integral part to ready the athlete for return to catching. The authors provide suggested drills that can be performed in multiple settings and adapted to fit accessibility of equipment, location, etc. The catching drills provided are by no means all-inclusive but offer a good source for the reader to incorporate into a sport-specific program for a catcher.
- Another point to consider is utilizing catching bullpens (generally 25- to 35-pitch pens) as a training strategy for readiness to return to sport. The catcher is a key position in baseball.
- The three most important physical skills for a catcher are receiving, blocking, and throwing. The catcher's ability to receive and block pitches properly is paramount to a pitcher's success.

Application of Chronic Training Variables

- The chronic training variables are applied in similar fashion as acute training variables in an undulating periodization model.
- In the latter stages of rehabilitation, manipulation of the intensity can be daily to weekly but is characterized by high-intensity low-volume training drills/activities.
- The purpose is to continually provide a stimulus for desirable adaptions and prevent accommodation and overtraining. The focus shifts to the energy requirements and sport-specific skills with high-intensity power parameters.
- Once the athlete returns to sport competition, the goal is to preserve strength, power, and sport performance levels with moderate intensities and volume with a maintenance program.

Sports Performance Testing

General Information

- General history
- Subjective questionnaires
- Medical history
- Sports injury history
- Surgical history
- Chronic conditions/medication

Specific Tests

- Static and dynamic postural assessments (Table 30-2), as well as active and passive ROM assessments (Table 30-3), are performed at the first postoperative visit and are continued throughout the entire rehab process.
- Because of position-specific ROM demands imposed on a catcher, qualitatively and quantitatively, ROM of foot/ankle, knee, and hip in progressive-loaded/weight-bearing positions are assessed with particular attention of knee around 10 weeks postoperative with increasing knee flexion (Table 30-4).
- Isometric strength testing is performed using either standard manual muscle testing techniques or a hand-held dynamometer at approximately 4 weeks postoperative.
- Isokinetic testing (180°/sec and 300°/sec) of knee flexion and extension is performed starting at approximately 12 weeks postop to determine muscular performance and balance.
- The Functional Movement Screen is utilized by the author. The FMS[65] has been shown to have good interrater,[66,67] intersession,[66] and intrarater reliability. A retrospective examination of professional football players revealed that players who scored a 14 or below on the FMS score increased their risk of sustaining an injury by 36%.[68] A score of 15 or greater is recommended for the competitive athlete.
- Additionally, the authors assess isometric strength and conduct knee isokinetic testing (180°/sec and 300°/sec) commencing at approximately 12 weeks postop to determine muscular performance and balance. Isometric strength is performed using standard manual muscle testing techniques, hand-held dynamometer, and/or isokinetic device (isometric mode) approximately 4 weeks postop and selectively at regular intervals throughout rehabilitation.
- The lower extremity functional test (Figure 30-43),[69] horizontal jump test[69] (Figure 30-44), single hop for distance test, triple hop test, and the wall sit test

BOX 30-5 Catcher Drills

Receiving

1. **Barehanded Drill**—Partner straight on in front of catcher from 10 feet away
   - Underhand toss at left knee x 10–15 reps
   - Underhand toss at right knee x 10–15 reps
   - Underhand toss alternating left/right knee x 10–15 reps
   - Underhand toss randomly left/right knee x 10–15 reps
   - On/off balance beam
2. **Balance Beam Drill** (see Figure 30-45)—Partner straight on in front of catcher from 10 feet away (underhand tossing)
   - Receiving stance x 15–20 reps various locations within strike zone
   - Spread stance (Figure 30-46) x 15–20 reps (facing Lt/Rt)
   - Weight-shifting/Sway x 15–20 reps Lt/Rt (balls tossed outside of knees)
3. **Angled Receiving Drill** (see Figure 30-46)—Partner/Machine thrown from mound
   - Catcher angled/facing third base; fastballs thrown at left knee; catcher rotates to right gradually until receiving pitches facing mound x 10–15 reps (pitches)
   - Catcher angled/facing first base; fastballs thrown at right knee; catcher rotates to left gradually until receiving pitches facing mound x 10–15 reps (pitches)
4. **Walkup Drill**—Partner/Machine thrown from mound
   - Catcher at 60 feet, catch/receive 5 pitches
   - Progressively move up decreasing distance every 3–5 pitches till approximately 40–45 ft (catch 5 pitches at this distance)
   - Return quickly to start position (60-ft catching/receiving 5 to end session)
5. **Machine Catching/Receiving**—Partner/Machine thrown from mound
   - Fastball, curveball, slider at left knee x 10–15 pitches each
   - Fastball, curveball, slider at right knee x 10–15 pitches each

Blocking

1. **Dry Blocks** (see Figure 30-47)—Place three baseballs (left, center, right) approximately 3 feet in front of the catcher. Catcher performs proper blocking technique behind each baseball commencing at middle baseball (i.e., middle - left - middle - right - middle)
2. **Mirror Blocks**—Requires 2 catchers facing each other. Designate leader and have other catcher mimic blocking techniques.
3. **All Pitch Blocking** (see Figure 30-48)—Machine/Partner thrown (fastball, curveball, slider)
   - Halfway Position—Mitt on the ground, then quickly proceed to get to knees prior to pitch arriving x 10–15 reps
   - Full Position (block/throw stance x 10–15 reps)
4. **Angled Blocking**—Focus on getting down quickly, sliding, and squaring up to the baseball; develops range of catcher x 10–15 reps.
5. **Rapid Fire**—Catcher blocks baseball and returns to block/throw stance in rapid succession x 5–8 reps

Throwing

1. **Quick Footwork Drill**—Catcher begins in block/throw stance. Partner flips baseball and catcher performs footwork for throwing returning to original stance as quickly as possible x 5 reps
2. **Quick Transfer Drill**—Partner flips baseball at catcher's chest area (upper right to facilitate the transfer of baseball to throwing hand), bring mitt/ball toward hand vs hand toward mitt/baseball and throwing into net 5–8 feet away x 10–15 reps. Can be performed standing or in block/throw stance.
3. **Footwork/Throw Drill** (see Figure 30-49)—Machine/Partner thrown baseball, the catcher starts in his block/throw stance and performs footwork after receiving pitch and throwing into net 5–8 ft away. This can be done with any pitch (fastball, curveball, slider).

(described in the section return to sport criteria) assess movement performance.

- Functional tests are performed with increasing submaximal effort and used in training sessions as well to ensure proper sequencing with repeated measures prior to maximal effort testing.
- Sport-specific testing comprises successful completion of interval hitting (Box 30-2), interval throwing (Box 30-3), return to running (Box 30-4), and catching drills (Box 30-5; Figs. 30-46 to 30-50).

Specific Criteria for Progression to the Next Stage to Determine Readiness for Catching

The criteria to progress from Phase I (Maximal Protection Phase) to Phase II (Moderate Protection Phase) are the following:

- Knee PROM of 0 to 90°
- Tolerance of at least 75% to 100% weight bearing
- Normal gait, with or without assistive device
- Independent quad control

Table 30-2 Static/Dynamic Postural Assessments

Position	Body Region	Specific Assessments
Standing Alignment (posterior view)	Ankle	Equal weight distribution Feet pointed forward, or are they rotated (toe in or toe out) Medial longitudinal arch height Abductor hallucis hypertrophy Calcaneal positioning (eversion/inversion)
	Knee	Genu varum/genu valgum, Q-angle
	Hip	Equal weight distribution Greater trochanter height PSIS height
	Spine	Scoliosis Lateral shift
Standing Alignment (lateral view)	Ankle	Feet pointed forward; rotated (toe in or toe out) Medial longitudinal arch height Abductor hallucis hypertrophy
	Knee	Genu recurvatum or lack of full extension
	Hip	Innominate rotation Anterior/Posterior pelvic tilt Innominate anterior/posterior positioning (bilateral comparison)
	Spine	Lumbar lordosis Thoracic kyphosis
Standing Alignment (anterior view)	Ankle	Equal weight distribution Feet pointed forward, or are they rotated (toe in or toe out) Medial longitudinal arch height Abductor hallucis hypertrophy
	Knee	Genu varum/genu valgum, Q-angle Patellar alignment
	Hip	Iliac crest height Greater trochanter height ASIS height

The criteria to progress from Phase II (Moderate Protection Phase) to Phase III (Controlled Advanced Phase) are the following:

- No effusion
- Knee PROM of 0 to 135° (or equal to uninvolved side)
- Normal gait using no assistive device
- Able to maintain single leg balance stance for at least 15 seconds
- Able to maintain a single leg squat to 60 degrees of knee flexion for at least 5 seconds with no wavering or loss of balance
- Satisfactory clinical exam

The criteria to progress from Phase III (Controlled Advanced Phase) to Phase IV (Return to Sport/Activity) are the following:

- Isokinetic quadriceps strength of at least 75% of uninvolved side
- Able to tolerate closed kinetic chain pivoting without pain or swelling
- Able to tolerate dynamic, closed kinetic chain, triplanar movements without compensation, swelling, or pain.
- Full, pain-free, symmetrical knee AROM/PROM

Table 30-3 AROM and PROM Assessments (non–weight bearing)

Body Region	Motion	ROM Norms[70]
Ankle	Dorsiflexion	0°–20°
	Plantarflexion	0°–50°
Knee	Flexion	0°–145° †
	Extension	0°
Hip	Flexion	0°–120°
	Extension	0°–20°
	Abduction	0°–45°
	Internal rotation	0°–40°
	External rotation	0°–40°

†Knee flexion limited to 0° to 90° during first 2 weeks postop; ROM progressed based on symptoms; goal of full, pain-free ROM at 6 weeks.

Specific Criteria for Release to Unsupervised Complete Participation in Catching

The criteria to progress from Phase IV to Returning to Sport are the following:

- Medical/Physician approval
- Successful completion of interval sport programs (hitting, catching drills, sliding, running, throwing)
- Satisfactory completion of the lower extremity functional test: time within 90% compared with normative data (less than 2 minutes—Females, less than 1½ minutes—Males) (see Figure 30-43)[69]
- Isokinetic quadriceps/ham strength of at least 90% of uninvolved knee
- Horizontal jump test greater than or equal to 90% height of uninvolved limb (see Figure 30-44)[69]
- Single leg hop test greater than or equal to 90% distance of uninvolved limb
  - Subjects will perform a single leg hop for distance with each lower extremity. After demonstration, each subject will be allowed one trial per leg. Beginning with the toes immediately behind the starting line, subjects will perform one hop to complete a trial. The hop will be measured from the starting line to the end of the toes after completion of a trial. Each limb will be tested two times with the maximal distance scored for each limb.
- Triple hop test greater than or equal to 90% of uninvolved limb
  - Perform a single leg triple hop for distance with each lower extremity. After demonstration, each subject will be allowed one trial per leg. The test will begin

with the toes immediately behind the starting line. The subject will perform three hops consecutively prior to the completion of a trial. The hop will be measured from the starting line to the end of the toes after the third hop on each trial. Each limb will be tested two times with the maximal distance scored for each limb.

- Maintain wall sit with knees flexed to 90 degrees for 3 minutes.

Recommended Ongoing Exercises

- Maintenance/preventative total body strength and conditioning program that addresses fundamental movement patterns and skills specific to the baseball athlete (i.e., squatting, running, hitting, throwing, etc.) and incorporates principles of dynamic stability and mobility, neuromuscular control, and proprioception.

Evidence

Bizzini M, Gorelick M, Drobny T: Lateral meniscus repair in a professional ice hockey goaltender: A case report with a 5-year follow-up. *J Orthop Sports Phys Ther* 36:89–100, 2006.

The purpose of this case report was to describe the outcomes of an accelerated, sport-specific, criterion-based rehabilitation protocol for a high-level athlete prescribed for an isolated lateral meniscus repair with a 5-year follow-up. The authors were able to return the athlete to sport 103 days

Procedure:

1. Patient stands on both legs.
2. Patient jumps side to side between two platforms, with the arms left free.
3. Allow one set of submax (easy side to side) warm-ups.
4. Each set consists of 20 jumps, with a 20-second rest period in between each set.
5. The objective is for the patient to complete the 20 jumps as quickly as possible.
6. The patient completes 3 sets of 20 jumps for the test. For each set the total elapsed time is recorded.

postop using the specified protocol. They also determined that no reinjury of the lateral meniscus occurred up to 5 years after surgery. The authors conclude that the sport-specific, criterion-based rehabilitation program showed a safe return to sport and a good long-term outcome. (Level IV evidence)

Brindle T, Nyland J, Johnson DL: The meniscus: Review of basic principles with application to surgery and rehabilitation. *J Athl Train* 2:160–169, 2001.

The purpose of this article was to review the basic meniscal anatomy, histology, and biomechanical principles of the meniscus and discuss how they apply to current surgical and rehabilitation methods. They found that injuries to a healthy meniscus are usually produced by a compressive force coupled with transverse-plane tibiofemoral rotation as the knee moves from flexion to extension. The goal of meniscal surgery and rehabilitation is to restore a functional meniscus to prevent the development of degenerative osteoarthritis in the involved knee and restore patient function. Restoration of function is based on factors such as individual needs, type of surgical procedure, which meniscus was repaired, coexisting knee, type of tear, patient age, preoperative knee status, knee range of motion or strength, and patient athletic expectations and motivations. The authors believe progressive weight bearing and joint stress are necessary to enhance the functionality of the meniscal repair and prolonged knee immobilization after surgery can result in the rapid muscular atrophy and a longer road to recovery. The authors conclude that aquatic therapy may be ideal during all phases of rehabilitation after meniscal surgery (regardless of the exact procedure), providing the advantages of controlled weight bearing and mobility progressions. (Level V evidence)

FIGURE 30-51. TRX (suspension training).

Escamilla RF: Knee biomechanics of the dynamic squat exercise. *Med Sci Sports Exerc* 1:127–141, 2001.

The purpose of this review was to examine knee biomechanics during the dynamic squat exercise. The authors reviewed and discussed tibiofemoral shear and compressive forces, patellofemoral compressive force, knee muscle activity, and knee stability relative to athletic performance, injury potential, and rehabilitation. They found that low to moderate posterior shear forces were generated throughout the squat for all knee flexion angles and low anterior shear forces were generated between 0° and 60° knee flexion. They also found that patellofemoral compressive forces and tibiofemoral compressive and shear forces progressively increased as the knees flexed and decreased as the knees extended, reaching peak values near maximum knee flexion. The authors conclude that performing a squat in the functional range between 0° and 50° knee flexion may be appropriate for many knee rehabilitation patients, because knee forces were minimum in the functional range. Quadriceps, hamstrings, and gastrocnemius activity generally increased as knee flexion increased, which supports athletes with healthy knees performing deeper squats between 0° and 100° knee flexion (parallel squat. For athletes with healthy knees, performing the parallel squat is recommended over the deep squat, because injury potential to the menisci and cruciate and collateral ligaments may increase with the deep squat.

Mintzer CM, Richmond JC, Taylor J: Meniscal Repair in the Young Athlete. *Am J Sports Med* 26:630–633, 1998.

This study was performed to determine the success rate and outcome of meniscal repair in a young athletic population. Twenty-nine meniscal repairs in 26 patients 17 years of age or younger were performed using arthroscopic techniques. All patients were seen for follow-up at an average of 5 years (range, 2 to 13.5 years), with assessment including the SF-36 Health Status Survey, International Knee Documentation Committee, a Lysholm score, and thorough physical examination. They found that all 26 patients were asymptomatic and demonstrated clinically healed repairs at follow-up. The 100% success/healing rate found is higher than that reported in the adult population. These results support the concept of meniscal preservation by aggressively repairing torn tissue, especially in the young athletic population. (Level IV evidence)

Myer GD, Paterno MV, Ford KR, et al: Rehabilitation after anterior cruciate ligament reconstruction: Criteria-based progression through the return-to-sport phase. *J Orthop Sports Phys Ther* 36;385–399, 2006.

This review article discussed the history of ACL reconstruction rehabilitation as well as provided an algorithm for progressing a patient post ACL reconstruction. The outcome measures all have validity and reliability. In general, thinking has switched from prolonged postop immobilization to return to sport activities at 8 weeks. Animal studies have revealed that ACL grafts demonstrate their weakest point at 6 to 8 weeks postop. At 1 year postop the threshold for graft failure is 11% to 50% of a native ACL. There is a fine line in exercise progression and clinicians should respect the stress strain curve of tissue. Decreased strength, joint position sense, postural stability, and force attenuation have been documented for 6 months to 2 years following ACL reconstruction. (Level V evidence)

Myer GD, Paterno MV, Ford KR, et al: Neuromuscular training techniques to target deficits before return to sport after anterior cruciate ligament reconstruction. *J Strength Cond Res* 3:1–28, 2008.

The purpose of this scientific commentary was to present an example of a progressive return to sport protocol designed to help the athlete to progress through objective measures of neuromuscular control, strength, power, and lower extremity symmetry that are rehabilitative landmarks after ACL reconstruction. The proposed return to sport training protocol involves four phases, including Dynamic Stabilization and Core Strengthening, Functional Strengthening, Power Development, and Sports Performance Symmetry, and incorporates quantitative measurement tools that will provide the athlete with objective feedback and targeted goal setting. The authors offer rationale for exercise selection to provide the care provider with a flexible decision-making approach that will aid in the modification of return to sport training to meet the individual athlete's abilities and to target objectively measured deficits. They conclude that this algorithmic approach may improve the potential for athletes to return to sport after ACL reconstruction at the optimal performance level and with minimized risk of reinjury. (Level V evidence)

Shelbourne KD, Patel DV, Adsit WS, et al: Rehabilitation after meniscal repair. *Clin Sports Med* 15:595–612, 1996.

The purpose of this study was to compare patient outcomes following completion of traditional meniscus repair rehabilitation (non-weight bearing for 6 weeks with the knee in 45° degrees of flexion, running at 3 months, and return to sport

at 6 months with patient outcomes following completing an accelerated rehabilitation protocol (weight-bearing, walking and movement as tolerated; return to full activity upon involved knee reaching full ROM and 75% strength of uninvolved leg). Sixty-one patients with isolated meniscus repairs were separated into two groups, 39 participated in the accelerated group and 17 patients completed the conservative rehabilitation program. Patients who underwent accelerated rehabilitation achieved full ROM (6 vs 10 weeks) and returned to full activity (10 vs 20 weeks) sooner than patients who participated in a traditional rehab program. At long term follow up patients did not differ with respect to repair status, activity, and function. The average follow up was 4.5 years; 7 years for traditional and 3.5 years for accelerated. Limitations include, unequal group size, differing long term follow ups between groups, and age of groups; the accelerated group was older than the traditional group (28 vs 20 yrs). (Level V evidence)

Tiggelen DV, Coorevits P, Witvrouw E: The effects of a neoprene knee sleeve on subjects with a poor versus good joint position sense subjected to an isokinetic fatigue protocol. *Clin J Sport Med* 18:259–265, 2008.

The purpose of this randomized trial was to examine the effects of a neoprene knee sleeve on the joint position sense in locally fatigued subjects using the Cybex Norm isokinetic dynamometer. Sixty-four healthy subjects underwent four consecutive assessments of the same active joint-repositioning test under different conditions (braced, nonbraced, fatigued, and nonfatigued). They investigated the effects of side (braced vs control side), assessment sequence (one to four), and proprioceptive acuity ("good" versus "poor,") and their interactive effect on the joint position sense. At baseline (first assessment, the difference in repositioning error between both knees was not statistically significant. During the second and third assessments (when each subject on the experimental side wore an NKS, significant reduction in repositioning error was demonstrated on the experimental sides compared with the control side (P = 0.001 and P = 0.001). Once the brace was removed (fourth assessment), no statistically significant difference was observed between control and experimental sides. They also found that all subjects benefited from the braced condition after the fatigue test. The authors conclude that bracing is helpful in individuals with a poor baseline proprioceptive acuity in both fatigued and nonfatigued states, but only helpful when fatigued for subjects with a good joint position sense. The present findings suggest a rationale for using neoprene knee sleeves as a preventative measure or treatment in subjects and patients to enhance proprioceptive acuity in a fatigued state. (Level II evidence)

Wilk KE, Escamilla RF, Fleisig GS, et al: A comparison of tibiofemoral joint forces and electromyographic activity during open and closed kinetic chain exercises. *Am J Sports Med* 24:518–527, 1996.

The purpose of this cross sectional study was to investigate knee joint kinetics and muscles during open kinetic chain (OKC) (knee extension) and closed kinetic chain (CKC) (leg press and squat exercises). Ten healthy, resistance-trained, male subjects performed four repetitions using a 12-repetition maximal weight for each exercise. Knee compressive forces reached a maximum during CKC exercises; squat (6139 N), leg press (5762 N), followed by OKC knee extension (4598 N). These peak forces occurred at 91, 90, and 75 degrees knee flexion respectively. Posterior shear forces at the knee reached a maximums during the squat (1783 N), leg press (1667 N), and knee extension (1178 N). These occurred at 90, 94, and 91 degrees of knee flexion, respectively. A maximal anterior shear force of 248 N occurred during OKC knee extension at an angle of 14 degrees knee flexion.

Yao J, Lancianese SL, Hovinga KR, et al: Magnetic resonance image analysis of meniscal translation and tibio-menisco-femoral contact in deep knee flexion. *J Orthop Res* 26:673–684, 2008.

The purpose of this study was to clarify meniscal displacement and cartilage-meniscus contact behavior in a full extension position and a deep knee flexion position. The also assessed whether the meniscal translation pattern correlated with the tibiofemoral cartilage contact kinematics. Magnetic resonance (MR) images were acquired at both positions for 10 subjects using a conventional MR scanner. Subjects achieved a flexion angle averaging 139° ± 3°. Both medial and lateral menisci translated posteriorly on the tibial plateau during deep knee flexion. The posterior translation of the lateral meniscus (8.2 ± 3.2 mm) was greater than the medial (3.3 ± 1.5 mm). They report that this difference was correlated with the difference in tibiofemoral contact kinematics between medial and lateral compartments. They found that contact areas in deep flexion were approximately 75% those at full extension and the percentage of area in contact with menisci increased significantly due to deep flexion. The authors conclude that these results, in combination with information about force and pressure in the knee, may lead to a better understanding of the mechanism of meniscal degeneration and osteoarthritis associated with prolonged kneeling and squatting.

Multiple-Choice Questions

QUESTION 1. The primary function(s) of mensci of the knee include which of the following?

A. Provide stress reduction and shock absorption.
B. Provide lubrication and nutrition.
C. Increase joint congruency and joint stability.
D. All of the above

QUESTION 2. As knee flexion angle increases, the compressive load transmitted through the posterior horns of each meniscus also increase, with _____% transmitted at 90° and _____% at 0° (full knee extension).

A. 25, 70
B. 85, 50
C. 60, 15
D. 90, 40

QUESTION 3. What essential goal must the athlete attain in order to successfully return to catching after meniscal repair?

A. Regaining full, symmetrical end-range flexion in fully loaded, weight-bearing positions
B. Full, symmetrical knee extension ROM in both non–weight-bearing and weight-bearing positions
C. Ability to perform a single leg squat beyond 120° knee flexion without loss of balance
D. None of the above

QUESTION 4. What type of periodization is incorporated by the author when implementing a rehabilitation program?

A. Undulating
B. Mesocycles
C. Macrocycles
D. Linear

QUESTION 5. According to Kiesel et al. (2007), athletes who scored a 14 or less on the FMS were ____ more at risk for injury?

A. 56%
B. 72%
C. 36%
D. 25%

Answer Key

QUESTION 1. Correct answer: **D** (found in Introduction)

QUESTION 2. Correct answer: **B** (found in Introduction)

QUESTION 3. Correct answer: **A** (found in Criteria to Progress from Stage to Stage section)

QUESTION 4. Correct answer: **A** (found in the Program Design section)

QUESTION 5. Correct answer: **C** (found in the Sport-Specific Testing section)

Chapter 31

Articular Cartilage Injury (Including Osteochondritis Dissecans) in the Young Athletic Knee

INTRODUCTION

Nathan A. Mall MD, Bryan M. Saltzman, MD, Andrew S. Lee, MD, and Brian J. Cole, MD, MBA

Epidemiology

Age

- Approximately 4% to 5% of the general population is thought to have focal, full-thickness cartilage defects.
  - Prevalence is higher in those undergoing arthroscopy, with one study finding 63% with chondral lesions, of which 19% were full thickness.
- A systematic review by Flanigan et al.[1] of 11 databases with athletes age 26 to 47 years (mean age of 33 years) demonstrated an overall prevalence of 36% for full-thickness focal chondral defects.
- DeHaven et al.[2] noted that athletes treated for internal derangement of the knee at University of Rochester Section of Sports Medicine over a 7-year period had a mean age of 22.9 years.
- Namdari et al.[3] analyzed 24 National Basketball Association (NBA) players between 1997 and 2006 and demonstrated a mean age of 28.6 years (range, 21 to 40) at which the athletes presented for surgical intervention of knee articular cartilage injury.
- Osteochondritis dissecans (OCD) has its prevalence highest in the 10 to 15 years age group; of note, in this demographic, 15% to 30% of cases involve bilateral knees.[4]

Sex

- Kujala et al.[5] noted the risk of knee osteoarthritis (OA) is five times higher in male former top athletes with previous knee injury than in the general population.
- Piasecki et al.[6] examined differences among high school athletes, determining that female basketball players sustained fewer cartilage lesions at the knee compared with males, yet there were no cartilage differences by gender with soccer or skiing.
- Stevenson et al.[7] demonstrated that in a cohort of 404 competitive alpine ski racers, female racers were 2.3 times more likely to have sustained a knee injury than were their male counterparts.

Sport

- Cartilage lesion location may be related to the player's sport.
  - Patellofemoral lesions are more common in basketball players, likely caused by contact forces from repeated jumping.
  - Increased participation by youth in such "cutting" (agility) sports as soccer, basketball, and football have reportedly increased the incidence of knee injuries.[8]
- In elite soccer players, 48% of lesions were found on the medial femoral condyle, 23% on the lateral femoral condyle, and 29% in the patellofemoral compartment.
- MRIs of collegiate and professional basketball players have demonstrated that 41% to 50% of players had abnormalities in their articular cartilage.

  - With 20 NBA players (40 total knees) from 1996 to 1999, Kaplan et al.[9] noted a prevalence of 47.5% for knee articular cartilage lesions.
  - In elite basketball players, the prevalence of asymptomatic articular cartilage lesions at the patellofemoral joint is from 35% to 41%.[9]
- 40.6% of retired NFL players under the age of 60 years reported arthritis of the knee in comparison with 11.7% of the general male population.[10]
  - A retrospective review of all National Football League (NFL) players between 1992 and 2006 revealed 118 knee articular cartilage injuries.[11]
  - During the 3-year period from 2005 to 2007, Hirshorn et al.[12] noted a prevalence of 20.1% for chondral injuries in the nation's top collegiate football players who had been asked to the NFL combine (a recruitment opportunity for players to display their abilities to prospective NFL teams).
  - In the 2005 NFL combine alone, Bradley et al.[13] reported that 2.4% of all football players (8 of 333) had osteochondral defects at the knee on initial medical evaluation.
- The knee joint is the most common joint injured in competitive alpine ski racing.[7]
- In a study by DeHaven et al.,[2] seven athletes with track injury sustained internal derangement of the knee (7.5% of total track injuries in this cohort) compared with eight athletes with baseball injury (10.3% of total baseball injuries in this cohort).

Position

- In evaluation of NFL combine athletes, the greatest prevalence of knee chondral injury was found with linebackers (32.2%), whereas the lowest prevalence of knee chondral injury was found with defensive backs (12.9%).[12]
  - Of note, linebackers in the Hirshorn et al.[12] report had the highest average body mass index (BMI) (31.9 kg/m^2), which in addition to this particular position's physical demands may help explain the high prevalence of articular cartilage injury in this football position.
- In their analysis of 118 NFL players' articular cartilage injury between 1992 and 2006, Brophy et al.[11] also reported that linemen had the greatest number of cartilaginous lesions (37% of total cohort).
- Namdari et al.[3] analyzed a cohort of 24 NBA players comprised of 11 guards, 10 forwards, and 3 centers who had knee articular cartilage damage.
  - Thus those positions that require fast cutting and agility movements over the course of a game seem to be overrepresented in this injury type.

Pathophysiology

Intrinsic Factors

- Athletes can suffer cartilage injury following repetitive microtrauma secondary to overuse or abnormal joint demands.
- Cartilage defects in younger athletes are typically caused by acute traumatic injury or injury secondary to osteochondritis dissecans (OCD).
  - The articular cartilage organization is similar to that of an open physis, and injuries likewise typically occur through the zone of provisional calcification.
- The cause of OCD is not delineated, with avascularity, repetitive trauma, and genetics all cited as independent causes; it may be multifactorial.
  - Genetic predisposition is a factor for articular cartilage injury, particularly with osteochondritis dissecans.[14,15]
  - Subchondral bone biomechanics plays a role in development of osteochondritis dissecans if the subchondral bone remains devascularized, which then subsequently fragments and increases mobility of the bone and overlying articular cartilage.[15]
- Joints that naturally have irregularly shaped articular surfaces are more likely to be injured in young athletes because of asymmetric loading and wearing patterns.[16]
- Increased BMI is strongly associated with knee articular cartilage injury in NFL quarterbacks, offensive tackles, and defensive backs.[12]
  - Research shows that young athletes with BMI greater than 30.5 kg/m^2 and weight greater than 222.5 lbs are at significantly increased risk for knee chondral damage.[12]
  - However, height is *not* a significant independent risk factor for cartilage injury.[12]
- Full-thickness cartilage defects do not heal and are likely to expand circumferentially over time; however, the natural history of cartilage defects has not been well studied.

Extrinsic Factors

- Participation in competitive sports, causing high intensity, direct joint impact
  - Consecutive arthroscopies (993) in Norway noted full-thickness cartilage lesions in 11% of knees, with sports participation as the most reported activity (49%).
- Delay in surgery
  - Church and Keating[17] noted an increase in degenerative changes in patients operated on with more than 12 months delay after injury as compared with less than 12 months delay.
- Intense physical activity and high-level sports contribute to osteochondritis dissecans.[18]

Traumatic Factors

- Traumatic cartilage damage is often found in the setting of an anterior cruciate ligament (ACL) tear.
  - Several studies have found changes in cartilage thickness and proteoglycan content in both the lateral and medial compartment following ACL injury.
- Fractures involving the articular surface necessitate precise reduction and fixation; 3-mm incongruities in the surface may involve increased local contact stress leading to OA posttraumatic OA.

- Abrasive wear on the knee joint with continued athletic activity results in superficial fibrillation of the cartilage, which progresses to subchondral bone.[19]
- Acute, large shear force as a sudden traumatic experience can disrupt the deep cartilage ultrastructure at the knee joint, ultimately damaging the cartilage.[19]
- Athletics with high levels of torsional loading, twisting, pivoting, rapid deceleration, and high impact forces increase susceptibility to developing articular cartilage damage owing to the effects of these combating force vectors on the integrity of the knee joint.[20]
- The NFL linebacker position must quickly pivot and exert lower extremity force in the course of a game; these rapid shear forces are proposed to be the cause for articular damage in this cohort.[12]
- Articular cartilage injuries in soccer players are hypothesized as follows[19]:
  - Extreme stresses befall the articular cartilage of the knee with the combination of high movement velocity and abrupt deceleration.
- Articular cartilage injuries in basketball players are hypothesized as follows[1]:
  - Plyometric jump training (an important component of competitive basketball) involves a strong contraction-extension mechanism at the patellofemoral joint.
  - Repetitive jumping causes repetitive stresses at the joint, which may cause patellofemoral joint damage at the articular cartilage.
- OCD in the elbow is typically seen more frequently in those that subject the elbow to repetitive trauma (gymnasts, pitchers); however, this relationship is not as obvious in OCD of the distal femur or talus.

Classic Pathological Findings

(See Figures 31-1 to 31-3.)

- MRI demonstrates a typical focal cartilage defect with adjacent bone edema on T2-weighted MRI sequence.
- Injury to articular cartilage in youth athletes occurs through the zone of provisional calcification at the joint.[15]

FIGURE 31-2. Full-thickness cartilage loss of on posterior MFC depicting denuded articular surface.

- In a full-thickness chondral injury, chondrocytes increase synthesis of extracellular matrix in an effort to repair the damaged section of cartilage.[20]
- The healing response to a full-thickness chondral injury begins with hematoma formation, followed by stem cell migration to produce type I collagen and allow vascular growth—note that this "healed cartilage" is less resilient to shear forces, easily damaged, and more likely to result in OA than is the original hyaline cartilage layer.[21]
- Outerbridge Classification of Cartilage Lesions[22]
  - Grade 0: Normal
  - Grade 1: Intact surface cartilage with softening and swelling
  - Grade 2: A partial-thickness defect with fissures on the surface that do not reach subchondral bone or exceed 1.3 cm in diameter
  - Grade 3: Fissuring to the level of subchondral bone in an area with a diameter greater than 1.3 cm
  - Grade 4: Exposed subchondral bone
- Chondral lesions are painful because the nerve endings of the subchondral bone after injury to overlying

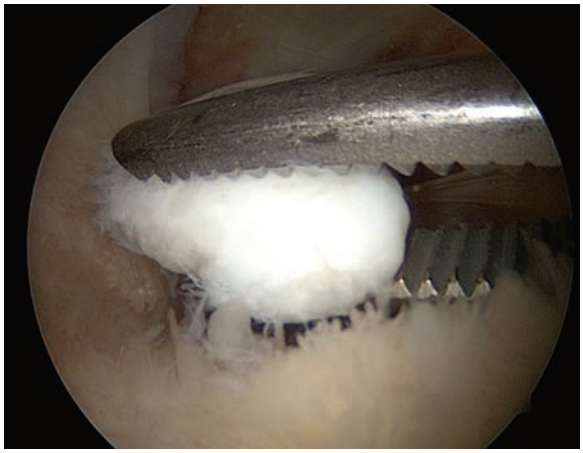

FIGURE 31-1. Arthroscopic photograph of a loose osteochondral fragment, which can produce mechanical symptoms in the knee.

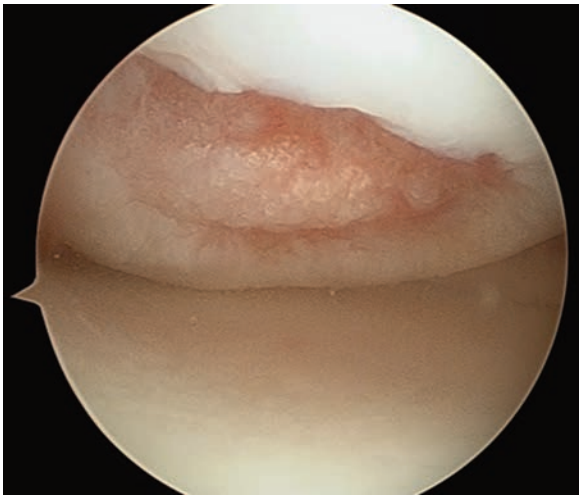

FIGURE 31-3. Chondral lesion.

articular cartilage become stimulated by the forces now faced by denuded bone.[19]
- Cartilaginous lesions that are full thickness can worsen as a result of structural changes in subchondral bone, intraarticular inflammatory cytokine release post damage, and stress forces concentrated around the rim of a chondral defect.[1]

Clinical Presentation

History

- Typically pain is present with weight bearing.
- Mechanical symptoms can be present if there is a flap of cartilage, a large cartilage defect, or a loose body.
- Swelling is classically reported with increased activity.
- Aching of joint after standing or during/after periods of inactivity
- Stiffness after periods of inactivity[23]
- Sensation of "giving way"
- Sensation of "catching"[23]
- Pain with stairs and steps, bent knee activity, and stiffness rising from a seated position can be present with patellofemoral cartilage defects, but characteristically also are associated with swelling.
- Levy et al.[19] reported from studies in young soccer players that the specific motions causing pain from chondral lesions were dependent on the location of the injury.
  - Patellar/trochlear lesions: pain with jumping, deceleration, extension phase of kicking
  - Anterior condylar lesions: pain with extension phase of kicking
  - Central condylar lesions: pain during pivoting, lateral movements
  - Posterior condylar lesions: pain with flexion phase of kicking, planting of the nonkicking leg
- In osteochondritis dissecans, patients often present with effusion, catching/locking (especially if loose body is present in the joint), and anterior knee pain.[14]
  - Adolescents with osteochondritis dissecans can, however, have vague symptoms.
- Some athletes will complain of a specific traumatic event from which the symptoms arose (i.e., slide tackle in soccer), whereas others will complain of insidiously progressive symptoms.[19]

Physical Examination

Abnormal Findings

- Swelling is a frequent sign of cartilage injury.
- Condyle defects may or may not have joint line tenderness, but frequently have tenderness to palpation on the medial or lateral condyle.
- Patellar or trochlear defects can present with anterior knee pain.
- Reduced active and passive range of motion (ROM)[24]; may be limited if a loose body is present or a significant effusion is limiting terminal flexion and extension.
- Functional strength loss at the knee joint[24]
- Crepitus can be evident.
  - A study by Ike et al.[25] of 20 athletes with knee joint chondral injury demonstrated a sensitivity of 54% with specificity of 100% for transmitted bony crepitus during clinical examination when the joint had tibial bare bone only, and a sensitivity of 88% with specificity of 100% for bone-on-bone rubbing owing to cartilage loss from injury.
- In particular, osteochondritis dissecans will demonstrate the following[14]:
  - Limited ROM
  - Effusion
  - Positive Wilson's test (reproducible pain with internal rotation of the tibia plus passive extension of the knee)
- A careful ligamentous examination should be performed because cartilage defects have been associated with ACL and other ligamentous deficiencies.
- Must evaluate overall limb alignment, and if clinical concern is present for malalignment, standing pelvis to ankle radiographs should be obtained.

Pertinent Normal Findings

- In the absence of concomitant ligamentous damage, there should be no increased ligamentous laxity on examination in comparison with the contralateral knee.[19]

Imaging

- Plain radiographs can
  - Help differentiate between more diffuse cartilage loss
  - Identify an OCD and/or a loose body if enough bone is present on the loose fragment
- X-rays are an important primary tool for assessment of the knee joint.
  - Those with K&L (Kellgren and Lawrence classification) grade 2 or more defined as OA
  - X-ray grading: Grade 0, no changes; Grade 2, definite osteophytes and possible narrowing of joint space; Grade 3, moderate multiple osteophytes, definite joint space narrowing, sclerosis and deformity; Grade 4, large osteophytes, marked narrowing of joint space, severe sclerosis and deformity of bone ends (Figure 31-4).
  - Evidence of osteochondritis dissecans lesions can be viewed with X-ray, most commonly on the lateral portion of the medial femoral condyle, and should be evaluated with standard weightbearing AP, lateral, and Merchant views[14] (Figure 31-5).
- Bilateral standing alignment radiographs should be obtained when clinical concern for varus or valgus alignment is present.
  - Weightbearing axis from the center of the femoral head to the midbody of the talus should be drawn and its intersection with the tibial plateau noted.
  - If this line falls into zone 2 or 3, realignment should be considered in the setting of a cartilage defect.
  - In some cases weightbearing axes falling into zone I may also benefit from realignment.
- MRI can be used to
  - Confirm the diagnosis

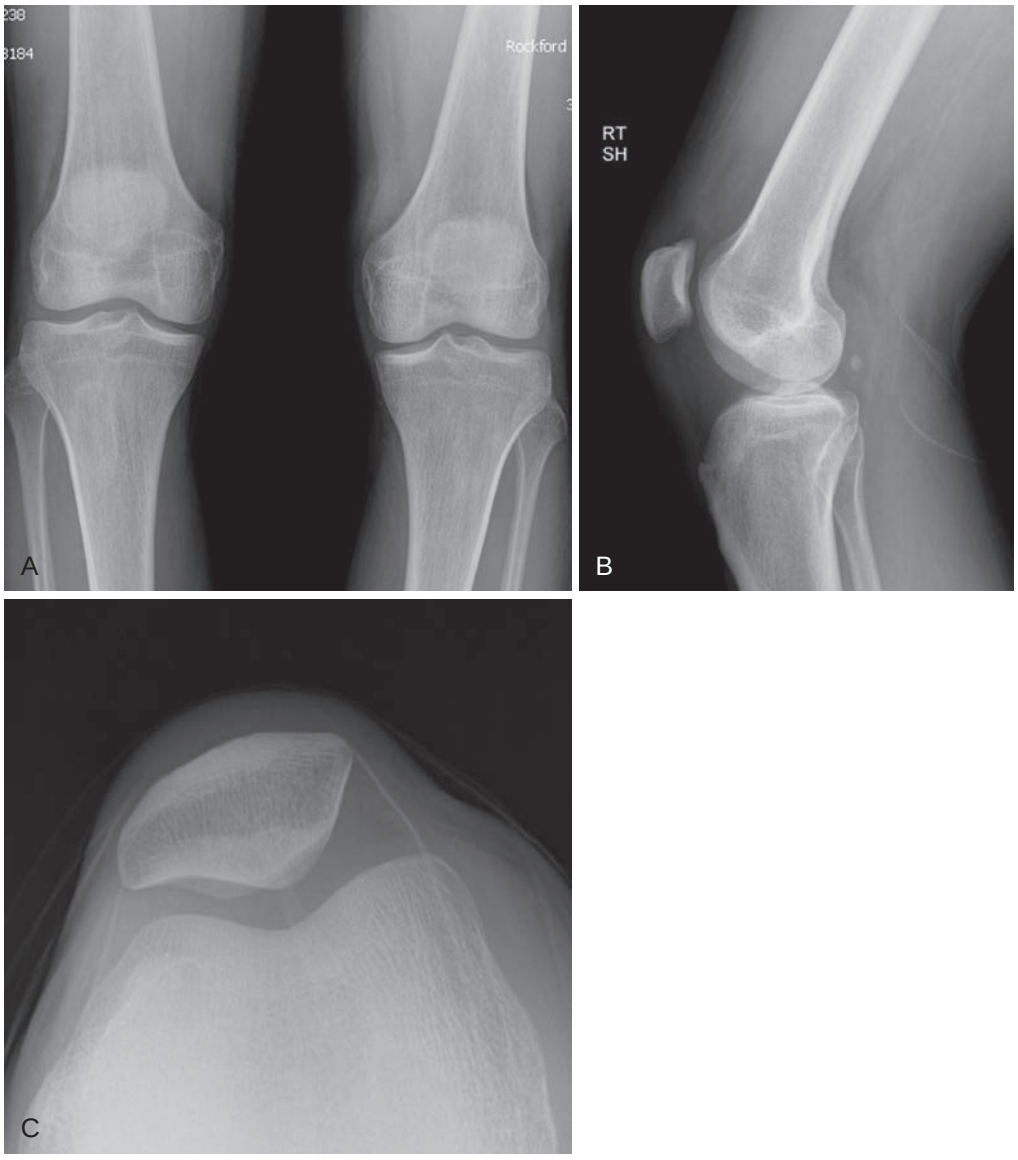

FIGURE 31-4. Radiographs with alternate views are important in delineating pathology and any observable changes: (**A**) Anteroposterior; (**B**) Lateral; (**C**) Merchant view.

  - Better define the cartilage lesion size and depth
  - Identify any concomitant pathology such as a meniscal tear which may mimic an articular cartilage defect on examination
  - Identify subchondral edema
- MRI is a valuable tool for evaluation of cartilage surface, tissue thickness, and subchondral bone signal intensity at the knee joint.[20]
  - Accuracy of 90% in evaluating cartilage injury in comparison with gold standard arthroscopy
  - Sequences utilized in assessing chondral pathology at the knee are T2 or intermediate (proton density) weighted fast spin-echo sequences.
  - Demonstrates chondral injury as regions of linear fissuring and surface irregularities with high signal joint fluid visible in the chondral defect
  - Depth, location, and size of the cartilage injury, as well as any concomitant bony or ligamentous damage can be determined through this means of imaging (Figure 31-6).
  - MRI grading
    - Grade 1, abnormal intrachondral signal but normal chondral surface
    - Grade 2, mild surface irregularity and/or focal loss of less than 50% thickness
    - Grade 3, severe surface irregularity with focal loss of 50% to 100% thickness
    - Grade 4, complete loss of articular cartilage with exposure of subchondral bone[26] (Figure 31-7).
- The gold standard imaging study for knee cartilage injury is arthroscopy.
  - Per Bachmann et al.,[27] the sensitivity for determining chondral injury with arthroscopy increases in proportion to the grade of the defect: I is 14%, II is 32%, III is 94%, IV is 100% (Figures 31-8 and 31-9).

FIGURE 31-5. Full body radiograph from pelvis to ankle allows for noting limb alignment, varus or valgus angulation.

FIGURE 31-6. MRI T2 Coronal view of meniscal injury with subchondral edema on the femoral condyle.

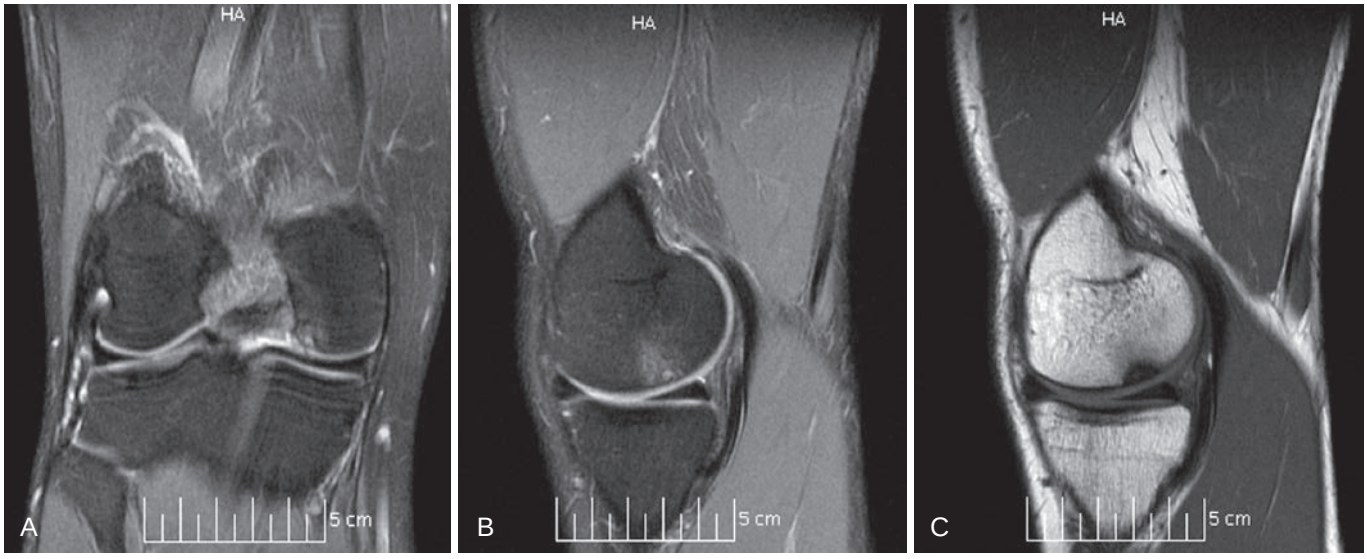

FIGURE 31-7. MRI of a 28-year-old physically active male reporting medial compartment pain with past history of skating injury, subchondral edema, and changes noted (**A**-**C**).

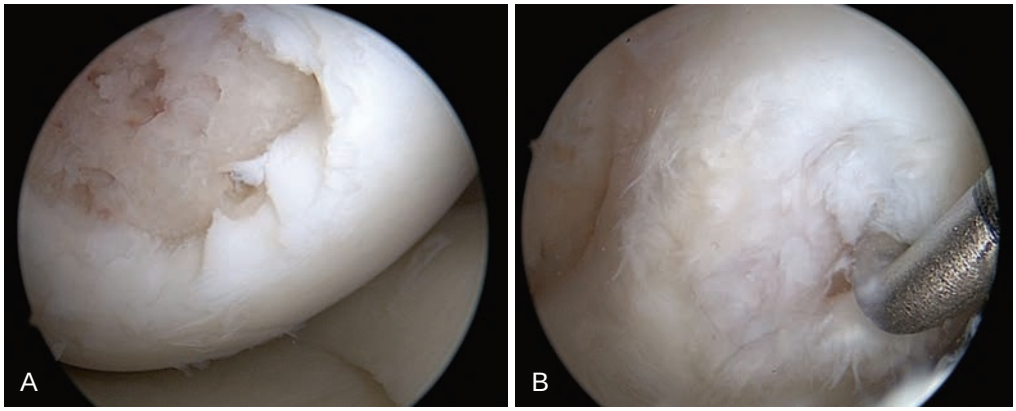

FIGURE 31-8. Arthroscopic display (**A**) and examination (**B**) of a grade IV (full-thickness) articular cartilage defect, located at the medial femoral condyle

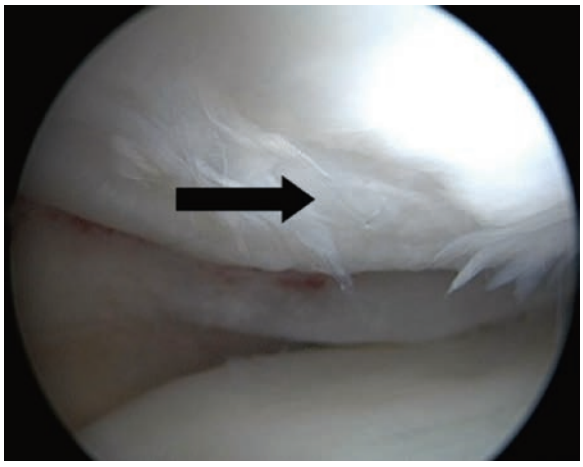

FIGURE 31-9. Grade IV lesion (*arrow*) of a 21-year-old female athlete with meniscal deficiency.

Differential Diagnosis

- Patellofemoral pain and cartilage defects of the patella or trochlea can produce similar symptoms.
  - Typically, these can be differentiated by the presence or absence of swelling.
- Generalized arthritis not amenable to cartilage restoration or repair
- Synovial impingement syndrome[14]
  - Pathologic plica
    - Pain aggravated by knee flexion and relieved with extension
    - Examination may reveal a thick, palpable cord
    - Normal radiographs, MRI with prominent plica
  - Hoffa syndrome
    - Swelling in the region of the knee fat pad
    - Tender to palpation in area of the fat pad
    - Positive Hoffa maneuver: apply compression to the sides of the fat pad while bringing knee into extension, causing pain/apprehension
- Osteochondroses/tendinitis (common in young athletes)[14]
  - Osgood-Schlatter
    - Tenderness, swelling, bony prominence evident around tibial tuberosity
  - Sinding-Larsen-Johansson
    - Tender to palpation focally near inferior pole of the patella
  - Patellar tendinitis
    - Pain focally in inferior pole of patella exacerbated by activity or palpation
    - Occurs often after a period of increased activity, intensity of sports training
    - Symptoms begin during activities only, but progress to occur with ADLs
    - Pain elicited on examination with decline squat test, which focuses stress on the patellar tendon
- Hip pathology[14]
  - For example, slipped capital femoral epiphysis, stress fracture
  - May present with referred pain to the knee joint
  - Significant pain at the hip when examined, which will not occur in the instance of focal knee cartilaginous injury
- Tumors[14]
  - For example, osteosarcoma, osteoid osteoma
  - Insidious onset not attributable by patient to any specific trauma from athletic endeavors
  - Will be evident with radiographic examination
- Meniscus tear[14]
  - Patient can often relay an instance during sport activities when he/she experienced a traumatic twisting movement at the knee while the knee was bent.
  - Maneuvers post injury that mimic this motion (such as getting out of a car) will elicit pain.
  - Examination demonstrates pain with squatting, positive McMurray test (pressing on joint line while stressing the meniscus), and present Cooper's sign (reported pain with turning over in bed at night).
- Ligamentous injury[14]
  - Instability is the major complaint
  - Many different examination techniques can deduce which ligament has sustained damage (Lachman test, anterior drawer test, pivot shift test, etc.).

Treatment

Nonoperative Management

- Nonsteroidal antiinflammatory medications
- Local ice/heat therapies
- Bracing, crutches to prevent weight bearing
- Weight reduction has the best evidence for improvement in pain and function
- Activity modification, such as resting from athletic activities
- Oral nutraceutical agents such as chondroitin sulfate, glucosamine, hyaluronic acid-based products either orally or by injection (have not be shown to be a cost-effective treatment)[20]
- Physical therapy for strengthening of the core, quadriceps; stretching of the anterior hip, hamstrings
  - Physical therapy can help strengthen the extremity and facilitate weight loss.

Guidelines for Choosing Among Nonoperative Treatments

- Asymptomatic partial-thickness chondral injuries can be managed conservatively.[20]
- Undisplaced intact chondral lesions may be treated nonsurgically.[20]
- Osteochondritis dissecans deemed stable can be managed nonsurgically.[14]
- Failure of conservative therapy with continued pain and symptoms related to the cartilage defect
  - Patients can have patellofemoral pain or pain related to other pathology intrinsic or extrinsic to the knee, which should be monitored.

Surgical Indications

- Relative indications[20]
  - Symptomatic (pain, swelling) partial-thickness or undisplaced intact chondral lesions

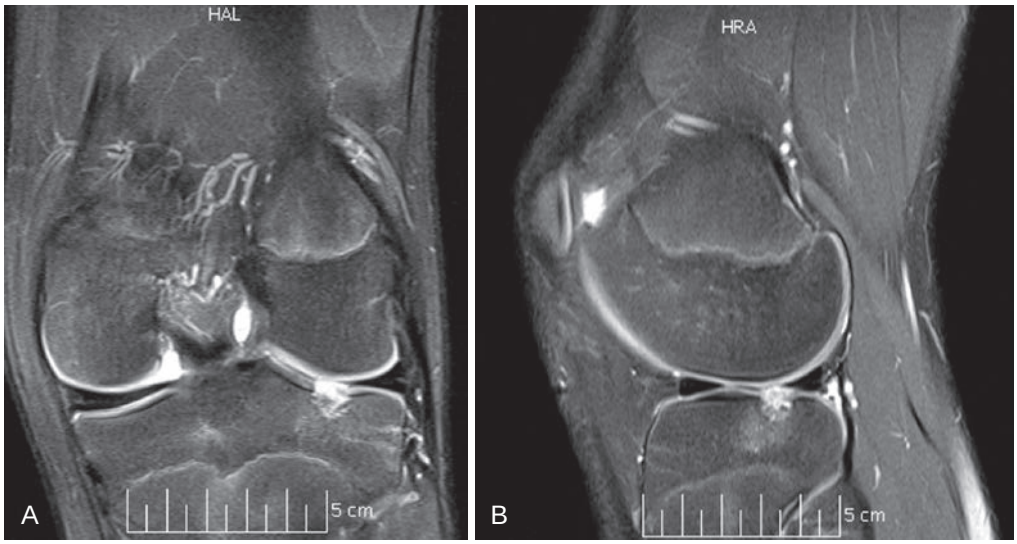

FIGURE 31-10. A 15-year-old male runner with past history of lateral right knee pain received microfracture of lateral tibial plateau as seen by (**A**) coronal and (**B**) sagittal MRI images.

- Absolute indications[14]
  - Those injuries that fail conservative treatment
  - Unstable lesions

Aspects of History, Demographics, or Exam Findings that Affect Choice of Treatment

- Length of time symptoms have been present has demonstrated an inverse relationship with outcomes.
- Patient age is a significant prognostic factor, but may be more related to physiologic age rather than chronologic age.
- Activity level and size of the lesion are factors in algorithms to determine treatment for symptomatic cartilage defects.
- Improved results have been demonstrated in patients with BMI less than 30.
- Indications for specific surgical interventions
  - Microfracture surgery[20]
    - For small, symptomatic articular cartilage lesions
    - Minimal costs in comparison to other techniques for those patients for whom invasive techniques are required but finances are an issue (Figure 31-10).
  - Autologous chondrocyte implantation (ACI)[20]
    - Requires a high level of patient compliance (involves 2 operations); best treatment for patients adherent to medical regimens and requests
    - Prolonged recovery time including many weeks of non–weight-bearing
  - Autologous and allogeneic osteochondral transplants[20]
    - Full-thickness osteochondral lesions if the knee is well-aligned and entirely stable on physical examination (Figure 31-11).

Aspects of Clinical Decision Making When Surgery Is Indicated

- Best surgical treatment option must be chosen for the athlete based on expected time to recovery, and patient adherence to pre- and postsurgical demands (i.e., physical therapy).
- Staging arthroscopy and ACI biopsy better delineate lesion size and location, depth, and concomitant pathology within the knee.
  - Lesions amenable to microfracture or osteochondral autografting can be performed at the time of staging arthroscopy
  - Some studies demonstrate that prior microfracture or other treatment may reduce the efficacy of ACI following clinical failure, leaving osteochondral allograft as the treatment of choice in most revision settings.
- Significant bony injury noted as bone edema on MRI warrants a procedure that addresses both injuries: either an osteochondral autograft for smaller lesions or osteochondral allograft for larger lesions.
  - Deeper lesions typically respond better to allograft or autograft fill; however, "sandwich" ACI techniques have been described with relatively good reported results.

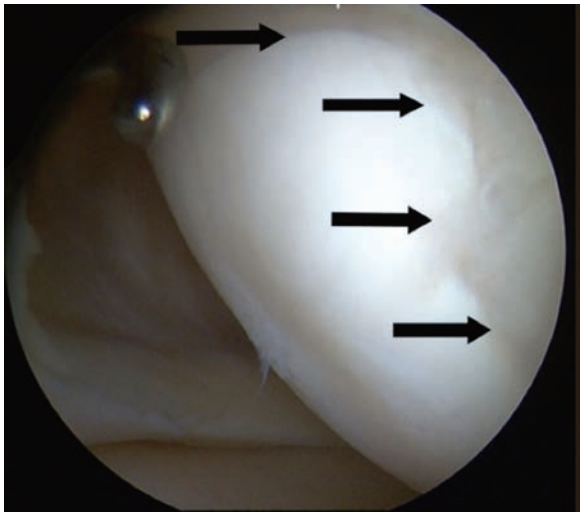

FIGURE 31-11. Osteochondral allograft to MFC in a 37-year-old male athlete with recurrent knee pain displaying excellent integration (*arrows* showing regions of integration).

- Microfracture, ACI, and other cell-based therapies have demonstrated reduced efficacy in patients with prolonged symptoms (greater than 1 year) or multiple prior procedures, which may influence the decision to use an osteochondral allograft.
- Patellofemoral defects are difficult to fill with osteochondral autograft or allograft because of the complex morphology that is patient specific despite adequate sizing (Figure 31-12).
- Lateral patellar facet lesions are typically treated with a concomitant anteromedialization of the tibial tubercle to help offload this area of the compartment, whereas medial facet lesions may benefit from a more vertical osteotomy and straight anteriorization (Figure 31-13).
- Loose bodies derived from OCD lesions of the weightbearing aspects of the femoral condyles may be amenable to fixation despite having relatively little bone on the loose fragment. Likelihood of healing is higher in younger individuals
- A survey among NFL team physicians by Brophy et al.[11] regarding knee articular cartilage injury demonstrated the following:
  - The most popular treatment for this type of injury was microfracture (43.3% of team physicians), second debridement (31.4%), then nonoperative management (13.2%), mosaicplasty (6%), osteochondral allograft (3.5%), and ACI (2.6%).
  - Size of the chondral injury was the most important factor to these physicians in making decisions about surgical management.

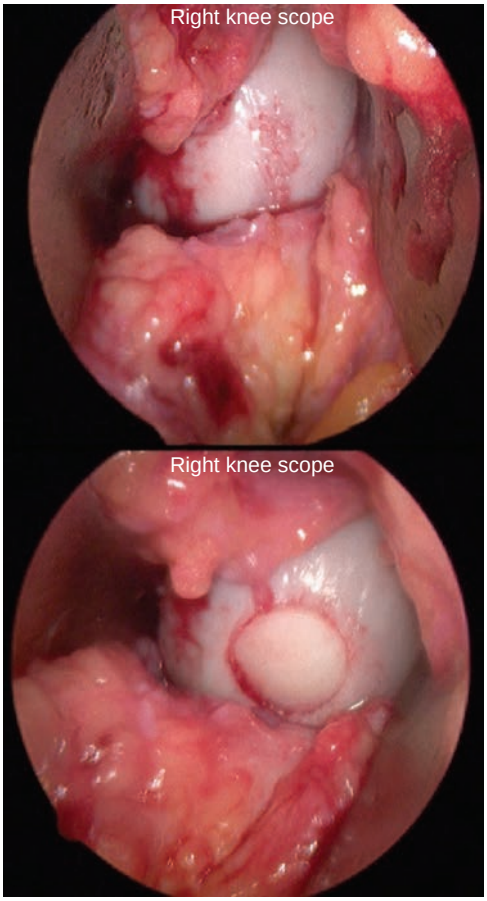

FIGURE 31-12. Osteochondral autograft transplantation (top) site of lesion before and (bottom) postimplantation.

Evidence

Flanigan DC, Harris JD, Trinh TQ, et al: Prevalence of chondral defects in athletes' knees: A systematic review. *Med Sci Sports Exerc* 42:1795–1801, 2010.

This was a systematic review of studies that evaluated the prevalence of articular cartilage injury in athletes and was specific to the knee joint. (Level IV evidence)

Frobell RB: Change in cartilage thickness, posttraumatic bone marrow lesions, and joint fluid volumes after acute ACL disruption: a two-year prospective MRI study of sixty-one subjects. *J Bone Joint Surg Am* 93(12):1096–1103, 2011.

This study investigated the change in cartilage thickness and resolution of bone bruise over time following an ACL injury. Patients were extracted from a larger study investigating acute reconstruction versus delayed reconstruction versus nonoperative treatment following and ACL tear. (Level IV evidence)

Gudas R, Stankevicius E, Monastyreckiene E, et al: Osteochondral autologous transplantation versus microfracture for the treatment of articular cartilage defects in the knee joint in athletes. *Knee Surg Sports Traumatol Arthrosc* 14(9):834–842, 2006.

This prospective randomized clinical study compared the outcomes of mosaic type osteochondral autologous transplantation (OAT) and microfracture (MF) procedures in the treatment of 60 highly competitive, well-trained athletes under 40 years old (mean 24.3 years) with knee joint cartilage defects. At a mean 37.1 months follow-up, both MF and OAT procedures showed positive clinical results, but OAT was consistently statistically superior with respect to "excellent/good results" (OAT 96% of patients vs. MF 52%), Hospital for Special Surgery and International Cartilage Repair Society scores, and return to sports at preinjury level (93% vs. 52%). (Level I evidence)

Micheli LJ, Moseley JB, Anderson AF, et al: Articular cartilage defects of the distal femur in children and adolescents: treatment with autologous chondrocyte implantation. *J Pediatr Orthop* 26:455–460, 2006.

This registry-based, multicenter observational prospective study of 37 patients assessed the outcome of ACI in adolescents who had sustained symptomatic chondral lesions, at mean age 16 years (range, 11 to 17). At various follow-up time points (between 2 and 4.3 years), 88% of patients rated to have "good" or "excellent" level successful interventions from the procedure. (Level IV evidence)

Mithofer K, Minas T, Peterson, L, et al: Functional outcome of knee articular cartilage repair in adolescent athletes. *Am J Sports Med* 33:1147–1153, 2005.

This case series of 20 adolescent athletes evaluated the outcome of ACI in patients with full-thickness articular cartilage lesions of the knee who had failed previous surgical (1+ operations) or nonsurgical management. At minimum 2 year follow-up (mean 47 months), 96% rated their results as being "good" or "excellent" with significant increases in postoperative Lysholm and Tegner activity scores, and 60% returned to a level of athletic competition that was equal or superior in comparison to pre-injury level. (Level IV evidence)

Mithofer K, Peterson L, Mandelbaum BR, et al: Articular cartilage repair in soccer players with autologous chondrocyte transplantation: functional outcome and return to competition. *Am J Sports Med* 33(11):1639–1646, 2005.

This case series of 45 soccer players evaluated the autologous chondrocyte transplantation surgery as a treatment option for articular knee cartilage injury. At 41 months after the surgery, 72% of these players reported good to excellent results with significant subjective improvement through Tegner activity rating scale; 33% returned to play soccer with 80% of those playing again at the same preinjury skill level. Those players returning to soccer were significantly younger than those who weren't able to return, and had less time between onset of symptoms and date of surgery. (Level IV evidence)

Mithofer K, Williams RJ, Warren RF, et al: High-impact athletics after knee articular cartilage repair: A prospective evaluation of the microfracture technique. *Am J Sports Med* 34(9):1413–1418, 2006.

This case series of 32 athletes—all of whom sustained articular cartilage injury while involved in high-impact, pivoting sports—assessed whether microfracture surgery could return athletes to their respective high-impact sports. At final follow-up, 66% of athletes reported good to excellent results, with significant increases from preoperative state in activities of daily living, Marx activity rating scale, and Tegner activity scores. Consistent among the 47% of the cohort who returned to regular athletic competition was an age of less than 40 years, chondral lesion less than 200 mm^2 in size, preoperative symptoms of less than 12 months duration, and lack of previous surgical procedures. (Level IV evidence)

Namdari S, Baldwin K, Anakwenze O, et al: Results and performance after microfracture in National Basketball Association athletes. *Am J Sports Med* 37(5):943–948, 2009.

This case control study evaluated 24 NBA athletes who underwent microfracture (MF) surgery after sustaining knee articular cartilage injury. Ultimately, 33% of this cohort did not return to play in the NBA, whereas 58% returned to play for more than one additional season. In comparison with control NBA athletes, those undergoing MF had a significant drop in points scored per game, and were 8.15 times less likely to continue in the NBA. (Level III evidence)

Nho SJ, Pensak MJ, Seigerman DA, et al: Rehabilitation after autologous chondrocyte implantation in athletes. *Clin Sports Med* 29:267–282, 2010.

This article describes the pathophysiology of cartilage injuries and expounds on the biology of cartilage healing. It then describes the keys to proper rehabilitation to maximize cell viability, incorporation of the graft, and return to play.

Riyami M, Rolf C: Evaluation of microfracture of traumatic chondral injuries to the knee in professional football and rugby players. *J Orthop Surg Res* 4:13, 2009.

This case series of 24 professional male football and rugby players evaluated the short-term outcome of microfracture surgery in the treatment of full-thickness articular cartilage defects in the knee. At mean 6.2 months follow-up, 83.3% of players had resumed full athletic training. Function and MRI knee scores progressively improved at 6, 12, and 18 months postoperative. (Level IV evidence)

Multiple-Choice Questions

QUESTION 1. A 21-year-old woman presents to her doctor with complaints of progressively worsening right knee pain since an episode of trauma while engaged in an athletic competition against her brother. It is determined through physical exam and imaging techniques that she has sustained damage to the articular cartilage of her right knee. In which of the following sports would she be more than twice as likely to sustain knee injury as compared to her brother?

A. Softball
B. Alpine ski racing
C. Squash
D. Ice skating

QUESTION 2. A 6 foot 8 inch collegiate football starting offensive tackle, weighing in at 320 lbs, presents to the team orthopedic surgeon with complaints of swelling and catching in his left knee. The symptoms have been present since his freshman year of college (he is currently a junior) and have not changed much in character. His father played in the NFL for 13 years also as an offensive tackle, and is left with osteoarthritis in his bilateral hips and knees. Which of the following is NOT an independent risk factor for the development of chondral injury in this athlete?

A. His BMI
B. Weight
C. Genetics
D. Height

QUESTION 3. A 14-year-old female soccer player complains to her physical therapist of new-onset left knee pain after kicking the soccer ball with enough force to fly 100 feet in practice 2 days ago. Which of the following collagen types is most likely being produced at this time at the site of injury by the patient's migrating stem cells?

A. Type I
B. Type II
C. Type III
D. Type IV

QUESTION 4. A 23-year-old professional NBA basketball player presents to the team orthopedic surgeon after landing awkwardly on his right knee in practice earlier that day. His doctor decides to order an MRI of the right lower extremity. Evaluation of the images demonstrates a mild irregularity at the chondral surface with loss of 32% thickness by computer measurements. What MRI Grade would this lesion be deemed?

A. Grade 1
B. Grade 2
C. Grade 3
D. Grade 4

QUESTION 5. A 16-year-old recreational basketball player presents to the monthly free orthopedic clinic at his local hospital. He had been given an appointment to return for a follow-up of his right knee pain 6 months ago, after he first presented with symptoms of joint pain and swelling 7 months ago. The patient reports that he hasn't been able to come in because he has to work 70 hours a week as a waiter to keep his job and pay to stay in his apartment. Now that he has finally returned the doctor orders an MRI of his right knee, which demonstrates a small chondral lesion of the articular cartilage. After discussing many different treatment options, it is decided that surgery will be performed. Which of the following is the most appropriate surgical intervention for this patient?

A. Microfracture
B. Autologous Chondrocyte Transplantation
C. Autologous Osteochondral Transplant
D. Allogeneic Osteochondral Transplant

Answer Key

QUESTION 1. Correct answer: **B** (see Epidemiology—Sex)

QUESTION 2. Correct answer: **D** (see Pathophysiology—Intrinsic Factors)

QUESTION 3. Correct answer: **A** (see Pathophysiology—Classic Pathologic Findings)

QUESTION 4. Correct answer: **B** (see Clinical Presentation—Imaging Studies)

QUESTION 5. Correct answer: **A** (see Treatment)

NONOPERATIVE REHABILITATION OF ARTICULAR CARTILAGE INJURIES

Andreas H. Gomoll, MD, and Reginald B. Wilcox III, PT, DPT, MS OCS

GUIDING PRINCIPLES OF NONOPERATIVE REHABILITATION

- Individualization
- Interdisciplinary team approach
- Restore the biomechanics of the knee
- Minimize pain and joint effusion
- Restore muscle function
- Restore soft tissue length
- Enhance proprioception and neuromuscular control
- Control loads across the lower extremity

Introduction

- These guidelines are for the postinjury rehabilitation course of a patient that has sustained an articular cartilage injury or undergone a restorative procedure. It is by no means intended to be a substitute for one's clinical decision making regarding the progression of a patient's postoperative course based on their physical exam/findings, individual progress, and/or the presence of postinjury complications. If a clinician requires assistance in the progression of a postinjury patient he or she should consult with the referring physician.
- The timelines are approximate ranges. The treating clinician should take into consideration patient/athlete presentation and achievement of clinical milestones in each phase.
- The acutely injured athlete will likely start with phase I of this guideline. However, the athlete who has been experiencing more of a subacute or chronic knee injury as the result of an articular cartilage lesion may begin this rehabilitation plan in phase II if pain and effusion are minimal and the athlete demonstrates little to no range of motion impairments.
- Following an articular cartilage injury, continuous monitoring of pain and effusion in response to all activity progression (exercise, weight-bearing, etc.) is vital to a successful rehabilitation process.

Phase I (weeks 0 to 4)

Protection

- Protected weight bearing with crutches is recommended to reduce the mechanical forces through the knee, to allow for a reduction in pain and effusion. The length of crutch use is determined by the location and severity of the lesion. Typically the individual with a large lesion on a weight-bearing surface of the knee will require a longer protected weight-bearing period.
- If patients present with a concomitant ligamentous injury, a significant inhibition of quadriceps function, and/or require some additional support beyond protected weight bearing, drop-lock rehabilitative hinged knee bracing is indicated to provide adequate stability to the knee during the acute phase of recovery and rehabilitation. If such a brace is needed, it would be locked in full extension for weight bearing activities and unlocked for non–weight-bearing activities.
- Individuals with persistent knee joint effusion may benefit from a compressive knee sleeve to assist in controlling effusion both during activities of daily living as well as exercise progression.

Management of Pain and Swelling

- The reduction of pain and joint effusion is crucial for restoring normal quadriceps function.[1]
- Treatment for pain/effusion
  - Cryotherapy (continuous cool system or ice packs) (Figure 31-14)
  - Elevation
  - High-voltage electrical stimulation
  - Cold laser
  - Compressive knee sleeve
  - Transcutaneous electrical nerve stimulation
  - Controlled passive range of motion
  - Analgesic and antiinflammatory medication. The latter can be contraindicated after certain procedures such as osteotomy and cartilage transplantation.

FIGURE 31-14. Cryotherapy and intermittent compression applied through a continuous cool device (Gameready; Coolsystems Corporation, Berkeley, CA) with elevation for effusion management.

Techniques for Progressive Increase in Range of Motion

- The early restoration of normal patellofemoral as well as tibiofemoral range of motion (ROM) is crucial to creating an optimal environment of healing for the knee.
- Specifically full knee extension, which for some individuals means a few degrees of hyperextension, is needed to ensure normal joint arthrokinematics to reduce patellofemoral and tibiofemoral contact pressure as well as minimize strain and fatigue of the quadriceps.[2] Full knee extension should be achieved within the first 2 weeks of therapy.
- Unless a mechanical block is noted, knee flexion range of motion typically will gradually progress toward normal as pain and effusion resolve.
- When regaining ROM following an articular cartilage injury it is important to not introduce shear forces while the joint is under compression, as this may have adverse effects on the lesion. ROM exercises should be done in a controlled manner. Evidence from both human and animal studies following articular cartilage repair supports early active and passive motion exercises to enhance tissue healing and reduce the potential risk of adhesions.[3] Unloading and immobilization have been reported to have a negative effect on the healing of articular cartilage.[4] Hence it is advised following an articular cartilage lesion that is going to be managed conservatively that one begins a controlled progressive range of motion program to promote healing and prevent further injury or degeneration.
- If an individual has access to a pool, it is recommended that aquatherapy be part of the rehabilitation plan. The buoyancy factor of water significantly decreases the amount of weight-bearing forces during pool exercises compared with land exercise.[5] After surgery, aquatherapy should be delayed until wound healing has occurred, usually after 2 weeks.

Manual Therapy Techniques

- Medial-lateral patella mobilizations performed by the therapist and patient to restore normal patella mobility
- Superior-inferior patella mobilizations performed by the therapist and patient to restore normal patella mobility (Figure 31-15)
- Tibiofemoral and tibiofibular mobilizations directed at restoring normal motion performed by the therapist

Soft Tissue Techniques

- Soft tissue mobilization is performed to prevent the development of scar tissue/adhesions from forming.

Stretching and Flexibility Techniques for the Musculotendinous Unit

- General flexibility exercises performed by the therapist and patient to restore normal length of musculotendinous units
  - Hamstrings
  - Gastrocnemius/soleus
  - Hip abductors/adductors
  - Hip flexors
  - Quadriceps (once good quadriceps muscle function is restored and joint effusion is minimal)
- If an individual is having difficulty regaining the appropriate muscle length/integrity through therapist and self-guided stretching alone, then modalities such as moist heat and ultrasound may be used as an adjunctive intervention to facilitate greater gains.[6]

Other Therapeutic Exercises

- During phase I of rehabilitation injured athletes should actively participate in core stability strengthening, their typical upper body strengthening routine, and a cardiovascular conditioning program as their injured knee allows. Their injured knee should be supported and protected from further injury during all exercise.

TIMELINE 31-1: **Nonoperative Rehabilitation of Articular Cartilage Injuries**

PHASE I (weeks 0 to 4)	PHASE II (weeks 4 to 8)
• Protected weight-bearing with crutches • Drop-lock knee brace • Compressive sleeve • PT modalities for pain & effusion management • A/AA/PROM-knee extension to full; flexion to at least 120° as tolerated • Manual therapy and soft tissue techniques as indicated • Aquatherapy, if available • General lower extremity stretching; caution with quadriceps stretching • Moist heat & ultrasound for tissue warm-up for stretching if indicated • Quadriceps sets • 4-way straight leg raises as tolerated • NMES to quadriceps if poor contraction noted • 4-way angle strengthening with elastic band • Stationary bike without resistance if ≥ 95°–100° of flexion • TBS/TAS/TLS activities as tolerated with knee protected	• Weight bearing as tolerated • Progression off crutches • Unlocked knee brace • Compressive sleeve if indicated • PT modalities for pain & effusion management if indicated • A/AA/PROM-knee extension and flexion to full as tolerated • Manual therapy and soft tissue techniques as indicated • Progressed aquatherapy, if available • General lower extremity stretching; caution with quadriceps stretching • Quadriceps sets • 4-way straight leg raises with weights as tolerated • NMES to quadriceps if poor contraction noted • 4-way angle strengthening with elastic band • Weight shifting drills • Balance activities • Bilateral leg press; limit 0°–90° • Functional drills (i.e., step-ups) • Stationary bike with progressed resistance and time • TBS/TAS/TLS activities as tolerated with knee protected

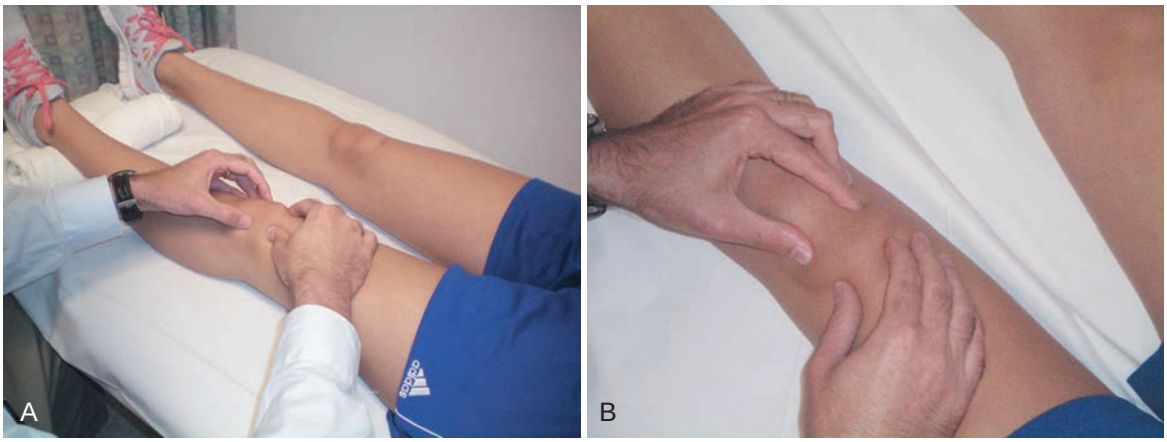

FIGURE 31-15. Therapist performed medial-lateral (**A**) and superior-inferior (**B**) patella mobilizations to enhance patella femoral motion.

Activation of Primary Muscles Involved

- Initially quadriceps muscle function restoration is key to early rehabilitation. The injured athlete should commence quadriceps sets, straight leg raises (begin with the locked knee brace if there is an active extension lag, then discontinue the brace for exercise when no lag is present), short (SAQ) and long arc (LAQ) AROM exercises. A/AA/PROM of knee to full extension and flexion as tolerated (avoid active knee extension (SAQ, LAQ, etc.) for 3 to 4 weeks if patellofemoral lesion is present); when active knee extension exercises are initiated they need to be completed within a range of motion that does not engage or compress the lesion. Hence it is important for the therapist and surgeon to communicate regarding the location of the lesion.
- If one is having difficulty initiating and/or maintaining an adequate quadriceps contraction with any of these exercises, the use of neuromuscular electrical stimulation (NMES) and/or biofeedback is indicated[7,8] (Figure 31-16).
- It is imperative that the injured athlete and the therapist make sure to not solely focus on the quadriceps. A balanced strengthening approach is needed to restore appropriate lower extremity function. A gradually progressed program of trunk, hip, and ankle exercises is needed to control normal lower extremity forces and excess forces through the injured knee.
- Lower extremity musculature needs to become strong following articular cartilage injury, to assist in absorbing normal lower extremity shock and dissipating applied loads across the knee joint.
- Throughout the early rehabilitation course, strengthening exercises should be chosen appropriately in order to minimize high sheer stress in conjunction with compressive forces. Hence the start of closed chain therapeutic exercises is delayed.

TIMELINE 31-1: **Nonoperative Rehabilitation of Articular Cartilage Injuries** (Continued)

PHASE III (weeks 8 to 12)	PHASE IV (weeks 12 +)
• DC drop-lock knee brace & crutches • Unloader OA knee brace and orthotics if indicated • A/ROM-knee extension and flexion to full as tolerated for maintenance • Manual therapy and soft tissue techniques as indicated • Progressed aquatherapy, if available • Swimming program; if pool is available • General lower extremity stretching • 4-way straight leg raises with weights as tolerated for exercise warm-up • Standing hip strengthening with either elastic band or circuit training equipment • Progressed weight-shifting drills • Balance activities • Perturbation training • Bilateral leg press progressed to unilateral leg press; limit 0°–90° • Functional drills (i.e., step-ups) • Stationary bike with progressed resistance and time • Elliptical trainer • Stairmaster • Walking program • TBS/TAS/TLS activities as tolerated	• Continue with maintenance program of lower extremity strengthening/stretching • TBS/TAS/TLS activities as tolerated • Begin and progress sports specific agility drills • Progress balance drills • Individualized impact loading program • Plyometric program • Return to pre-injury sports program as directed by physician and physical therapist as tolerated depending upon symptom presentation and size of lesion

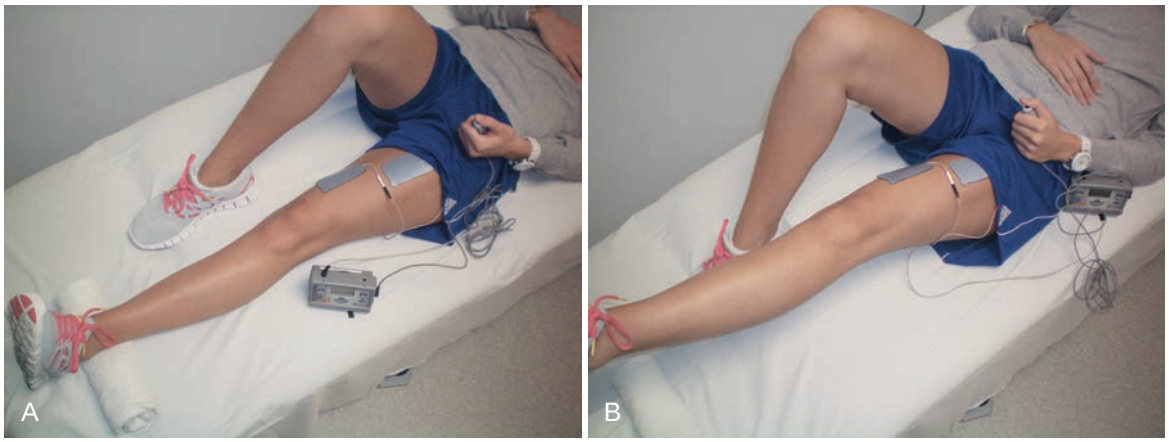

FIGURE 31-16. Neuromuscular electrical stimulation (300PV; Empi Corporation, St Paul, MN) applied to the quadriceps muscle during quadriceps sets (**A**) and straight leg raises (**B**).

Open and Closed Kinetic Chain Exercises

- Closed kinetic chain (CKC) exercises: Typically not indicated in the first phase of rehabilitation because of the weight-bearing stress they incur across either the femoral or tibia lesion following the acute injury.
- Open kinetic chain (OKC) exercises
  - A/AA/PROM of knee to full extension and flexion as tolerated. (Avoid active knee extension for 3 to 4 weeks if patellofemoral lesion is present; and for more than 6 months after cell-based cartilage repair in the patellofemoral joint to allow for tissue maturation.)
  - Hip, hamstring, calf stretching
  - 4-way ankle strengthening with elastic band
  - Quadriceps sets
  - Multiangle quadriceps/hamstring isometric contractions to start at 90° of flexion, as it is unlikely to produce excessive compressive or shear forces across most articular cartilage lesions. Caution is recommended with any isometric contractions between 20° and 75°, as there may be high compressive forces on most lesions in this range.
  - 4-way straight leg raises
    - Supine
    - Side lying for abductors
    - Side lying for adductors
    - Prone
  - Stationary bike without resistance if greater than or equal to 95° to 100° of flexion

Techniques to Increase Muscle Strength, Power, and Endurance

- To enhance the overall muscular function of the hip and knee musculature, it is advisable to work with a high-repetition low load to enhance muscular endurance and reduce the risk of injury. When progressing such exercises as the 4-way straight leg raises, athletes are advised to work up to 2 to 3 sets of 15 to 20 reps with no knee extension lag. When able to complete up to 60 repetitions in total, a progression in load (i.e., adding ankle weights in 1-lb. increments) is indicated.

Functional Exercises

- Gait training with crutches with protected weight bearing
- Encourage gradually progressed periods of time on feet with crutches to promote a return to daily activities.

Milestones for Progression to the Next Phase

- Minimal to no knee joint line tenderness
- Minimal knee pain at rest and/or light activities
- A steady reduction in knee joint effusion with no persistent effusion following progressively more challenging activities of daily living and/or therapeutic activities
- Full knee extension ROM comparable with the contralateral knee
- At least 120° of knee flexion
- Normal passive and active patellofemoral mobility. Passive patella mobility is assessed with the patient's knee in a relaxed and extended position. Active patella mobility is assessed during functional activities.
- Adequate quadriceps control (i.e., able to do at least 15 to 20 straight leg raises without a brace or lag and able to ambulate household distances with least assistive device with natural knee flexion and extension ROM).

Phase II (weeks 4 to 8, depending on lesion size and location)

- Note on rehabilitation after cell-based cartilage repair procedures (microfracture, autologous chondrocyte implantation [ACI, Carticel])
  - Generally speaking, cell-based repair procedures require a slower progression to allow for tissue maturation, which is initially very soft and vulnerable to shear forces. Therefore progression to phase II mostly does not occur until 12 weeks postop, while continuing to focus on restoration of motion and patellar mobility, reduction of swelling, and recruitment of

quadriceps and hamstring muscles through isometrics and electrical stimulation.

Protection

- At this point in rehabilitation the injured athlete should be ready to progress to weight bearing as tolerated. However, this timeframe will be dictated by the size, nature, and location of the lesion as well as the quantity of ROM restoration and overall muscular strength. In order to begin weaning from bilateral crutches the athlete should have full knee extension, at least 100° of knee flexion, have no lag with a straight leg raise or with walking. He/she may need one crutch or cane in the contralateral upper extremity for some assistance to avoid a pronounced limp for community distances. Those individuals with a large lesion on the weight-bearing surface of the femur may need to stay with bilateral crutches for another week or 2 to minimize pain and joint effusion.
- If the athlete has good quadriceps control, the drop-lock rehabilitative hinged knee brace is set for full motion and worn for an additional 2 weeks as he/she progresses overall activity level.
- Individuals with persistent knee joint effusion may still benefit from a compressive knee sleeve to assist in controlling effusion during both activities of daily living as well as exercise progression.

Management of Pain and Swelling

- If persistent pain and effusion are limiting rehabilitation progress, the continued use of the following interventions is still warranted. However, as each week passes the need for each intervention should be reduced.
  - Cryotherapy (continuous cool system or ice packs)
  - Elevation
  - High-voltage electrical stimulation
  - Cold laser
  - Compressive knee sleeve
  - Transcutaneous electrical nerve stimulation
  - Controlled passive range of motion
  - Analgesic medication

Techniques for Progressive Increase in Range of Motion

Manual Therapy Techniques

- Continue with medial-lateral patella mobilizations performed by the therapist and patient to restore normal patella mobility if still limited.
- Continue with superior-inferior patella mobilizations performed by the therapist and patient to restore normal patella mobility if still limited.
- Continue with tibiofemoral and tibiofibular mobilizations directed at restoring normal motion performed by the therapist if still limited.

Soft Tissue Techniques

- Continue with soft tissue mobilizations to prevent the development of scar tissue/adhesions from forming if soft tissue integrity has not been normalized.

Stretching and Flexibility Techniques for the Musculotendinous Unit

- General flexibility exercises performed by the therapist and patient to restore normal length of musculotendinous unit
  - Hamstrings
  - Gastrocnemius / soleus
  - Hip abductors/ adductors
  - Hip flexors
  - Quadriceps stretching is typically appropriate at this stage of rehabilitation as long as there is good quadriceps muscle contraction and normalized patellofemoral movement.
- At this stage of rehabilitation the muscle length/integrity should be near normal, and adjunctive modalities such as moist heat and ultrasound are typically not warranted. Continued therapist and athlete guided stretching should be all that is needed to maintain appropriate tissue length.

Other Therapeutic Exercises

- During phase II of rehabilitation the injured athlete should continue to actively participate in core stability strengthening, their typical upper body strengthening routine and a cardiovascular conditioning program. Upright and/or recumbent exercise biking should be tolerated easily at this point of rehabilitation. If the injured athlete has successfully transitioned to full weight bearing without an assistive device, the gradual introduction of single line walking on a treadmill or stable ground can be introduced followed by the use of an elliptical trainer.

Activation of Primary Muscles Involved

- Continued focus on quadriceps muscle function restoration is crucial to rehabilitation. The injured athlete should be able to do repetitive progressed 4-way straight leg raises with weight and without a lag and the knee brace. Progression toward a graduated bilateral to unilateral leg press machine should commence during phase II to enhance functional quadriceps and general lower extremity strength prior to beginning higher level closed chain therapeutic exercises. It is still important that the injured athlete and their therapist make sure to not solely focus on the quadriceps. A balanced strengthening approach is needed to restore appropriate lower extremity function. A gradually progressed program of trunk, hip, and ankle exercises is needed to control normal lower extremity forces and excess forces through the injured knee.

Sensorimotor Exercises

- All the following therapeutic activities would be indicated once the injured athlete has regained appropriate quadriceps control, has little to no effusion, and can tolerate at least partial weight bearing without side effects for up to an hour.
  - Weight shifting side to side drills
  - Weight shifting forward and backward drills

- Weight shifting diagonal drills
- Bilateral mini-squats; limit 0° to 45°
- Bilateral minisquats on an unstable surface (wobble board, tilt board, air disc, etc.); limit 0° to 45°
- Balance activities onto and off from various unstable surfaces

Open and Closed Kinetic Chain Exercises

- OKC exercise
  - A/AA/PROM of knee to full extension and flexion as tolerated (avoid active knee extension (SAQ, LAQ, etc.) for 3 to 4 weeks if patellofemoral lesion is present); when active knee extension exercises are initiated, they need to be completed within a range of motion that does not engage or compress the lesion. Hence it is important for the therapist and surgeon to communicate regarding the location of the lesion.
  - Hip, hamstring, calf stretching
  - 4-way ankle strengthening with elastic band
  - Quadriceps sets
  - Multi-angle quad/hamstring isometric contractions
  - 4-way straight leg raises
    - Supine
    - Side lying for abductors
    - Side lying for adductors
    - Prone
- CKC exercises: When selecting closed chain exercises for a specific patient, knowledge of the defect location is critical, as it has been shown that different activities require various contacts on the tibiofemoral joint.[9,10] If the lesion is located in the anterior aspect of the tibiofemoral joint, full knee extension with CKC exercises needs to be avoided. Conversely if the lesion is in the posterior aspect of the joint, loading greater than 45° of flexion with CKC exercises should be initially avoided.
  - Leg press (allows for graded weight-bearing through the knee) in advance of doing minisquats; limit 0° to 90° (Figure 31-17)

FIGURE 31-17. Exercise such as a bilateral leg press assist the athlete in functional lower extremity strengthening while getting used to weight bearing through the involved knee.

  - Lunges
  - Step-ups
  - Step-downs
  - Stationary bike without resistance if greater than or equal to 95° to 100° of flexion. One needs to make sure the seat height is appropriate for any given lesion. The lower the seat height, the higher the patellofemoral joint compressive forces are. The higher the seat height, the less is the overall knee flexion range of motion. Initially seat height should be set high and then progressively lowered to normal seat height as range of motion progresses.

Techniques to Increase Muscle Strength, Power, and Endurance

- To continue to enhance the overall muscular function of the hip and knee musculature, it is advisable to work with a high-repetition low load to enhance muscular endurance and reduce the risk of injury. When progressing both OKC and CKC exercises athletes should work up to 2 to 3 sets of 15 to 20 reps with proper form without pain. When able to complete up to 60 repetitions in total, a progression in load and/or activity is indicated.

Neuromuscular Dynamic Stability Exercises

- See preceding Sensorimotor Exercises section.

Functional Exercises

- Gait training as needed to ensure proper gait mechanics without assistive device(s). Once able to fully weight bear without crutches without residual pain and/or effusion, a walking program can commence.

Milestones for Progression to the Next Phase

- Full flexion and extension ROM
- Full weight bearing with all activities
- No knee joint line tenderness
- Minimal to no knee pain with moderate activities
- No knee joint effusion following progressively more challenging activities of daily living and/or therapeutic activities
- Adequate strength
  - Hamstrings within 20% of contralateral extremity (as measured either via a comparison between isometric hand-held dynamometry and/or isokinetic dynamometry)
  - Quadriceps within 30% of contralateral extremity (as measured either via a comparison between isometric hand-held dynamometry and/or isokinetic dynamometry)
- Balance testing within 30% of contralateral extremity (as measured by assessing differences between single leg stance time and the Star Excursion Balance Test)
- Able to bike for 30 minutes or longer

Phase III (weeks 8 to 12)

Protection

- Most patients with a large lesion on a weight-bearing surface with uncorrected abnormal alignments and/or meniscus injury may benefit from an unloader osteoarthritic brace to unload the involved compartment. If an athlete has poor dynamic foot posture (i.e., excessive pronation in stance phase), the use of foot orthotics may be indicated in order to minimize the applied load across the articular cartilage of the knee. It is also recommended that athletes begin their low-impact activities with well-cushioned shoes and work out on softer surfaces in order to acclimate to returning to activities that produce normal to high ground reaction forces.

Management of Pain and Swelling

- At this stage of rehabilitation pain/effusion should not be an issue. The athlete may have some transient pain/minor effusion following a newly progressed activity. If so the use of Cryotherapy (continuous cool system or ice packs), elevation, and high-voltage electrical stimulation can be used following exercise to assist with pain/effusion reduction.

Techniques for Progressive Increase in Range of Motion

Manual Therapy Techniques

- At this stage of rehabilitation ROM deficits should not be an issue. If the athlete is prone to joint and/or soft tissue tightness, provide instruction in periodic self-mobilization of the patellofemoral, tibiofemoral, and tibiofibular joints prophylactically.

Soft Tissue Techniques

- At this stage of rehabilitation soft tissue deficits should not be an issue. If the athlete is prone to joint and/or soft tissue tightness, instruction in periodic self-massage/soft tissue techniques prophylactically is warranted.

Stretching and Flexibility Techniques for the Musculotendinous Unit

- At this stage of rehabilitation the muscle length/integrity should be normal, and general flexibility exercises performed by the athlete to maintain normal length of the musculotendinous unit prior to and following exercise are:
  - Hamstrings
  - Gastrocnemius / soleus
  - Hip abductors/ adductors
  - Hip flexors
  - Quadriceps

Other Therapeutic Exercises

- During phase III of rehabilitation the injured athlete should continue to actively participate in core stability strengthening, typical upper body strengthening routine, and a cardiovascular conditioning program. Upright and/or recumbent exercise biking and a progressed walking program on either a treadmill, elliptical trainer, or outdoors on stable ground should be tolerated well.

Activation of Primary Muscles Involved

- At this stage of rehabilitation a continued balanced strengthening approach is needed to restore appropriate lower extremity function. A gradually progressed program of trunk, hip, and ankle exercises is recommended to control normal lower extremity forces and excessive forces through the injured knee.

Sensorimotor Exercises

- All the following therapeutic activities should be progressed in terms of difficulty (i.e., repetitions, time, intensity, etc.).
  - Weight-shifting side to side drills
  - Weight-shifting forward and backward drills
  - Weight-shifting diagonal drills
  - Bilateral minisquats; limit 0° to 45°
  - Bilateral minisquats on an unstable surface (wobble board, tilt board, air disc, etc.); limit 0° to 45° (Figure 31-18)
  - Balance activities onto and off from various unstable surfaces
  - Perturbation drills

Open and Closed Kinetic Chain Exercises

- OKC exercises
  - 4-way straight leg raises for an exercise warmup
    - Supine
    - Side lying for abductors
    - Side lying for adductors
    - Prone

FIGURE 31-18. Minisquats on an unstable wobble board. The athlete is instructed to perform the minisquat while minimizing wobble board movement.

- LAQ
- Stationary bike with gradually progressed resistance and time
- Can begin swimming program

- CKC exercises:
  - Leg press (allows for graded weight bearing through the knee) in advance of doing minisquats; limit 0° to 90°
  - Bilateral squats; limit 0° to 60°
  - Lunges
  - Step-ups
  - Step-downs
  - Progressed walking program (treadmill, elliptical trainer, or outdoors) in terms of distance, cadence, incline, etc.
  - Can begin use of Stairmaster
  - Wall sits
  - Standing hip strengthening (abduction/adduction) with either resistive bands or circuit training equipment

Techniques to Increase Muscle Strength, Power, and Endurance

- To continue to enhance the overall muscular function of the hip and knee musculature it is advisable to work with a high-repetition low load to enhance muscular endurance and reduce the risk of injury. When progressing both OKC and CKC exercises, athletes should work up to 2 to 3 sets of 15 to 20 reps with proper form without pain. When able to complete up to 60 repetitions in total, a progression in load and/or activity is indicated.

Neuromuscular Dynamic Stability Exercises

- See preceding Sensorimotor Exercises section.

Functional Exercises

- As long as the athlete is tolerating the previously started walking program, this walking program should be advanced in terms of time, distance, intensity, and terrain as tolerated.

Sport-Specific Exercises

- Agility and sport specific activities can commence at this stage of rehabilitation as long as clinically the athlete's knee is progressing as expected and that pain and effusion are under control. Such activities should be sport specific and initiated at about 50% effort and progressed to full effort into phase IV of rehabilitation as tolerated. Initiate to full effort only when such activities do not induce recurrent or persistent pain or effusion.

Milestones for Progression to the Next Phase

- Full nonpainful ROM
- No knee joint effusion following progressively more challenging activities of daily living and/or therapeutic activities
- Adequate strength
  - Hamstrings within 10% of contralateral extremity (as measured either via a comparison between isometric hand-held dynamometry and/or isokinetic dynamometry)
  - Quadriceps within 10% of contralateral extremity (as measured either via a comparison between isometric hand-held dynamometry and/or isokinetic dynamometry)
- Balance testing within 20% of contralateral extremity (as measured by assessing differences between single leg stance time and the Star Excursion Balance Test)
- Able to walk for 1 hour or longer

Phase IV (weeks 12+)

Protection

- Continued use of unloader osteoarthritic brace to unload the involved compartment and foot orthotics if previously recommended, minimizing the applied load across the articular cartilage of the knee

Management of Pain and Swelling

- At this stage of rehabilitation pain/effusion should not be an issue. The athlete may have some transient pain/minor effusion following a newly progressed activity. If so the use of Cryotherapy (continuous cool system or ice packs), elevation, and high-voltage electrical stimulation can be used following exercise to assist with pain/effusion reduction.

Techniques for Progressive Increase in Range of Motion

Manual Therapy Techniques

- At this stage of rehabilitation ROM deficits should not be an issue. If the athlete is prone to joint and/or soft tissue tightness, provide instruction in periodic self-mobilization of the patella femoral, tibiofemoral, and tibiofibular joints prophylactically.

Soft Tissue Techniques

- At this stage of rehabilitation soft tissue deficits should not be an issue. If the athlete is prone to joint and/or soft tissue tightness, instruction in periodic self-massage/soft tissue techniques prophylactically is warranted.

Stretching and Flexibility Techniques for the Musculotendinous Unit

- At this stage of rehabilitation the muscle length/integrity should be normal, and general flexibility exercises performed by the athlete to maintain normal length of the musculotendinous unit prior to and following exercise are:
  - Hamstrings
  - Gastrocnemius / soleus
  - Hip abductors/ adductors
  - Hip flexors
  - Quadriceps

Other Therapeutic Exercises

- During phase IV of rehabilitation the injured athlete should continue to actively participate in core stability strengthening, typical upper body strengthening routine, and a cardiovascular conditioning program. Upright and/or recumbent exercise biking and a progressed jogging program on either a treadmill, elliptical trainer, or outdoors on stable ground should be tolerated well.

Activation of Primary Muscles Involved

- At this stage of rehabilitation a continued balanced strengthening approach is needed to restore appropriate lower extremity function. A gradually progressed program of trunk, hip, and ankle exercises is recommended to control normal lower extremity forces and excess forces through the injured knee.

Sensorimotor Exercises

- Progressed weight-shifting side to side drills
- Progressed weight-shifting forward and backward drills
- Progressed weight-shifting diagonal drills
- Bilateral minisquats; no range of motion limit as long as asymptomatic
- Bilateral minisquats on an unstable surface (wobble board, tilt board, air disc, etc.); no range of motion limit as long as asymptomatic
- Progressed balance activities onto and off from various unstable surfaces
- Perturbation drills

Open and Closed Kinetic Chain Exercises

- OKC exercises
  - 4-way straight leg raises for an exercise warmup
    - Supine
    - Side lying for abductors
    - Side lying for adductors
    - Prone
  - LAQ
  - Stationary bike with progressed resistance and time
  - Swimming program
- CKC exercises
  - Progressed leg press from bilateral press to unilateral press as tolerated (allows for graded weight-bearing through the knee)
  - Bilateral squats; typically would limit 0° to 80°, but this range of motion should be adjusted based on the location of the lesion.
  - Lunges
  - Step-ups
  - Step-downs
  - Progressed running program (treadmill, elliptical trainer, or outdoors) in terms of distance, cadence, incline, etc.
  - Standing hip strengthening (abduction/adduction) with either resistive bands or circuit training equipment

Techniques to Increase Muscle Strength, Power, and Endurance

- To continue to enhance the overall muscular function of the hip and knee musculature, it is advisable to work with a high-repetition low load to enhance muscular endurance and reduce the risk of injury. When progressing both OKC and CKC exercises athletes should work up to two to three sets of 15 to 20 reps with proper form without pain. When able to complete up to 60 repetitions in total then a progression in load and/or activity is indicated.

Neuromuscular Dynamic Stability Exercises

- See preceding Sensorimotor Exercises section.

Plyometrics

- Plyometrics should be started with slow, controlled movements and then progressed to more explosive type activities. The rationale behind a plyometric program is to train the musculature, connective tissue, and nervous system to perform through cycles of stretch-shortening with proper technique and mechanics. It has been shown that modifiable knee injury risk factors of decreased landing forces, decreased varus/valgus moments, and enhanced muscle activation have resulted from plyometrics, dynamic balance and strengthening programs, stretching, body awareness and decision-making drills, and core stabilization drills.[11]

Functional Exercises

- As long as the athlete is tolerating the progression from a walking program to a jogging/running program, this program should be advanced in terms of time, distance, intensity, and terrain as tolerated (Box 31-1).

Sport-Specific Exercises

- The overall timing of return to full preinjury athletic activity is dependent upon the athlete, lesion type and location, other comorbidities, and the specific sports-related activities that the athlete needs to be able to achieve. During phase IV of rehabilitation the athlete should be in a position to begin sport-specific practices, first at 50% effort level and then progressed at no faster than a 10% incremental intensity per week until back to full intensity.

Milestones for Progression to Advanced Sport-Specific Training and Conditioning

- Full nonpainful ROM
- No knee joint effusion following progressively more challenging sport-specific drills and training
- Adequate strength
  - Hamstrings within 5% of contralateral extremity (as measured either via a comparison between

BOX 31-1 Return to Running Program*

Phase I: Walking Program

Patient should be able to walk, pain free, aggressively (roughly 4.2 to 5.2 miles per hour), in a controlled environment, preferably on a treadmill, before beginning the plyometric and walk/jog program.

Phase II: Plyometric Routine

A mile run typically consists of 1500 foot contacts, 750 per foot. This program integrates 470 foot contacts per leg, which would be equivalent to two thirds of the foot contacts during a mile run. Successful completion of this phase is a good indicator that an athlete is ready to attempt running a half to three-quarters of a mile distance.

EXERCISE	SETS	FOOT CONTACTS PER SET	TOTAL FOOT CONTACTS
Two-leg ankle hops: in place	3	30	90
Two-leg ankle hops: forward/backward	3	30	90
Two-leg ankle hops: side to side	3	30	90
One-leg ankle hops: in place	3	20	60
One-leg ankle hops: forward/backward	3	20	60
One-leg ankle hops: side to side	3	20	60
One-leg leg broad hop	4	5	20
	22		470

REST INTERVALS:

Between Sets: 90 seconds
Between Exercises: 3 minutes

GENERAL GUIDELINES

- Stretch Gastro, Soleus, Quads and Hamstrings between exercises.
- If a patient experiences pain or is unable to complete an exercise, stop, stretch, and apply ice to the involved area. Patient should be pain free the next day; attempt to restart the routine.

Phase III: Walk/Jog Progression

Patient should begin this program on level ground if:
1. Successfully completed Phase I and II
2. Does not have pain with normal daily activities

	WALK	JOG	REPETITIONS	TOTAL TIME
Stage I	5 minutes	1 minute	5 times	30 minutes
Stage II	4 minutes	2 minutes	5 times	30 minutes
Stage III	3 minutes	3 minutes	5 times	30 minutes
Stage IV	2 minutes	4 minutes	5 times	30 minutes
Stage V	Jog every other day with a goal of reaching 30 consecutive minutes; begin with 5 minutes of walking, gradually increasing the pace. End with 5 minutes of walking, gradually decreasing the pace to a comfortable walk.			

*When beginning a return to running program a runner and therapist should take into consideration the original injury/underlying health status in order to modify this program accordingly. A runner should progress through this program one phase at a time.

isometric hand-held dynamometry and/or isokinetic dynamometry)
  - Quadriceps within 5% of contralateral extremity (as measured either via a comparison between isometric hand-held dynamometry and/or isokinetic dynamometry)
- Balance testing within 10% of contralateral extremity (as measured by assessing differences between single leg stance time and the Star Excursion Balance Test)
- Able to complete full sport-specific workouts two to three times per week without recurrent pain and knee joint effusion

Performance Enhancement and Beyond Rehabilitation: Training/Trainer and Optimization of Athletic Performance

- Once an athlete has achieved the above milestones and has returned to athletic activity following conservative treatment of an articular cartilage lesion of the knee, it is advisable to continue a generalized core and lower extremity strengthening program. Such a program will ensure maximal muscular function to minimize stress through the knee joint.

- The continued use of the unloader brace and orthotics (if prescribed) are advised to assist in minimizing applied forces across the knee joint.

Specific Criteria for Return to Sports Participation: Tests and Measurements

- Before discussion of return to sports activity following conservative management of the athlete with an articular cartilage lesion, it is important for the clinician to know that, generally, the return to sport rate for those having undergone a surgical repair for an articular cartilage lesion is 73%.[12]
- It has also been shown that those with a smaller lesion, shorter duration of symptoms, less invasive surgical procedure, and fewer prior surgical procedures have a higher return to sports rate.[10]
- Currently there is no literature that reports return to sports following conservative management of the athlete with an articular cartilage lesion. One could predict based on the surgical literature that the younger athlete with the smaller lesion that is on a joint surface that withstands less weight-bearing forces will be more successful in returning to her/his previous sports activity.
- Specific criteria
  - Full nonpainful ROM
  - No knee joint effusion following progressively more challenging sport specific drills, training, and scrimmages
  - Adequate strength maintained after beginning sports specific training
  - Hamstrings within 5% of contralateral extremity (as measured either via a comparison between isometric hand-held dynamometry and/or isokinetic dynamometry)
  - Quadriceps within 5% of contralateral extremity (as measured either via a comparison between isometric hand-held dynamometry and/or isokinetic dynamometry)
  - Able to complete full sport-specific workouts three to four times per week without recurrent pain and knee joint effusion

Evidence

Alentorn-Geli E, Myer GD, Silvers HJ, et al: Prevention of noncontact anterior cruciate ligament injuries in soccer players. Part 2: a review of prevention programs aimed to modify risk factors and to reduce injury rates. *Knee Surg Sports Traumatol Arthrosc* 17:859–879, 2009.

This review article outlines the most recent literature regarding the effects of prevention programs to alter risk factors associated with noncontact ACL injuries in soccer players. Preseason injury prevention and in-season maintenance programs of plyometrics, dynamic balance, body awareness, decision making, and core strengthening have been shown to be the most successful in modifying injury risk factors. (Level IV evidence)

Delitto A, Rose SJ, McKowen JM, et al: Electrical stimulation verses voluntary exercise in strengthening thigh musculature after anterior cruciate ligament surgery. *Phys Ther* 68(5):660–663, 1988.

This prospective, randomized trial followed 20 patients after ACL surgery: 10 in the voluntary quadriceps exercise group and 10 in the electrical stimulation group. Those in the electrical stimulation group demonstrated higher percentages of flexion and extension torque when compared with the voluntary exercise group at 3 weeks postop. (Level I evidence)

Harrison RA, Hillman M, Bulstrode S: Loading of the lower limb when walking partially immersed. *Physiotherapy* 78:165, 1992.

This descriptive study reported on the buoyancy of the water and how it decreases the amount of weight-bearing forces to approximately 25% of the individual's body weight when submerged to the level of the axilla, and 50% of the individual's body weight when submerged to the level of the waist. (Level IV evidence).

Martelli S, Pinskerova V: The shapes of the tibial and femoral articular surfaces in relation to tibiofemoral movement. *J Bone Joint Surg Br* 84(4):607–613, 2002.

This study of cadaver knees using two techniques, MRI and computer interpolation of sections of the articular surfaces of the knee, reported the shapes of the tibial and femoral articular surfaces. These shapes suggest contact zones of the articular cartilage during typical knee movements. (Level IV evidence)

Mithoefer K, Hambly K, Della Villa S, et al: Return to sports participation after articular cartilage repair in the knee. *Am J Sports Med* 37(S1):167S–176S, 2009.

This systematic review of athletic participation after articular cartilage repair demonstrated that at an average of 42 months postop, up to73% of patients were able to return to their preinjury level. The time to return to sports ranged between 7 and 18 months. (Level III Evidence)

Patel VV, Hall K, Ries M, et al: A three-dimensional MRI analysis of knee kinematics. *J Ortho Res* 22(2):283–292, 2004.

This descriptive study described the normal, in vivo tibiofemoral joint kinematics in multiple weight-bearing positions of 10 volunteers using MRI techniques. (Level IV evidence)

Perry J, Antonelli D, Ford W: Analysis of knee joint forces during flexed-knee stance. *J Bone Joint Surg* 57A(7):961–967, 1975.

This cadaver based study described the forces of the quadriceps, patella, and tibia during flexed knee stance. They found that the quadriceps force was equivalent to 20% of the average maximum quadriceps strength at 15° and to 50% at 30°, compared with tests on five normal subjects. (Level IV evidence)

Robertson VJ, Ward AR, Jung P: The effect of heat on tissue extensibility: A comparison of deep and superficial heating. *Arch Phys Med Rehabil* 86:819–825, 2005.

This double-blind, prospective, repeated-measures trial compared the effects of deep heating and superficial heating on tissue extensibility. Twenty four subjects were randomized into 3 groups; deep heating, superficial heating, and no heating. The extensibility of the calf musculature was assessed following intervention. It was found that deep heating in the

absence of stretching increased the tissue extensibility more than the other 2 groups. (Level II evidence)

Rodrigo JJ, Steadman JR, Silliman JF: Improvement of full thickness chondral defects healing in the human knee after debridement and microfracture using CPM. *Am Knee Surg* 7:109–116, 1994.

This descriptive study reporting the effects of the use of a CPM following surgical intervention for the management of full-thickness articular surface defects found better gross healing of the lesion when evaluated by arthroscopic visualization as compared with those that did not use a CPM. This study suggests that those who include frequent range of motion activities following surgery and maybe even articular cartilage injuries can promote better healing. (Level IV evidence)

Snyder-Mackler L, Dellitto A, Bailey SL, et al: Strength of the quadriceps femoris muscle and functional recovery after reconstruction of the anterior cruciate ligament. A prospective, randomized clinical trial of electrical stimulation. *J Bone Joint Surg Am* 77:1166v1173, 1995.

This prospective randomized trial of 110 patients following ACL reconstruction were assigned to treatment with high intensity NMES, volitional exercise, low intensity NMES, or combined high and low intensity NMES. After 4 weeks the strength of the quadriceps femoris and the kinematics of the knee during stance phase were assessed. Those that received high intensity NMES (from either of the two groups) demonstrated significantly better quadriceps strength and kinematics of the knee. (Level I evidence)

Spenser JD, Hayes KC, Alexander IJ: Knee joint effusion and quadriceps reflex inhibition in man. *Arch Phys Med Rehabil* 65(4):171–177, 1984.

This descriptive study reported on the role of effusion in producing the reflex inhibition and atrophy of the quadriceps musculature following knee trauma. Ten subjects were assessed in this study following incremental injection of saline into the knee joint. All subjects demonstrated a reduction in the Hoffmann reflex amplitude following saline injection. The threshold for reflex inhibition of the vastus medialis was between 20 and 30 mL and between 50 and 60 mL for the rectus femoris and the vastus lateralis. (Level IV evidence)

Vanwanseel B, Lucchinett E, Stussi E: The effects of immobilization on the characteristics of articular cartilage: Current concepts and future directions. *Osteoarthritis Cartilage* 10(5): 408–419, 2002.

This descriptive animal-based study looking at the morphological, biomechanical, and biochemical properties of articular cartilage reports that thinning and softening of the cartilage is significant after 11 weeks of immobilization. The tissue deformation rate following this immobilization under load increased significantly. (Level IV evidence)

Multiple-Choice Questions

QUESTION 1. Which of the following are considered key factors to consider when devising a nonsurgical rehabilitation program for a patient who has had an articular cartilage injury?

A. Minimize pain and joint effusion
B. Restore muscle function
C. Enhance proprioception and neuromuscular control
D. All the above

QUESTION 2. What type of joint forces should be avoided while performing exercises during the early phases of rehabilitation following articular cartilage injury?

A. Shear forces
B. Distraction forces
C. Compressive forces
D. A and C

QUESTION 3. Which muscle group should one be cautious with when stretching during the early phases of rehabilitation following articular cartilage injury?

A. Hamstrings
B. Hip abductors
C. Quadriceps
D. Gastrocnemius/Soleus

QUESTION 4. What type of knee brace may a patient with an articular cartilage lesion need during the later stages of rehabilitation and return to sports to unload a specific compartment of the knee?

A. Drop-lock rehabilitative brace
B. Compression sleeve
C. Neoprene hinged brace
D. Unloader OA brace

QUESTION 5. What signs and symptoms let the clinician know that the athlete is not tolerating a given activity level during the course of rehabilitation?

A. Recurrent effusion
B. Joint line tenderness
C. Residual pain leading to a limp with ambulation
D. All the above

Answer Key

QUESTION 1. Correct answer: **D** (see Introduction)

QUESTION 2. Correct answer: **D** (see Phase I)

QUESTION 3. Correct answer: **C** (see Phase I)

QUESTION 4. Correct answer: **D** (see Phase III)

QUESTION 5. Correct answer: **D** (see throughout all phases)

POSTOPERATIVE REHABILITATION AFTER FEMORAL CONDYLE OR TROCHLEAR GROOVE MICROFRACTURE

Luke T. O'Brien, PT, SCS, PES, and J. Richard Steadman, MD

Indications for Surgical Treatment

- Full-thickness defect (grade IV)
- Unstable full-thickness lesion
- Degenerative joint disease lesion
- Requires proper knee alignment

Brief Summary of Surgical Treatment

- Correct joint environment at time of surgery
- Rough shave to remove cartilage remnants
- Curettes to remove calcified cartilage layer
- Surgical awls—penetrate subchondral bone
- Perforations 3 to 4 mm apart
- Don't "connect the dots"
- Maintain subchondral plate integrity
- Formation of "super clot"

Before Surgery: Overview of Goals, Milestones, and Guidelines[1]

- Must have proper patient selection
  - Patient understands postoperative process.
  - Patient will have to undergo strict rehabilitation program.
- Must have proper alignment
- Must use proper technique
- Must improve joint environment
- Proper rehabilitation

[1]*Prehabilitation, if appropriate, is described in the Nonoperative Rehabilitation section of this chapter.*

Phase I (days 0 to 14): Immediate Postoperative Period

Clinical Pearls

- Patella mobility is the key to the knee.
- A frequent complication of knee surgery is the formation of restrictive scar.
- Mobilization of the patella as well as the quadriceps and patellar tendon helps to maintain the integrity of the anterior interval and the suprapatellar pouch.
- Restrictive scar formation and the subsequent loss of these joint "spaces" increases not only patellofemoral joint contact pressure, but also tibiofemoral contact pressure.

Goals

- Protect the microfracture.
- Begin restoring tibiofemoral and patellofemoral range of motion.
- Reduce postoperative pain, swelling, and inflammation.
- Minimize the effects of immobilization/non–weight-bearing.

Protection

- All trochlear groove microfractures are braced in an immobilizer for 8 weeks. This is done to ensure that the median ridge of the patella does not engage the trochlea. The immobilizer is used at all times, including during sleep, unless in continuous passive motion (CPM).

- No brace is used for femoral condyle/tibial plateau lesions.
- Femoral condyle and tibial plateau microfractures mobilize with touch toe weight bearing for 8 weeks.
- Trochlear groove microfractures mobilize with partial weight bearing for 2 weeks.
- CPM (0° to 50°) is used 8 hours per day for 8 weeks. This improves the quality of the repair tissue, as well as ensuring congruency of the microfracture with the surrounding articular cartilage.[1]

Management of Pain and Swelling

- Femoral nerve block for 24 hours postoperatively
- Oral pain medication
- Continuous cryotherapy for pain and inflammation reduction
- Early range of motion exercises to facilitate resorption of swelling exudate

Techniques for Progressive Increase in Range of Motion

Range of Motion Restrictions

- Typically FROM for femoral condyle/tibial plateau
- May have ROM restrictions for trochlear groove, depending upon the size of the lesion

Manual Therapy Techniques

- Patella mobilization—medial/lateral mobilization of the patella, as well as the patella and quadriceps tendons. Superior/inferior mobilization of the patella. This helps limit scarring of the anterior interval and suprapatellar pouch, and the resultant increase in joint contact pressure.[2]
- Posterior tibial mobilizations in extension to ensure that symmetrical knee extension is attained.
- PROM—seated off the end of the bed with physical therapist assistance for initial flexion ROM. This is a particularly helpful position for trochlear groove microfractures with range of motion restriction or the presence of a femoral nerve block. Progress to independent wall slide as tolerated.
- Anterior-posterior tibial mobilization to ensure symmetrical extension.

Soft Tissue Techniques

- Lymphatic drainage techniques for swelling as required

Stretching and Flexibility Techniques for the Musculotendinous Unit

- Sit and reach stretch with strap around foot. Done to maintain ankle dorsiflexion while patient has a protected weight-bearing status

Other Therapeutic Exercises

- Well-leg biking/rowing and or arm bike for maintenance of cardiovascular fitness

Activation of Primary Muscles Involved in Injury Area or Surgical Structures

- Quadriceps sets. There are three benefits of teaching an isolated quad set in which the patella glides superiorly and the knee moves into terminal extension.
  - First, it resists muscle atrophy.
  - Second, it reinforces full knee extension, eliminating the possibility of developing a flexion contracture.
  - Finally, a quad set that locks the joint in terminal extension opens the anterior interval by 1 cm, and by doing so reduces the risk of anterior interval scarring.
- Hamstring sets. Usually performed as an isometric straight leg pulldown, or a straight leg bridge on a stable surface
- Gluteal isometrics
- Calf pumps for prevention of blood clots

Milestones for Progression to the Next Phase

- Approximately 115° of knee flexion to allow for a revolution on a stationary bike

Phase II (weeks 2 to 8 postoperative)

Clinical Pearls

- Regaining symmetrical knee extension is essential to the normal functioning of the knee.
- It allows weight-bearing force to be distributed over the entire available chondral surface, decreasing potential point loading.
- Full knee extension also allows the quadriceps to fire in inner range, which is essential for full muscular development.

TIMELINE 31-2: **Postoperative Rehabilitation After Femoral Condyle or Trochlear Groove Microfracture**

PHASE I (weeks 1 to 2 postop)	PHASE II (weeks 3 to 8 postop)
• TTWB x 8 wks for femoral condyle (FC), PWB x 2 wks for trochlear groove (TG) • CPM 0–50, 8 h/day • Immobilizer for TG microfractures • FPROM as tolerated • Patella mobilization • Quadriceps, gluteal and hamstring isometrics • Ice	• TTWB for FC • Immobilizer for TG • CPM 8 h/day • Stationary bike, no resistance • Deep water running • FPROM • Patella mobilization • Quadriceps, gluteal and hamstrings isometric • Ice

Goals

- Protect the microfracture.
- Restore full tibiofemoral and patellofemoral joint range of motion.
- Eliminate swelling and inflammation.
- Minimize the effects of immobilization/non–weight-bearing.

Protection

- Continue touch toe weight-bearing status for femoral condyle microfractures. Trochlear groove microfractures begin to wean off crutches over a period of 10 days after 2 weeks.
- Immobilizer use is continued for trochlear groove cases.
- CPM is continued 8 hours/day through 8 weeks.

Management of Pain and Swelling

- Pain medication use is typically ceased during this time.
- Cryotherapy three to four times daily for 20 minutes duration for pain and inflammation reduction
- Range of motion exercises

Techniques for Progressive Increase in Range of Motion

Manual Therapy Techniques

- Patella mobilization and posterior tibial mobilization are continued.
- PROM—Patients are encouraged to gently add overpressure to wall slides by placing their well leg on top of the surgical leg. Flexion on a Swiss ball is also added, with the PT gently applying overpressure at the end of range. All overpressure techniques should work into joint stiffness, but never reproduce joint pain.
- Stationary bike is introduced to facilitate ROM gains. Patients begin with 10 minutes duration and increase periodically to achieve 30 minutes duration by 8 weeks. All biking is done with no resistance through 8 weeks.

Soft Tissue Techniques

- Lymphatic drainage techniques for swelling as required.
- Trigger point release of hip flexor/tensor fascia lata is occasionally necessary owing to extended time in CPM and/or ambulating in an immobilizer.

Stretching and Flexibility Techniques for the Musculotendinous Unit

- Sit and reach stretch with strap around foot

Other Therapeutic Exercises

- Well-leg biking/rowing and or arm bike for maintenance of cardiovascular fitness
- Deep water aquajogging, ensuring that feet do not touch the bottom of the pool
- Upper body resistance training while ensuring adherence to weight-bearing and ROM precautions

Activation of Primary Muscles Involved in Injury Area or Surgical Structures

- Quadriceps, hamstrings, and gluteal isometrics are continued and hold times progressed.
- Biofeedback may be used during quadriceps isometrics to facilitate a minimum level of performance during endurance holds for time.
- Straight leg raises are only introduced when the patient is able to demonstrate a quad set that locks the knee in end of range extension. Performing a straight leg raise in the presence of a quadriceps lag places a trochlear groove microfracture under unnecessary stress.

Milestones for Progression to the Next Phase

- 8 weeks post surgery. This ensures sufficient time has passed for the microfracture to tolerate weight-bearing stress.
- Full passive range of motion
- Quad set that locks the knee in terminal extension

Phase III (weeks 9 to 12 postoperative)

Clinical Pearls

- Successfully increasing patients with microfractures weight-bearing tolerance is most safely achieved by controlling total load volume.
- This is most easily done by using cardiovascular equipment, where duration and intensity parameters are easily monitored and progressed.

TIMELINE 31-2: Postoperative Rehabilitation After Femoral Condyle or Trochlear Groove Microfracture (Continued)

PHASE III (weeks 9 to 12 postop)	PHASE IV (weeks 13 to 18 postop)	PHASE V (weeks 19 to 24 postop)
• DC brace for TG • Wean off crutches for FC • Add resistance to stationary bike • Treadmill walking 7% incline • Lap kicking with fins in the pool • Shallow ⅓ knee bends • Double leg bridging • Standing TKE with resistance cord • Joint mobilization as necessary • Ice as necessary	• PROM—maintain full motion • Mobilizations as needed • Foam roller for soft tissue • Progress cardiovascular equipment use • CKC exercises—double leg shallow ROM or single leg static • CKC rhythmic stabilization • Balance and proprioception • Ice as necessary	• PROM—maintain full motion • Mobilizations as needed • Foam roller for soft tissue • Active warm up before strength work • Cardiovascular conditioning • CKC exercises—double leg FROM + single leg controlled ROM • Dynamic stability—introduce unstable surfaces

Goals

- Protect the maturing microfracture.
- Increase unprotected weight-bearing tolerance.
- Initiate muscular endurance base-building activities for the lower extremity.

Protection

- Femoral condyle microfractures begin weaning off crutches after 8 weeks. This is typically achieved though ceasing their use in the home environment. Crutches are still used for outside activity with progressively increased weight bearing. Crutch use is ceased once patients are able to demonstrate that full weight bearing does not increase pain or joint swelling, or lead to a loss of range of motion.
- Immobilizer brace is no longer used for trochlear groove microfractures after 8 weeks.
- CPM is no longer used after 8 weeks.

Techniques for Progressive Increase in Range of Motion

Manual Therapy Techniques

- Techniques for tibiofemoral and patellofemoral mobility are continued only in the presence of joint ROM limitations.

Other Therapeutic Exercises

- Alter-G treadmill (if available)—used to assist weaning off crutches. Patients are typically started at 65% of body, and progressed daily with 5% increments.
- Treadmill walking 7% incline—typically started at 5 to 10 minutes duration with time increased by 10% each session
- Stationary bike—Resistance is progressively added with a goal of achieving 30 minutes of moderate resistance cycling by week 12. Proper technique, including seat height, is critical.
- Pool—lap kicking with fins for non–trochlear groove microfractures. Walking in chest deep water with progression to waist deep water to assist in weaning off crutches.
- Upper extremity resistance program can now incorporate standing positions.
- Deep water aquajogging, UBE, and well-leg rowing can all be used for cardiovascular exercise.

Activation of Primary Muscles Involved in Injury Area or Surgical Structures

- Quadriceps work is predominately in non–weight-bearing positions and focuses on shallow range of motion (0° to 30°).
- Gluteals and hamstrings (posterior chain) can largely be worked through full range in non–weight-bearing positions.

Sensorimotor Exercises

- Toe and heel raises are used to improve foot and ankle balance strategies, as well as improving dorsiflexion and plantarflexion strength.

Open and Closed Kinetic Chain Exercises

- Low-load, high repetition predominates the repetition and set structure for all open kinetic chain (OKC) and closed kinetic chain (CKC) exercises in this phase.
- Double leg bridging and side-lying manual-resisted hip extension are incorporated to develop hip extension.
- Knee extension is developed through low-impact exercises such as prone manual-resisted terminal knee extension and standing sports cord-resisted terminal knee extension.
- Shallow-range double leg squats to promote hip and knee extension. Care is taken to avoid squats deeper than 30° in trochlear groove microfractures, as this significantly increases load on the maturing cartilage surface.

Milestones for Progression to the Next Phase

- 12 weeks from surgery
- Successfully completed progressive loading program without an increase in joint symptoms (pain, swelling or loss of motion)

Phase IV (weeks 13 to 18 postoperative)

Clinical Pearls

- Microfracture cartilage continues to mature over a 12-month period.
- It is normal for patients to have an awareness of their microfracture area during some strengthening exercises and with daily activities such as descending stairs.
- While awareness of the surgical area is normal, pain is not, and therefore it should never be "worked through."

Goals

- Protect maturing microfracture
- Develop a lower extremity muscular endurance base
- Begin thigh girth normalization
- Develop hip and knee stability

Techniques for Progressive Increase in Range of Motion

Soft Tissue Techniques

- Foam roller soft tissue mobilization with emphasis on quadriceps, hamstrings, hip flexors, gluteals, and iliotibial band

Stretching and Flexibility Techniques for the Musculotendinous Unit

- Incorporate active warmup techniques prior to strength work.

Other Therapeutic Exercises

- Unrestricted stationary biking, treadmill 7% incline walking, and pool activity
- May incorporate elliptical trainer as a cardiovascular training option
- Unrestricted upper extremity and core training programs
- Completing a functional movement screen to identify faulty movement patterns may be incorporated as appropriate in this phase.[3] Corrective exercises can be integrated into the treatment plan.

Activation of Primary Muscles Involved in Injury Area or Surgical Structures

- Development of an endurance base of the quadriceps, gluteals, and hamstrings should be the primary focus during this phase.
- Because many patients' operative knee typically displays few symptoms by this phase, careful monitoring of total load volume is necessary to limit the risk of irritating the joint and setting back the rehabilitation timeline.

Sensorimotor Exercises

- Specific exercises for balance are not emphasized at this time. Rather, proprioceptive training is incorporated into existing exercise design (e.g., single leg Romanian deadlift).

Open and Closed Kinetic Chain Exercises

- CKC activities in this phase focus on body weight resistance, double leg through full range exercises, or single leg static positions. OKC exercises are not emphasized.
- Double leg exercises include: squat progression (regular squat, squat to calf raise and squat to weight shift and hold) (Figure 31-19), double leg shuttle/leg press and static holds in reverse lunge position.
- Single leg CKC examples include Romanian deadlift and single leg bridges.

Neuromuscular Dynamic Stability Exercises

- In this phase, it is preferable to focus on the development of static stability before progressing to dynamic stability in the next phase.
- Exercises can focus on medicine ball, tubing, or kettle bell perturbations incorporating push/pull or rotational movements (e.g., static box hold with medicine ball push/pull) (Figure 31-20) and static reverse lunge holds with straight arm rotations.
- Rhythmic stabilization applied through the shoulders or trunk can also be added to these static positions.

Milestones for Progression to the Next Phase

- 18 weeks since surgery
- Demonstrated appropriate levels of stability and form in performing double leg and static single leg activities. Stability is measured by the patient's ability to perform without loss of balance. Form is determined by how the patient performs the activities (i.e., does the patient lower her/himself straight down with equal weight distribution?). The therapist must determine the patient's ability to perform these activities.
- No negative joint reactions (pain, swelling or loss of motion) in response to increase training load.

Phase V (weeks 19 to 24 Postoperative)

Clinical Pearls

- A linear periodized strength plan is the most appropriate structure for rehabilitation.
- It is characterized by an initial high volume of repetitions and sets, and low resistance.
- The following phases involve a gradual decrease in volume and an increase in intensity.
- This gradual increase in intensity corresponds well with the load tolerance of maturing microfracture cartilage.

Goals

- Develop a lower extremity muscular strength base.
- Minimize thigh girth differences.
- Successfully load the microfracture in single leg, full range of motion activities.

Techniques for Progressive Increase in Range of Motion

Soft Tissue Techniques

- Foam roller soft tissue mobilization with emphasis on quadriceps, hamstrings, hip flexors, glutes, and iliotibial band.

Stretching and Flexibility Techniques for the Musculotendinous Unit

- Incorporate active warmup techniques prior to strength work. These include sun salutations, hip crossover (Figure 31-21), scorpion (Figure 31-22), hand walks, and elbow to instep.

Other Therapeutic Exercises

- VO_2 Max testing using either a UBE or a stationary bike can be completed.
- Data from this test can be used to develop a cardiovascular base building program relevant to the athletes sport and season start date.

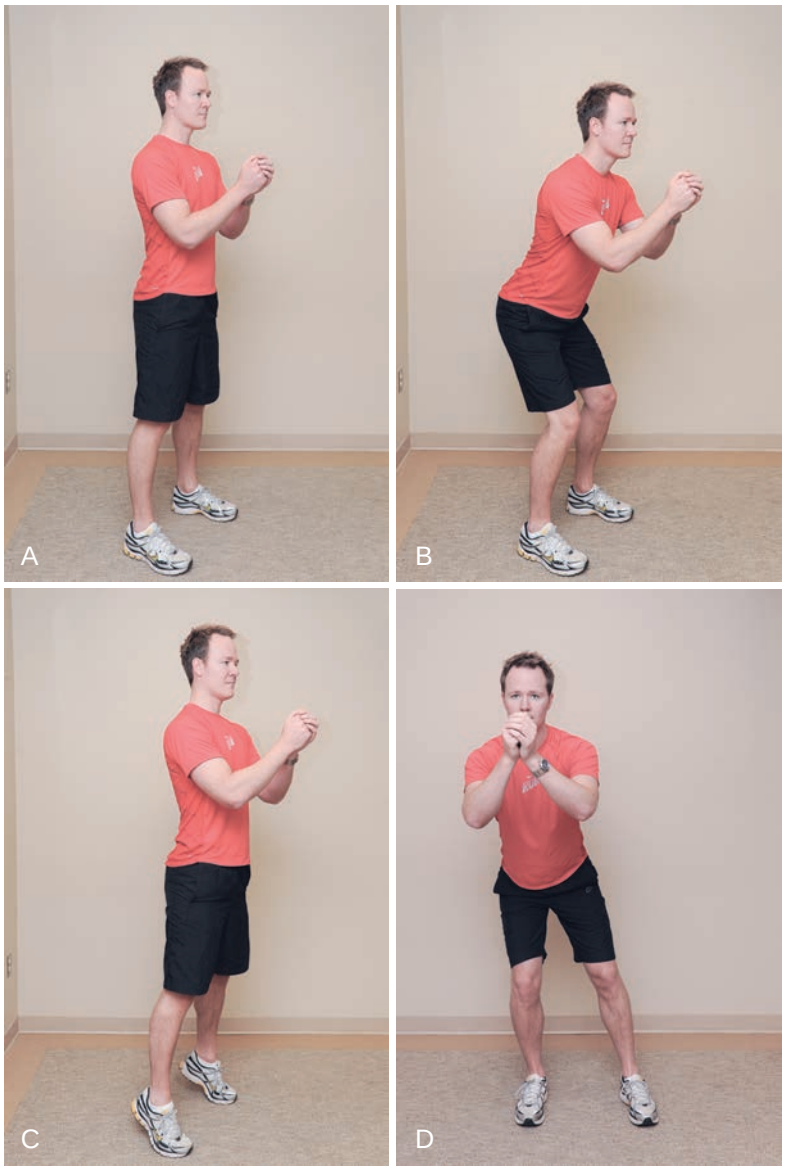

FIGURE 31-19. Squat progression. **A,** Start position. **B,** Regular squat. **C,** Squat to calf raise. **D,** Squat to weight shift.

- Upper extremity and core conditioning can shift from earlier maintenance programs, to periodized strengthening plans specific to the demands of the athlete's sport.

Activation of Primary Muscles Involved in Injury Area or Surgical Structures

- The emphasis of this phase is on the development of muscular strength of the major muscle groups of the lower extremity (quadriceps, gluteals, and hamstrings). This is initiated through body weight-resisted, single leg activity. Initially exercise range of motion may be controlled, with full range allowed once gains in strength and pelvic stability allow.

Sensorimotor Exercises

- Specific exercises for balance are not emphasized at this time. Rather, proprioceptive training is incorporated into existing exercise design.
- Unstable surfaces (BOSU, half foam rolls, and tilt board) may be introduced to progress double or single leg exercises (e.g., BOSU tuck squats).

Open and Closed Kinetic Chain Exercises

- Single leg CKC exercises are now emphasized. These are predominately compound exercises that incorporate hip and knee flexion and extension (e.g., balance squat; Figure 31-23), single knee bends, and reverse lunges.
- Posterior chain work is continued and progressed: for example, Romanian deadlift with kettle bells, double leg bridges on slider disc—alternating leg flexion/extension.

Neuromuscular Dynamic Stability Exercises

- Incorporating medicine balls (single knee bend with medicine ball chop), elastic tubing (single knee bend

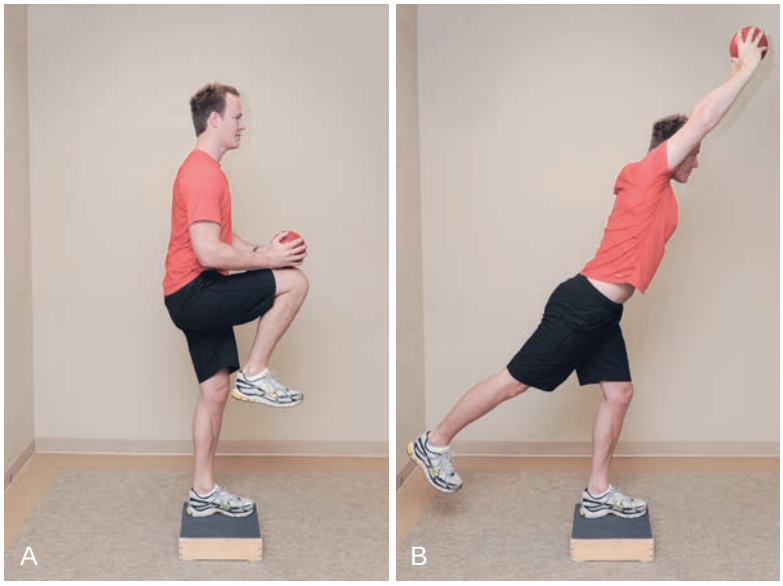

FIGURE 31-20. Static box hold with medicine ball push/pull. **A,** Start position. **B,** Finish position.

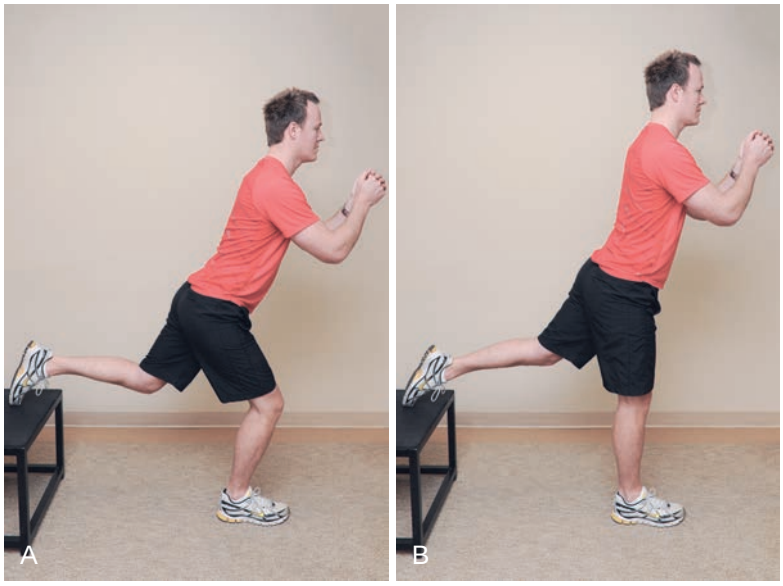

FIGURE 31-21. Hip crossover. **A,** Start position. **B,** Finish position.

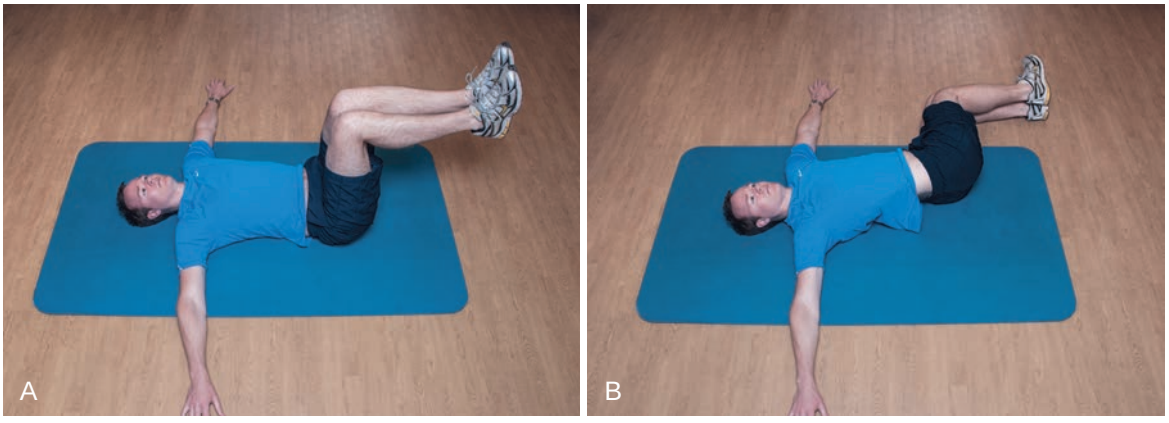

FIGURE 31-22. Scorpion. **A,** Start position. **B,** Finish position.

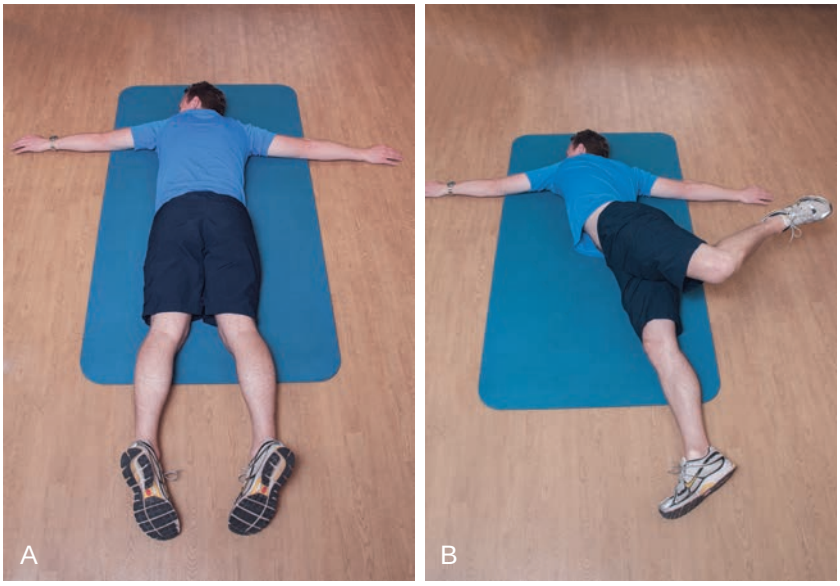

FIGURE 31-23. Balance squat. **A,** Start position. **B,** Finish position.

with single arm row; Figure 31-24) or rhythmic stabilization (single knee bends with rhythmic stabilization at different points in range) can be used to provide dynamic stability challenges to almost any CKC exercise.

Milestones for Progression to the Next Phase

- 24+ weeks post surgery
- Adequate levels of strength and stability in the performance of single leg activities. Strength and stability are measured visually by the therapist. Adequate strength is seen when patients can lower on a single leg and return to upright with little difficulties. Stability is shown by performing the activities without loss of balance or need of support.
- No negative joint symptoms (pain, swelling, or loss of motion) in response to increase training load.

Phase VI (weeks 24 to 36 postoperative)

Clinical Pearls

- Because of high impact stress, delay the start of a running progression for as long as possible.
- Calculate how many weeks will be required to condition the athlete to running. Initial running should take place on a forgiving surface, using 1-minute running followed by 4-minute walking

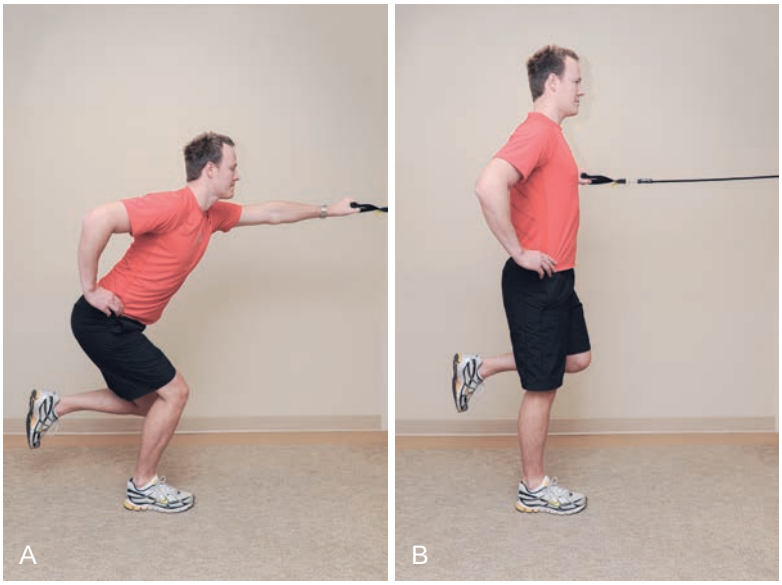

FIGURE 31-24. Single knee bend with single arm row. **A,** Start position. **B,** Finish position.

intervals. Running time is increased by 1 minute per week (associated with a 1-minute decrease in walking time) so that the patient is able to complete 20 minutes of continuous running after 5 weeks. Subtract that from the targeted return to play date to provide a goal date to begin the progression. Working backward like this decreases the risk of overloading the joint and inhibiting the recovery.

Goals

- Thigh girth symmetry
- Successful resumption of running (if required for athlete's sport)
- Return to play

Techniques for Progressive Increase in Range of Motion

Soft Tissue Techniques

- Foam roller soft tissue mobilization with emphasis on quadriceps, hamstrings, hip flexors, glutes, and iliotibial band.

Stretching and Flexibility Techniques for the Musculotendinous Unit

- Incorporate active warm up techniques prior to strength/running work.

Other Therapeutic Exercises

- Continue cardiovascular conditioning. Anaerobic threshold training can begin once an aerobic base has been built.
- Upper extremity and core training can begin to integrate sport-specific elements.

Activation of Primary Muscles Involved in Injury Area or Surgical Structures

- Development of muscular strength and power focusing on the posterior chain and the quadriceps predominates this point of rehabilitation.

Open and Closed Kinetic Chain Exercises

- Many of the exercises from phase V are continued now, with the addition of resistance. Resistance can be applied through use of a resistance cord, kettlebells, or dumbbells (e.g., single leg squat with sport cord, reverse lunge with dumbbells, or cowboy squat with kettlebells).
- A lifting program incorporating traditional lifts (e.g., barbell squats and deadlifts), is started once the athlete begins a running progression.
- Low weight is used to begin while appropriate lifting technique is being taught and the knee is adapting to the increased load.
- Weight is increased as technique, muscular performance, and the knee allows.

Neuromuscular Dynamic Stability Exercises

- Dynamic stability activities can be incorporated into daily programs for exercise variety, but are not emphasized in this phase.

Plyometrics

- In attempting to shield the microfracture from unnecessary impact stress, muscular power is developed by emphasizing speed of muscular contraction with the foot remaining in contact with the ground. This is in contrast to traditional plyometrics, which involve the foot leaving the ground. Examples of such modified plyometric exercises include high bench step ups with hip drive (Figure 31-25), prone shuttle press with arm

FIGURE 31-25. High bench step up with hip drive. **A,** Start position. **B,** Finish position.

FIGURE 31-26. Prone shuttle press with arm drive. **A,** Start position. **B,** Finish position.

drive (Figure 31-26), and lateral hip drive with sport cord resistance.

Functional Exercises

- A running progression can begin in this phase as long as thigh girth measurements are within 1 centimeter, and a functional strength test (The Sport Test) is passed. A standard running progression is given in Table 31-1.
- Some sports (baseball, American football) may not require 20 minutes of running.
- The running progression may then be shortened (or lengthened) to match the demands of specific sports or positions.

Sport-Specific Exercises

- Upon successful completion of a running progression, athletes involved in cutting and pivoting sports need to complete speed and agility drills before returning to training.
- Specific drills will vary depending upon the needs of the athlete and the demands of his sport.
- As a general guideline, drills should progress from single plane to multiplane agilities, and from moderate running speed to sprinting. A sample three times per week for 4 weeks progression is outlined in Table 31-2.

Table 31-1 Standard Running Progression

Running Week #	Run Time (minutes)	Walk Time (minutes)	Total Duration (minutes)
1	1	4	20
2	2	3	20
3	3	2	20
4	4	1	20
5	20	0	20

Table 31-2 A Sample Three Times per Week for 4 Weeks Progression

Agility Week #	Sample Agility
1. Linear cone drills	1. Weave run 2. Zig-Zag shuffle 3. Dip and touch 4. Circle around
2. Linear cone drills	1. Jump over—sprint 2. Front/Back shuttle 3. Sprint—shuffle shuttle 4. Figure 8's
3. Zig-zag cone drills	1. Up 2, back 1 2. Shuffle, explode touch 3. Sprint, shuffle touch 4. Run through with hand plants

Criteria for Return to Sport

- Symmetrical patellofemoral and tibiofemoral range of motion
- Thigh girth within 1 cm of unaffected side
- Successful completion of running progression and speed and agility drills without provocation of joint symptoms (pain, swelling or loss of motion)
- Sufficient time must have passed from surgery to allow the microfracture to mature into a durable repair tissue.

After Return to Sport

Exercises and Other Techniques for Prevention of Recurrent Injury

- All future cardiovascular and strength conditioning work should be considered in light of the athlete having an altered chondral surface. Low-load activities should always be preferred over high-load activities when practical.
- Permanently avoid leg extension and forward lunges. Both these place large amounts of unnecessary load on the anterior knee.
- Medical review should be conducted if the athlete experiences persistent pain and/or effusion after activity.

Evidence

Ahmad CS, Kwak SD, Ateshian GA, et al: Effects of patellar tendon adhesion to the anterior tibia on knee mechanics. *Am J Sports Med* 26(5):715–724, 1998.

This cadaveric study examined the effects of patellar tendon adhesion on the knee extensor mechanism and on the kinematics and contact areas for both the patellofemoral and tibiofemoral joint. Adhesion decreased knee extension force, and increased patellofemoral joint reaction force. (Nonclinical Study)

Gill TJ, McCulloch PC, Glasson SS, et al: Chondral defect repair after the microfracture procedure: A nonhuman primate model. *Am J Sports Med* 33(5):680–685, 2005. (Descriptive laboratory study)

Microfracture was performed in primates and repair tissue was evaluated at 6 and 12 weeks. At 6 week, there was limited repair but at 12 weeks the defects were completely filled. This research may indicate that the repair tissue created by microfracture is vulnerable in the first 6 to 12 weeks postoperative and restricting weightbearing may protect the repair.

Hurst JM, Steadman JR, O'Brien L, et al: Rehabilitation following microfracture for chondral injury in the knee. *Clin Sports Med* 29(2):257–265, 2010. (Level 5)

This paper details postoperative care and rehabilitation following microfracture in the knee.

Ramappa AJ, Gill TJ, Bradford CH, et al: Magnetic resonance imaging to assess knee cartilage repair tissue after microfracture of chondral defects. *J Knee Surg* 20(3):228–234, 2007. (Level 4)

This paper reported on a patient who underwent second look arthroscopy and MRI following microfracture. The study showed that the MRI has high sensitivity and specificity for determining fill of the cartilage lesion. In addition, the study demonstrated that most defects had 100% fill following microfracture.

Rodrigo JJ: Improvement of full-thickness chondral defect healing in the human knee after debridement and microfracture using continuous passive motion. *Am J Knee Surg* 7:109–116, 1994. (Level 4)

This study compared grade of cartilage lesion at second look arthroscopy in patients who used CPM following microfracture to those patients who did not use CPM. The paper reported that those patients who used CPM appeared to have superior healing of cartilage defects treated with microfracture.

Steadman JR, Briggs KK, Rodrigo JJ, et al: Outcomes of microfracture for traumatic chondral defects of the knee: average 11-year follow-up. *Arthroscop* 19(5):477–484, 2003. (Level 4)

This paper reported the function outcomes of patients at an average of 11 years following microfracture for traumatic chondral defects of the knee. The results showed significant improvement in Lysholm and Tegner scores at final follow-up. Multivariate analysis revealed age as a predictor of improvement in function.

Yen YM, Cascio B, O'Brien L, et al: Treatment of osteoarthritis of the knee with microfracture and rehabilitation. *Med Sci Sports Exerc* 40(2):200–205, 2008. (Level 5)

This paper details specific postoperative and rehabilitation for patients with osteoarthritis of the knee who have undergone microfracture.

Multiple-Choice Questions

QUESTION 1. An immobilizer is used for 8 weeks following trochlear groove microfracture for which of the following reasons?

A. To minimize scar tissue formation
B. To prevent the median ridge of the patella from engaging the trochlear in weight-bearing positions
C. To prevent flexion contractures
D. To provide stability to a postsurgical joint

QUESTION 2. Femoral condyle microfractures mobilize TTBW for

A. 2 weeks.
B. 4 weeks.
C. 6 weeks.
D. 8 weeks.

QUESTION 3. A running progression should begin

A. as soon as thigh girth is symmetrical.
B. 20 weeks post surgery.
C. as soon as possible.
D. as late as possible while still allowing the athlete sufficient conditioning time prior to returning to play.

Answer Key

QUESTION 1. Correct answer: **B** (see Phase I)

QUESTION 2. Correct answer: **D** (see Week 2–4)

QUESTION 3. Correct answer: **D** (see Phase VI)

POSTOPERATIVE REHABILITATION AFTER AUTOLOGOUS CHONDROCYTE IMPLANTATION FOR CARTILAGE RESTORATION

Scott D. Gillogly, MD, FACS, and Kate McDonald, BScPT, OCS, COMT

Indications for Surgical Treatment

- Failure of nonoperative treatment
- Persistent activity-related pain
- Significant articular cartilage defect—size, depth, and number of defects; location; and containment all contribute to determining the best treatment option.
- Progression of a localized articular defect to significant joint osteoarthritis
- Symptomatic predominantly full-thickness chondral defects (grade III to grade IV lesions) and osteochondritis dissecans lesions of the femoral condyle and trochlea
- Medium to large focal chondral lesions typically larger than 2.5 cm^2
- Concomitant procedures will often be required in order to correct biomechanical factors that contributed to the injury and to optimize the healing environment.
- Patient age and activity requirements—This surgery is indicated for younger patients (typically less than 50 to 55 years of age) with higher exercise requirements. A hemiarthroplasty or total knee replacement may be indicated for older, more sedentary patients with advanced cartilage damage.

Brief Summary of Surgical Treatment

Major Surgical Steps

- Chondral biopsy is required initially to culture and grow the autologous chondrocytes.
- Autologous chondrocyte implantation (ACI) is an open procedure requiring adequate exposure (Figure 31-27).
- The defect(s) is prepared by sharply demarcating the edge of the defect and removing all degenerated cartilage remnants down thru the calcified cartilage layer without violating the subchondral plate.
- The defects is sized by making a template and transferring the size and shape to the covering membrane of periosteum or an absorbable Type I/III collagen membrane.
- Covering membrane is sutured to the edges of the defect and sealed with fibrin glue to make a water tight seal.
- Defects with uncontained edges may require alternate methods to securely attach the covering membrane such as microsuture anchors or drill holes through bone.
- Autologous cells are then injected under the membrane and the injection site closed and sealed. Any concomitant procedures such as anterior cruciate ligament reconstruction, osteotomy, patellofemoral realignment, or meniscal transplantation are done prior to completing the cell implantation, which should be the last portion of the procedure.

Factors That May Affect Rehabilitation

Anesthetic

- Regional anesthesia may be used. This femoral and/or sciatic nerve block may wear off 8 to 24 hours following surgery. Patient may alternatively be fitted with a continuous nerve block pump—the level of anesthesia can be independently varied—decreased for rehabilitation sessions so that the patient has some quadriceps control, and increased post rehabilitation to afford more pain relief.

Surgical

- Size: Larger lesions require slower rehabilitation.
- Depth: Deeper lesions may require a bone graft which will slow rehabilitation.
- Location: Femoral condyle lesions require protection from weight-bearing forces; patella-trochlea lesions require protection from shear forces.
- Containment: Cleaner boundaries and superior surrounding cartilage is preferable.
- Concomitant procedures: Simultaneous surgeries, such as femoral osteotomy, high tibial osteotomy, or distal tibial realignment (Fulkerson) will each have specific protocol requirements. In general follow the protocol for the technique that is the most conservative. (See Modifications for Concomitant Surgeries section.)

Before Surgery: Overview of Goals, Milestones, and Guidelines[2]

- Prehabilitation is very important prior to cartilage restoration procedures. Postsurgical pain and immobility may be significant and result in fairly significant muscular atrophy. Obviously the stronger the patient is prior to surgery, the easier it will be to maintain and regain muscle.
- One or two prehabilitation sessions of physical therapy should be sufficient to instruct the patient. Focus on the following specific areas:
  - Weight loss
  - Core strengthening (e.g., planks, side planks, abdominal roller, physioball exercises)
  - Hip abductor strengthening (side-lying abduction, single leg balance on wobble board, speedskaters—see Figure 31-39).

[2]*Prehabilitation, if appropriate, is described in the Nonoperative Rehabilitation section of this chapter.*

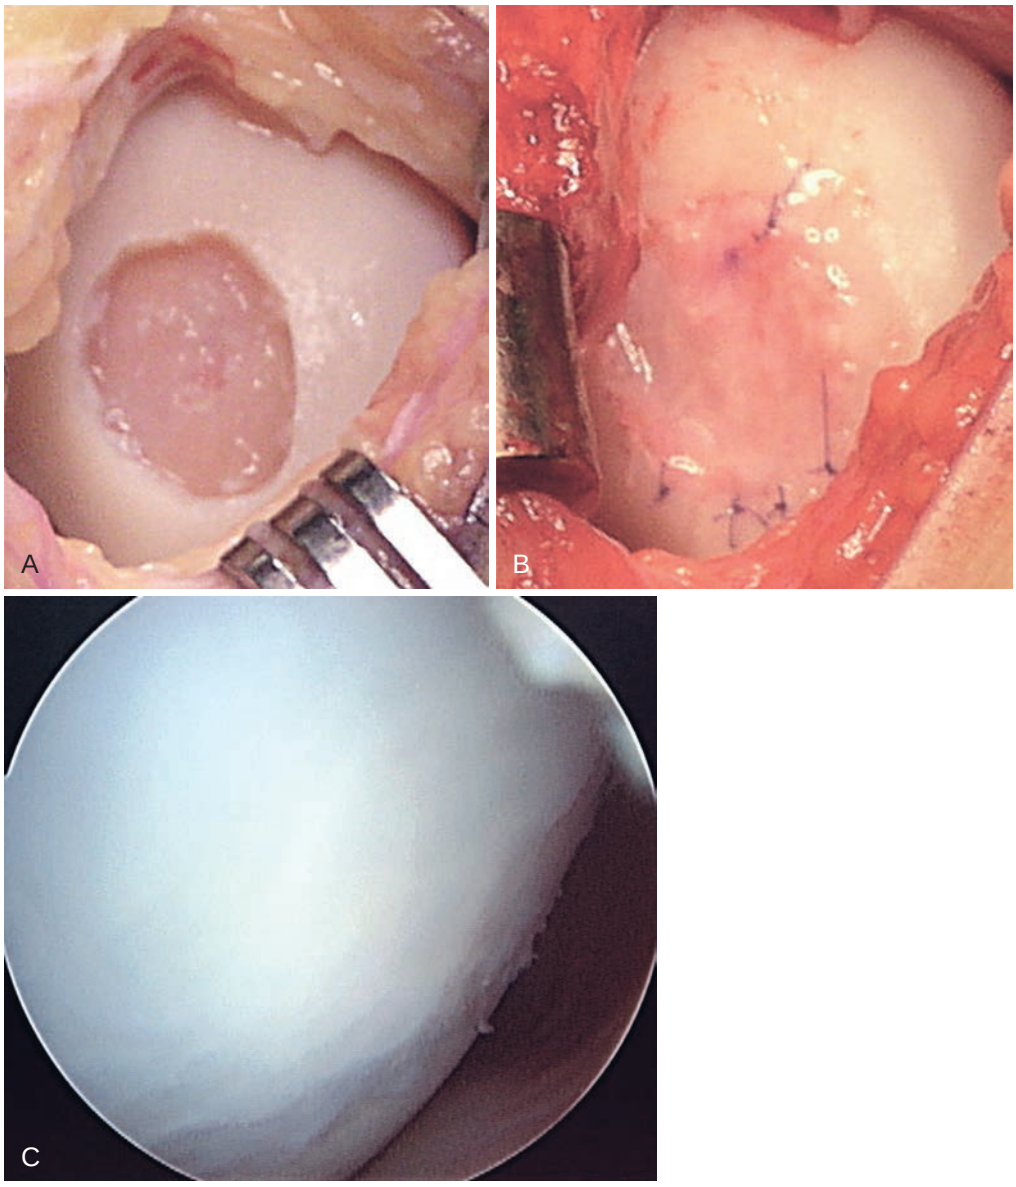

FIGURE 31-27. Autologous chondrocyte Implantation. **A,** Defect has been debrided to a stable edge with surrounding normal articular cartilage. **B,** Periosteum or membrane cover has been sutured into place and sealed with fibrin glue containing the autologous chondrocytes. **C,** The same defect at second look arthroscopy 11 months after implantation showing excellent repair tissue fully filling the defect.

  - Quadriceps strengthening (vastus medialis oblique holds—sit, maintaining good posture on a level surface, with both feet on the ground. Hold the surgical knee in static, active knee extension for 5 minutes. Once finished, slide back onto the bed so that it is not necessary to do open chain knee flexion, sit-to-stands—similar to squats but patient sits down onto a low mat table and then stands again without using arm support, leg presses)
  - General cardiovascular fitness
- In addition, it may be advisable to teach the patient the initial postoperative regime including crutch walking, heel prop, quad sets, ankle pumps, and hamstring and calf stretches during the prehabilitation sessions (refer to Phase I). This is necessary because the patient is often in significant pain and/or on strong analgesia at the initial postsurgery visit.

GUIDING PRINCIPLES OF POSTOPERATIVE REHABILITATION

- Appreciate the anatomic structures involved and their individual rates of healing.
- Appreciate stresses applied in different ranges of motions, with different activities.
- Determine location, size, depth, and number of lesions.
- Determine whether concomitant procedures have been performed. Follow the more conservative protocol.
- Respect ROM requirements and weight-bearing progressions. These will differ for the different surgical techniques and different locations (Table 31-3).

Table 31-3 Comparison of Autologous Chondrocyte Implantation—Femoral Condyle and Patella-Trochlea

	Weight Bearing	PROM Knee Flexion Goals	Return to Sport
ACI-Femoral condyle	Restriction of weight bearing for 8 weeks—10–20 lbs only. 100% weight bearing at weeks 6–8—earlier with permission from MD.	PROM is restricted only by pain; the following are conservative numbers and can be progressed faster. 90° weeks 1–2 105° by week 3 115° by week 4 135° by week 6	6 months Low impact—golf, swimming, skating, rollerblading, cycling 7–8 months Moderate impact—light running, aerobics 12 months High impact —tennis, volleyball, basketball, football, baseball
ACI-Patella-trochlea	Weight bearing can be accelerated more quickly. 25% weight bearing week 2 50% weight bearing week 4 100% weight bearing week 6 (When the knee is in full extension, weight bearing will not load the repair sites.)	Passive ROM knee flexion is progressed slower in the patella-trochlea patient to avoid shear. 90° by weeks 2–3 105° by weeks 3–4 120° by week 7 135° by weeks 8–9	6 months Low impact 7–8 months Moderate impact 12 months High impact

Healing Timeframes: The Four Phases of Chondrocyte Maturation

It is important for the rehabilitation specialist and athlete to be cognizant of the stages of chondrocyte maturation, so that they can fully appreciate the importance of adhering to the protocol timeline.

- Proliferation (early protection) phase
  - Proliferation of chondrocytes occurs during the first 6 postoperative weeks, with cellular activity observed in the first 24 hours. During the hours immediately following surgery, the cells line the base of the defect. They multiply and produce a matrix to fill the lesion. (Patients with ACI-patella surgery will awaken ideally in prone, to take maximum advantage of this early healing process.)
  - Protection is essential during the first 6 weeks. However, gentle weight bearing and range of motion is necessary to stimulate cellular growth.
- Transition phase: This typically occurs during the second 2 months post surgery. During this phase, the cartilage tissue is compressible and spongy and continues to require controlled forces only.
- Remodeling phase: This takes place during the third to sixth postoperative month. Hyaline cartilage is remodeling into a more organized structure, allowing for improved strength and durability. Low to moderate impact activities can be tolerated toward the end of this phase.
- Maturation phase: This can vary from 9 to 18 months in duration. The tissue repair becomes fully mature with stiffness similar to the surrounding tissue.

Phase I (days 0–14): Immediate Postoperative Period

Clinical Pearl

It is imperative to retain full passive knee extension immediately postoperative (e.g., by performing prone hangs or heel props (Figures. 31-28 and 31-29) or using a passive extension device). The patient should additionally be educated against resting with a pillow under the knee. Educating the patient on the importance of this step is invaluable in gaining full compliance.

FIGURE 31-28. Prone hang exercise. The patient should perform this stretch as a low-load, long-duration stretch aimed at regaining full passive knee extension. Moist heat can be applied to the hamstring.

FIGURE 31-29. Heel prop exercise. Maintaining this position for a 20-minute period will provide a low-load, long-duration stretch to regain full passive knee extension.

Goals

- Decrease pain and effusion.
- Protection from load and shear forces
- Immediate restoration of full passive knee extension
- Gradually increase passive knee flexion, limited by patient's pain only.
- Regain quadriceps control.
- Achieve safe crutch walking with full understanding of weightbearing requirements.

Protection

- The patient may present to the clinic in a knee immobilizer. This may be utilized as long as the nerve block continues to be effective, as the patient will have very little active leg control.
- As soon as quadriceps control returns (the patient no longer has a quads lag), a hinged brace should be fitted.
- Lock the brace at the angle achieved in rehabilitation and increase range of knee flexion to mirror the patient's gains in passive knee flexion ROM achieved in rehabilitation.
- Weightbearing must be limited. Two crutches (two-point or three-point gait) should be used and the patient is advised to use heel-toe gait on the affected side while only placing 10% to 20% of body weight on the surgical leg. Complete non–weight-bearing has been shown to negatively affect growing articular cartilage. Conversely, the controlled compression and decompression forces created through weight bearing are believed to nourish the growing articular cartilage and to provide the necessary signals to the tissues to allow matrix production that matches environmental need.
- A compression stocking should be utilized for edema control and to prevent blood clots in the first week. This should be followed by use of a lightweight, shorter compression stocking until edema subsides.

Management of Pain and Swelling

- Pain pump for continuous nerve block may be inserted during surgery
- Oral pain medications
- Cryotherapy for pain and inflammation reduction
- Patient education: The patient should NEVER place a pillow under the knee in an effort to find a position of comfort—this will result in difficulty and pain in attempting to regain passive knee extension.
- The patient should sleep in the hinged knee brace.
- A continuous passive motion (CPM) machine can be used up to 4 hours a day (using ROM gained in PT). This can help with pain management and in regaining motion. Emphasis on full passive knee extension while using CPM should be encouraged from Day 1.
- A compression stocking is worn initially. When control is gained over edema, this can be replaced with a shorter, light compression stocking.

Techniques for Progressive Increase in Range of Motion

Manual Therapy Techniques

- Immediate motion from Day 1
- Maximize passive knee extension immediately. Use a patient-controlled passive knee extension device, heel prop, or prone hangs.
- Perform in 20-minute sessions five times per day.
- Grade 2 to 3 anterior-posterior mobilizations (APs) to the tibiofemoral joint can be used to increase this range.
- Passive patella-femoral joint mobilization, both in the medial-lateral and cephalad-caudad directions, will prevent loss of patella-femoral ROM and resulting potential loss of tibiofemoral ROM. Perform three times a day.
- Passive knee flexion is progressed per patient tolerance. There is no limitation to this increase, except for the pain tolerance levels of the athlete. Perform three times a day.

Clinical Pearl

> Passive knee flexion is limited only by patient tolerance. The increase in ROM is expected to be slower in patella-trochlea ACI patients than in femoral condyle ACI patients. It can be particularly beneficial to aim for an increase in ROM, even if it is just a few degrees, at each treatment session. It is discouraging for a patient to tolerate pain and then not make any gains. This range will always be limited by swelling. Make every effort to reduce swelling, including patient education. If you are not successful, always seek the orthopedic surgeon's opinion, in case knee aspiration is necessary.

Soft Tissue Techniques

- Gentle effleurage to decrease edema in the calf area can be beneficial. Avoid the surgical area during this phase.
- Stretching/flexibility techniques for the musculotendinous unit
- Gentle hamstring and calf stretching will help improve patient comfort and prevent future soft tissue restrictions.

Other Therapeutic Exercises

- As soon as the patient is ready for cardiovascular exercise, an upper body ergometer can be used.
- As soon as patient gains sufficient passive knee flexion, the patient should begin stationary cycling for limited periods (10 to 15 minutes).

Activation of Primary Muscles Involved in Injury Area or Surgical Structures

- Immediate ankle pumps are advised to aid in edema control and prevent blood clots.
- Quad sets are taught as soon as the patient regains limb control (i.e., once nerve block wears off). Neuromuscular electrical stimulation should be utilized.

- Active assisted straight leg raise (SLR) is added Day 4. Progress to four-way SLR as the patient's tolerance increases.
- Crutch walking should be reviewed. This is difficult initially because the patient has to be completely non–weight-bearing while the nerve block remains effective. Actual gait training should be repeated when leg control returns—10 to 20 lbs heel-toe weight bearing, two crutches, and lace-up shoes. Teach patient how to ascend and descend stairs.
- Week 2—Introduce terminal knee extensions (Figure 31-30)—patient must use crutches for support. Maximum supervision required.

Phase II (weeks 2 to 6 postoperative)

Goals

- Decrease pain and effusion.
- Maintenance of full passive knee extension
- Continued restoration of passive knee flexion.
- Regain quadriceps control.
- Gradually increase strengthening and cardiovascular demand.
- Encourage correct heel-toe gait with crutches (being mindful of the appropriate weightbearing allowances).

FIGURE 31-30. Terminal knee extension exercise. This exercise helps to target the quadriceps muscle and maximize controlled knee extension.

Protection

- Continued use of hinged knee brace. Increase the range of motion in the brace as the patient gains ROM in rehabilitation.
- ACI-Femoral condyle lesion
  - Continued restriction of weight bearing initially—10% to 20% of body weight continues to be the

TIMELINE 31-3: **Postoperative Rehabilitation After Autologous Chondrocyte Implantation of the Femoral Condyle**

PHASE I (weeks 1 to 2 postop)	PHASE II (weeks 2 to 6 postop)	PHASE III (weeks 6 to 10 postop)

• Hinged knee brace—locked at PROM flexion gains in rehab
• PT modalities
• Immediate motion Day 1
• ROM Passive knee extension—full PROM ASAP. Perform in 20 minute sessions 5 times per day.
• ROM Passive knee flexion—progress as per patient tolerance—3 times a day
• ROM Patella-femoral joint mobilization—3 times a day
• Weightbearing—10–20 lbs, heel-toe gait with 2 crutches
• Ankle pumps, quads sets, SLR with NMES
• Stationary bike when ROM allows
• Hamstring, calf, quadriceps stretching
	• Hinged knee brace
	• PT modalities
	• ROM—no precautions, full extension, increase PROM knee flexion as tolerated, PF mobs
	• PROM knee flexion goals:
	  • ACI-Femoral condyle lesion:
	  • 90° weeks 1–2
	  • 105° by week 3
	  • 15° by week 4
	  • 35° by week 6
	  • These are conservative and can be progressed faster.
	  • ACI—Patella-trochlea lesion
	  • 90° by weeks 2–3,
	  • 105° by weeks 3–4,
	  • 120° by week 7.
	• Weight bearing
	  • ACI-Femoral condyle lesion
	  • Continued restriction of weightbearing initially—10 to 20 lbs only
	  • 50% weightbearing at weeks 4–6
	  • ACI—Patella-trochlea lesion
	  • Weightbearing can be accelerated more quickly.
	  • 25% body weight week 2
	  • 50% weightbearing at week 4
	  • Full weightbearing at week 6
	• Ankle pumps, quads sets, SLR with NMES, short arc quads, TKEs
	• Manual rhythmic stabilization of trunk in sitting, nonsurgical leg single leg balance
	• Stationary bike
	• Hamstring, calf, quad (rectus fem) stretching
	• TBS/TAS/TLS activities as recommended and tolerated
	• Week 4—isometric leg press, aquatic treadmill walking
		• DC Brace at week 6
		• Passive Knee ROM
		  • ACI-Femoral condyle
		  • At least 135° PROM knee flexion
		  • ACI-Patella-trochlea
		  • 120° week 7
		  • 135° weeks 8–9
		• Full PROM knee extension, PF mobs, gentle scar tissue mobilization
		• Weightbearing:
		  • ACI-Femoral condyle lesion:
		  • 50% weightbearing with crutches at weeks 4–6.
		  • 100% weightbearing at 6–8 weeks—earlier with permission from MD.
		  • ACI-Patella-trochlea lesion:
		  • 100% weightbearing weeks 6–8
		• Continue previous stretches, add pretzel, Thomas test stretch
		• Continue stationary bike, aquatic TM (lower water level), treadmill wks 8–9
		• TBS/TAS/TLS activities as recommended an tolerated
		• Week 6—isometric leg press, standing weightshifts, rocker board, physioball bridging and walkouts
		• Week 8—Mat squats, double-leg leg press, cup walking, heel raises (double leg), stationary mini-lunge with cable chops
		• Week 9—front step-ups, single leg rockerboard
		• Week 10—elliptical, lateral step ups

restriction that is sufficient to encourage cartilage growth but light enough to protect the growing tissues.
  - 100% weight bearing at weeks 6 to 8 only
- ACI-Patella-trochlea lesion
  - Weight bearing can be accelerated more quickly
  - 25% body weight at week 2
  - 50% weight bearing at week 4
  - Full weight bearing at week 6

Management of Pain and Swelling

- Oral pain medication may remain necessary, particularly at night and for rehabilitation sessions.
- Continued use of cryotherapy (three times per day), elevation of the limb, ankle pumps.
- Continued use of a compression sleeve (lightweight).
- Continued use of CPM, ROM to mirror gains in rehabilitation.

Techniques for Progressive Increase in Range of Motion

Manual Therapy Techniques

- ROM precautions: None
- PROM: Manual ROM of the patella-femoral joint—medial/lateral and cephalad/caudad.
- PROM: Continue to maintain tibiofemoral extension. Every effort should be made to mirror patients opposite limb extension ROM.
- PROM knee flexion goals
  - ACI-Femoral condyle lesion
    - 105° by week 3
    - 115° by week 4
    - These are conservative and can be progressed faster.
  - ACI-Patella-trochlea lesion
    - 90° by weeks 2 to 3
    - 105° by weeks 3 to 4
    - 120° by week 6
    - ROM progression of passive knee flexion is slower with patella-trochlea than femoral condyle lesions.

Clinical Pearl

At this stage, consider performing passive knee flexion with the hip in extension. This is most easily achieved with the patient in side lying, with the involved leg on the table. This will help to prevent loss of extensibility of the rectus femoris muscle, a two-joint muscle. This position also provides the rehabilitation specialist with excellent leverage (Figure 31-31).

TIMELINE 31-3: Postoperative Rehabilitation After Autologous Chondrocyte Implantation of the Femoral Condyle (Continued)

PHASE IV (weeks 10 to 14 postop)	PHASE V (weeks 14 to 24 postop)	PHASE VI (weeks 24 to 52 postop)

• PROM—maintain full motion, joint mobilizations as needed
• Weightbearing 100%
• Continue lower limb stretches. Add Frog, Pretzel, modified Thomas test stretch
• Stationary bike, treadmill walking, elliptical, StairMaster
• TBS/TAS/TLS activities as recommended an tolerated
• CKC: High step-ups, backward stationary lunges, double leg squats, leg press, heel raises (double and single leg); week 12, single leg leg press
• OKC: speedskaters, open chain knee extension 0°–20°, leg curls
• Single leg balance, walking agility drills
	• PROM—maintain full motion
	• Weightbearing status—aquatic TM run 24 weeks
	• Continue lower limb stretches. Add Frog, Pretzel, modified Thomas test stretch
	• Stationary bike, treadmill/road walking, elliptical, StairMaster
	• PNF lower limb and/or trunk in supine or sitting
	• TBS/TAS/TLS activities as recommended and tolerated
	• CKC: Progress height of high step-up, backward lunge walking, forward lunge walking, single leg squats (vary surface, add perturbations)
	• OKC: speedskaters on proprioceptive equipment, cable kicks in PNF patterns
	• Walking agility—increase complexity
		• Previous levels of functional activities
		• End range sustained stretches
		• Single leg stand/squat on balance device. Increase complexity
		• PNF lower limb patterns in standing and supine
		• PNF upper limb/trunk in tall kneeling, half kneeling, single leg stand on rocker board
		• Physioball ex: bridge back on ball with leg extensions, bridge back on floor, single leg curls
		• CKC: lunges on 2 BOSU, LSU
		• OKC: open chain knee ext 0–20, open chain kicking
		• 6 mo—pool run, 7 mo—treadmill run, increase distance on bike, elliptical, StairMaster
		• Agility drills—fast walk
		• Single leg cone touches, single leg deadlifts
		• 4–7 mo—upper body plyometrics, static stance lower body
		• 7–8 mo—box jump—progress direction, number, single leg
		• 8–9 mo—single leg hop agility drills
		• Sports:
		  • 6 mo—Low impact: golf, swimming, skating, rollerblading, cycling
		  • 7–8 mo—Moderate impact: light running, aerobics
		  • 12 mo—High impact: tennis, volleyball, basketball, football, baseball

FIGURE 31-31. Side-lying knee flexion. Use this position to use to gently gain passive knee flexion range of motion. The rehabilitation specialist is afforded excellent leverage and can maintain the patient in pelvic neutral in this position. Hold-relax can be added.

FIGURE 31-32. Side-lying abduction with the leg maintained in slight hip extension. The patient should keep the abdominal contracted to protect the spine and localize the abduction motion.

Stretching and Flexibility Techniques for the Musculotendinous Unit

- Maintain gastroc/soleus ROM—passive stretching in supine, on table.
- Maintain or improve hamstring ROM; angle of stretch can be varied to include the iliotibial band or adductor group.

Other Therapeutic Exercises

- Upper extremity exercises during this phase may include upper body ergometer (UBE) and general weight equipment (such as latt pulldowns, pec deck, tricep pushdowns, biceps curls, scaption). Perform all exercises in a seated position.
- Core exercises may include single leg planks, superman, single leg pushups and reverse planks. In all these exercises, the surgical leg is non–weight-bearing and held off the ground.

Activation of Primary Muscles Involved in Injury Area or Surgical Structures

- Ankle pumps, ankle alphabet exercises
- Quads sets with NMES or biofeedback
- SLR—4 way with NMES or biofeedback

Clinical Pearl

Side-lying abduction is very important. Limited weight bearing may cause muscular atrophy of the gluteal group. Ensure that the patient is in the correct side-lying position with lower limb slightly extended to ensure maximal gluteus medius recruitment. (Figure 31-32)

Sensorimotor Exercises

- Begin active angular replication exercises for motor control. These can be introduced during the SLR exercises.

Techniques to Increase Muscle Strength, Power, and Endurance

- Upper body strengthening
- UBE
- Stationary bike
- Aquatic treadmill at week 4. Remember that chest-high water level is 25% weight bearing, waist-high water level is 50% weight bearing.

Neuromuscular Dynamic Stability Exercises

- Manual rhythmic stabilization of trunk and core, performed in sitting.
- Nonsurgical leg single leg balance retraining.

Phase III (weeks 6 to 10 postoperative)

Goals

- Achieve full PROM of knee flexion.
- Maintain full PROM knee extension.
- Gradually improve quadriceps strength and endurance. Focus on eccentric quadriceps control.
- Progress functional activities during this period.
- Maintain cardiovascular fitness and upper body strength.

Protection

- Brace is discontinued at week 6. Ensure quad lag is eliminated before discontinuing brace.
- ACI-Femoral condyle lesion:
  - 100% weight bearing at weeks 6 to 8—earlier with permission from MD.
- ACI-Patella-trochlea lesion
  - 100% weight bearing at week 6

Management of Pain and Swelling

- Oral analgesic use is continued as needed.
- Cryotherapy is used post therapy to mitigate postexercise inflammation and soreness.

Techniques for Progressive Increase in Range of Motion

Manual Therapy Techniques

- No knee ROM precautions
- Maximize PROM knee flexion (at least 135°), maintain full PROM of knee extension.
- Continue patella-femoral joint mobilization—cephalad/caudad direction important for assisting in tibiofemoral ROM.
- Maintain hip joint mobility. Consider Hip PAs performed in prone or slight hip extension; add hip ER/IR, being cautious of the possible effects of torque on the knee joint.
- Assess PROM of ankle dorsiflexion. Compare to contralateral limb.

Soft Tissue Techniques

- Gentle scar tissue mobilization can be introduced at this stage.
- Soft tissue techniques may be applied to the quadriceps, hamstrings and calves. Avoid the knee joint.

Stretching and Flexibility Techniques for the Musculotendinous Unit

- Continue to focus on gastrocnemius/soleus (now performed in standing), hamstrings, and quadriceps stretches.
- Add Pretzel (piriformis/glutes) stretch, if the knee can tolerate it (see Figure 31-38).
- Thomas test stretch with added PROM knee flexion to improve flexibility of the rectus femoris muscle (Figure 31-33)

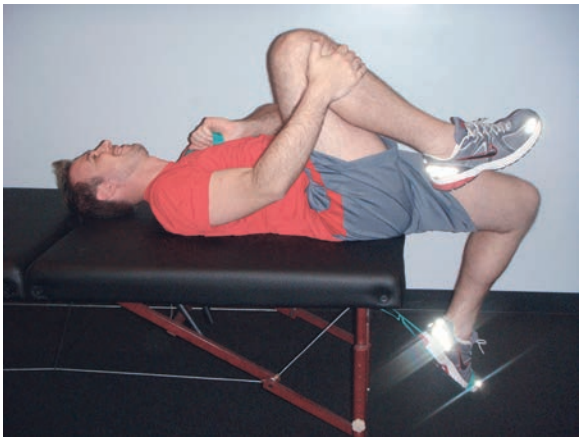

FIGURE 31-33. Thomas test stretch with additional passive knee flexion provided by the stretch band. This allows for simultaneous hip extension and knee flexion, thus targeting the rectus femoris muscle.

Other Therapeutic Exercises

- Cardiovascular—UBE, stationary biking.
- Week 8—Introduce elliptical training and Stairmaster. Gradually build up tolerance.
- Aquatic treadmill walking—Gradually lower water level to tolerance and with respect to the appropriate weight-bearing requirements.
- Week 9 to 10—treadmill walking
- Upper body strengthening can be progressed to preoperative levels.
- Consider combination exercises involving the core and upper body at this stage (e.g., physioball walkouts—roll prone on ball, walk on hands), and consider adding pushups or serratus hunches.

Activation of Primary Muscles Involved in Injury Area or Surgical Structures

- Basic surgical limb strengthening includes four-way straight leg raises with increased resistance. Quad lags should be completely eliminated at this stage. Discontinue use of NMES when quads lag is eliminated.
- Terminal knee extensions in standing—increase resistance
- Week 6—isometric leg press
- Week 8—stationary minilunge with cable chop. The cable chop involves holding a theraband, or attachment to a cable machine and performing a D1 or D2 proprioceptive neuromuscular facilitation (PNF) pattern. All effort is made to maintain core stability.
- Week 8—minisquats 0° to 45° using correct biomechanics. Avoid genu valgum and prevent knee over toes.
- Week 8—Begin double leg leg press through as much ROM as machine will allow.
- Week 8—double leg heel raises
- Week 9—front step-ups.
- Week 10—lateral step-ups. Target eccentric quadriceps and hip abductor control.

Clinical Pearl

The weight shift exercise in standing encourages the patient to weight bear in an equal distribution over the bilateral limbs. It targets hip, knee, and ankle proprioception, which encourages improved joint position awareness, increased joint stability, and decreased patient apprehension.

Begin training with the patient shifting laterally, feet hip distance apart. The patient should avoid side flexion of the trunk and a Trendelenburg at the hip. The patient should shift 90% of weight onto the right leg and then shift 90% of weight onto the left leg (Figure 31-34).

When the patient can achieve this rhythmically and comfortably, progress to stride standing, shifting weight forward onto the front leg (90% weight bearing) and backward onto the back foot (90%

FIGURE 31-34. Lateral weight-shift exercise, performed in standing. Note the maintenance of the vertical trunk while shifting 90% of weight onto the stance leg.

FIGURE 31-35. Anterior-posterior weight shift. Legs are hip distance apart; weight is shifted forward and backward to replicate the weight shifting required form in a nonantalgic gait pattern.

weight bearing) rhythmically (Figure 31-35). Scales can be utilized in order to perform this accurately. In the clinical setting, the rehabilitation specialist can instruct the patient to shift 90% of her/his weight onto the one leg, while keeping the toes of the opposite leg on the floor. This ensures safety when this exercise is first introduced. As weight-bearing tolerance is allowed to progress, this exercise can be further modified in order to allow full single leg weight bearing. It is therefore an excellent tool to use in the clinic.

Again, as patient tolerance allows progress to step-overs—the surgical leg stays fixed on the floor and the patient steps forward and backward with the nonsurgical leg, replicating the stance phase of the gait pattern.

These can be initiated at week 8, and progressed according to weight-bearing tolerance.

Sensorimotor Exercises

- Weightshift exercise in standing
- Rocker board balance retraining. Begin double leg AP direction, progress to lateral. Progress to single leg AP at week 8 to 9.
- Progress to wobble board—circles, right-left, front-back, balance on double leg. Progress to single leg at week 8 to 9.
- Active joint positioning of knee and hip
- Balance equipment (such as the BOSU, Dynadisc) can be incorporated at this stage. Progress patient as appropriate, keeping the exercises challenging.
- Use of physioball—bridging with back on floor, single leg and double leg; bridging with back on ball, add leg extensions and physioball walkouts with single leg extension.

Open and Closed Kinetic Chain Exercises

- Closed chain proprioception activities: rocker board, wobble board, BOSU, etc. utilizing double leg and single leg stance
- Closed chain strengthening exercises: At week 8 introduce leg press, mat squats (double leg), forward step-ups, lateral step-ups—progress resistance.
- Open chain strengthening exercises: short arc quads, VMO holds

Techniques to Increase Muscle Strength, Power, and Endurance

- Progress bike endurance.
- Introduce elliptical training at weeks 7 to 8.
- Aquatic treadmill—Continue walking program.

Neuromuscular Dynamic Stability Exercises

- It is safe, and indeed advisable, to progress proprioceptive challenge on balance equipment as cartilage healing progresses. Consider adding complexity challenges to the exercises (e.g., add perturbations, utilize multijoint exercises such as scaption progressive resistive exercises while balancing single leg on the rocker board).

Plyometrics

- Lower limb plyometrics should be avoided at this stage of critical cartilage repair.

Functional Exercises

- Gait correction is vital at this stage. Consider cup walking (Figure 31-36) at weeks 7 to 8. Cup walking was originally utilized in prosthetic gait training. It encourages a reciprocal gait pattern, full weight bearing

FIGURE 31-36. Cup walking. Cups are laid out and the patient has to step over each cup in a reciprocal pattern. This teaches the patient lower limb dissociation and equal distribution of weightbearing forces. This helps to correct an antalgic gait pattern.

over the surgical side, and forces the patient to pull the foot and knee up in order to clear the cups. Even gait cadence should be emphasized
- Ensure that the patient is walking up stairs reciprocally by weeks 8 to 9. Descending stairs reciprocally will lag behind ascending because of the slower recovery of eccentric quadriceps control.
- Ensure that patient weight bears equally through both lower limbs when transitioning from sit to stand. This can be measured by using scales or by closely observing the lower limb kinetic chain and ensuring that each hip lines up with the respective knee and ankle. Additionally, ensure that the feet are placed in a straight line in the frontal plane, otherwise the foot that is placed further back will be the one bearing most of the weight.
- Throwing athletes may incorporate the Throwers 10 program for the upper limbs.

Sport-Specific Exercises

- This is only appropriate for upper body training during this time period.

Phase IV (weeks 10 to 14 postoperative)

Goals

- Improve muscle strength and endurance.
- Progress functional activities.
- Encourage continued compliance. The patient must respect that overuse of the limb will have a detrimental effect on short-term healing and long-term cartilage integrity.

Techniques for Progressive Increase in Range of Motion

Manual Therapy Techniques

- Maintain full PROM of both the tibiofemoral and patella-femoral joints.
- Hip mobilizations—Maintain or regain full ROM.
- Maintain full ankle dorsiflexion ROM.

Soft Tissue Techniques

- Soft tissue release of the quadriceps, hamstrings, gastroc/soleus complex, and glutes. This is not always necessary. However, occasionally a patient may be aware of significant muscle pain, usually in the quadriceps muscle. The possibility of a deep vein thrombosis (DVT) should always be ruled out. Please consult with the referring physician immediately, if you have any concerns. Effleurage-type massage may be effective in decreasing edema and improving patient comfort.
- Continue gentle scar tissue mobilization.

Stretching/Flexibility Techniques for the Musculotendinous Unit

- Maintain/achieve sufficient flexibility of the lower limb muscles.
- Progress to targeting hip ER and IR ROM—frog stretch (Figure 31-37) and pretzel stretch (Figure 31-38)
- Continue to focus on iliopsoas and rectus femoris length by performing the modified Thomas test stretch.

Other Therapeutic Exercises

- Progress upper body strengthening exercises.
- Progress core recruitment exercises.
- TM walking, elliptical, StairMaster, stationary bike

Activation of Primary Muscles Involved in Injury Area or Surgical Structures

- As before with progressive resistance
- Increase leg press through full range; add resistance; aim for equal weight distribution when using both legs.

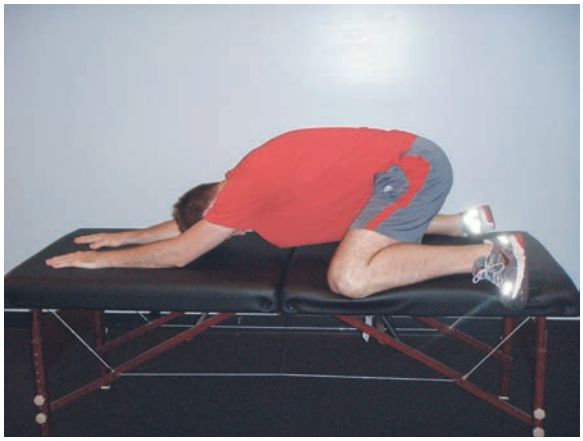

FIGURE 31-37. The frog stretch. The patient must turn out the feet and can vary the position of the pelvis to obtain maximal stretch.

FIGURE 31-38. The pretzel stretch. A low-load, long-duration stretch which aims to restore external rotation of the hip.

Sophisticated digitized leg press machines are able to calculate weight distribution. In the absence of such machines, carefully observe the patient and encourage the patient to avoiding protecting the surgical leg. Ensuring alignment of the feet, ankles, and knees can aid in this goal. As the patient gains strength and confidence, and as pain decreases, he/she should be encouraged to gradually progress to equal weight distribution between both legs.

- Progress to single leg at week 12.
- Add leg curls
  - Single leg heel raises—extended (gastrocnemius) and flexed (soleus) knee

Open and Closed Kinetic Chain Exercises

- CKC
  - High step-ups—Progress to waist height.
  - Backward stationary lunges
  - Double leg squats
  - Athletes are encouraged to avoid locking out the tibiofemoral joint. Stance used should be hip width apart with careful focus on maintaining correct joint mechanics.
- OKC
  - Speedskaters (Figure 31-39)
  - Open chain knee extension 0° to 20°

Techniques to Increase Muscle Strength, Power, and Endurance

- Advance endurance sets to strength exercises (shorter repetitions: 6 to 8)

Neuromuscular Dynamic Stability Exercises

- Progress use of balance equipment. Focus predominantly on single leg exercises and compare sides to judge progress. Time how long patient can stand on a single leg without support on various pieces of balance equipment, such as the rocker board, wobble board, and BOSU. Aim to get the surgical leg to balance for as long as the nonsurgical side. Observe that the patient does not use incorrect hip, knee, or ankle strategies, such as foot pronation or knee genu valgum.

FIGURE 31-39. Speedskaters. The patient must maintain balance over the stance leg, with the weightbearing knee in neutral (avoid genu valgum) and core control. Emphasize the eccentric motion of the nonstance leg.

Functional Exercises

- Lower limb agility drills can be performed utilizing fast walking without sudden changes in direction or pivoting.

Sport-Specific Exercises

- The running athlete must still avoid any lower body impact exercises at this stage.

Milestones for Progression to the Next Phase

- Full range of motion.
- Acceptable strength level
  - Hamstrings within 10% of contralateral leg—isokinetic testing
  - Quadriceps within 10% to 20% of contralateral leg—isokinetic testing
- Balance testing within 30% of contralateral leg. Again, sophisticated balance testing machines are available. However, in the absence of such equipment, measure single leg balance time on the wobble board without allowing the edge of the board to make contact with the ground. Compare sides.
- Able to walk 2 miles or bike for 20 minutes
- 50 lateral step-ups (8-inch height). This is an easily measurable activity, which ensures that sufficient eccentric quad control has been achieved in order to progress to Phase V.

Phase V (weeks 14 to 24 postoperative)

Goals

- Improve muscle strength and endurance.
- Progress functional activities.
- Encourage continued compliance. The patient must respect that overuse of the limb will have a detrimental effect on short-term healing and long-term cartilage integrity.
- Hamstrings and quadriceps strength within 10% of contralateral leg
- Balance testing within 10% of contralateral leg

Techniques for Progressive Increase in Range of Motion

Manual Therapy Techniques

- Maintain full PROM of both the tibiofemoral and patella-femoral joints.
- Continue hip and ankle mobilizations if necessary

Soft Tissue Techniques

- Assess the need for soft tissue release of the quadriceps, hamstrings, gastroc/soleus complex, and glutes. This is only necessary if the patient continues to complain of specific muscle pain. Trigger points can be assessed and treated. Any edema can be addressed with effleurage massage. Again, always rule out the possibility of DVTs.
- Continue gentle scar tissue mobilization.

Stretching/Flexibility Techniques for the Musculotendinous Unit

- Maintain/achieve sufficient flexibility of the lower limb muscles.
- Continue to focus on iliopsoas and rectus femoris length by performing the modified Thomas test stretch.

Other Therapeutic Exercises

- Progress upper body strengthening exercises.
- Progress core recruitment exercises.

Activation of Primary Muscles Involved in Injury Area or Surgical Structures

- As before with progressive resistance
- Progress to single leg leg curls and leg extensions at week 14; increase resistance.
- Be cautious with full ROM open chain knee extensions with the patella-trochlea patients. Avoid them completely if they create pain.

Sensorimotor Exercises

- PNF lower limb patterns performed in supine. Be sure to add knee flexion and extension into the patterns to recruit the primary operative muscles. PNF upper limb and trunk patterns in half kneeling and static lunge position.

Open and Closed Kinetic Chain Exercises

- CKC
  - High step-ups—Progress to waist height.
  - Backward lunges—Progress to backward lunge walking; progress to forward lunge walking.
  - Double leg squats—Progress to single leg squats. Vary surface, add perturbations, add upper body/trunk motion.
  - Athletes are encouraged to avoid locking out the tibiofemoral joint. Stance used should be hip width apart, with careful focus on maintaining correct joint mechanics.
- OKC
  - Speedskaters—Increase resistance; the patient can stand on a BOSU or rocker board.
  - Cable kicks in PNF patterns

Techniques to Increase Muscle Strength, Power, and Endurance

- Advance endurance sets to strength exercises (lower repetitions: 6 to 8)
- Alternately focus on endurance (16 to 20) sets and hypertrophy (6 to 8) resistance training

Neuromuscular Dynamic Stability Exercises

- Progress use of balance equipment. Focus predominantly on single leg exercises and compare sides to judge progress. Here again, single leg balance on the wobble board, whereby the edge of the board is not allowed to make contact with the floor, is an effective comparison tool. This same principle can be applied to other balance equipment.
- Add sport-specific drills (e.g., a baseball pitcher can perform trampoline pitching while balancing single leg on a BOSU; a soccer player can replicate kicking with band resistance balancing on a balance board).

Plyometrics

- Plyometrics are still not introduced at this stage, in order to protect the cartilage repair.

Functional Exercises

- Lower limb agility drills can be performed utilizing fast walking. Increase unpredictability of training, by throwing balls and calling direction changes.
- Increase walking distance, speed and inclines as time progresses.

Sport-Specific Exercises

- Gradual reintroduction of impact exercises toward the end of this stage

Phase VI (weeks 24 to 52 postoperative)

Goals

- Prepare patient for return to sport.

Management of Pain and Swelling

- Cryotherapy application post exercise

Techniques for Progressive Increase in Range of Motion

- Full AROM and PROM must be achieved by 4 months.
- Ensure maintenance of patella-femoral ROM.

Soft Tissue Techniques

- Seldom necessary at this stage

Stretching and Flexibility Techniques for the Musculotendinous Unit

- Full, passive knee extension ROM remains critical. Most patients will be easily able to maintain this, especially if their gait pattern is optimal and, as a result, they use knee extension with every step that they take. The occasional patient may continue to struggle. Regular hamstring and gastrocnemius stretching remains useful in these cases. Use of low-load, long-duration passive knee extension may still be required on a daily basis.

Other Therapeutic Exercises

- Continue and progress multijoint exercises.

Activation of Primary Muscles Involved in Injury Area or Surgical Structures

- Aim to return to preinjury levels of function toward the end of this phase.

Sensorimotor Exercises

- Single leg standing on wobble board (or similar device). Increase complexity by adding ball toss, close eyes, add perturbation of board or trunk, and initiate single leg squats.
- PNF lower limb patterns performed in supine and standing. Be sure to add knee flexion and extension into the patterns to recruit the primary operative muscles. PNF upper limb and trunk patterns in half kneeling and static lunge position
- Continued use of physioball—Continue increasing challenge and complexity of exercises (e.g., sitting on physioball with single leg support), perform cable PNF with upper limbs and maintain balance. Perform with eyes closed.

Open and Closed Kinetic Chain Exercises

- Advance the previous exercises in accordance with sport-specific demands.
- CKC progression includes:
  - Single leg squats standing on a wobble board
  - Lunges on two BOSU surfaces, increasing resistance and decreasing support
  - Lateral step-ups with trunk perturbations
- OKC
  - Restrict open chain knee extensions to 0° to 20°.
  - If patient participates in a kicking sport, open chain kicking agility exercises can be incorporated.

Techniques to Increase Muscle Strength, Power, and Endurance

- Pool running can be introduced at the 6-month mark.
- Treadmill running can be introduced at the 7-month mark.
  - Carefully observe the patient's running pattern. Ensure an even rhythm, light grading, equal weight bearing, correct use of upper limbs, and core recruitment.
- Increase endurance on the elliptical, bike and StairMaster. It is usually preferable to increase distance before speed/intensity but individual preference must be respected.

Clinical Pearl

> Use pain and/or swelling to monitor whether you are progressing too quickly. It is an accurate sign of overuse and should be respected accordingly.

Neuromuscular Dynamic Stability Exercises

- Agility drills—cariocas and cone drills can only be performed at a fast walking pace until the 7-month mark, when light running can be added. Speed and complexity can be progressed at that stage.
- Cone touches—Place two cones slightly more than hip distance apart. Stand on one leg in between them. Reach left hand to right cone and reverse, repeat for 20 reps (Figure 31-40).
- Single leg deadlifts (patient holds PVC pipe vertically behind back. Patient performs a single leg deadlift maintaining contact of the PVC pipe against the occiput and tailbone throughout the motion.)
- Deep knee bends (full range, good mechanics) can be introduced to teach efficient eccentric quadriceps release.
- Always challenge the patient.

Plyometrics

- Month 4 to 7—Consider upper body plyometrics while utilizing static stance for lower body (e.g., hold static squat position while throwing ball against wall, physioball bridge with back on ball while performing overhead ball toss and crunches).

FIGURE 31-40. Cone touch exercise. The patient must maintain a neutral knee position on the stance leg. Maintenance of core control is essential.

- Months 7 to 8—Teach box jumping. Monitor patient's level of discomfort during and after the exercise. Ensure patient learns to land with light grading ("light, like a panther") and maintains correct joint positioning (do not allow the knees to go forward over the toes, keep the knees apart and avoid genu valgum) throughout the movement. As time progresses, advance from double leg jumps forward to double leg jumps sideways to double leg jumps over the box. Continue the progression to single leg jumps forward to single leg jumps sideways. For safety, do not allow the patient to become overly fatigued. The patient should be allowed to rest often. The exercises should be discontinued immediately as soon as the patient is no longer able to maintain correct form.
- Month 8 to 9—Progress to single leg hopping agility drills.

Sport-Specific Exercises

- Low-impact sports such as golf, swimming; skating, rollerblading, and cycling are permitted at 6 months.
- Moderate impact sports such as running and aerobics may be performed at 7 to 8 months.
- High-impact sports such as tennis, volleyball, basketball, football, and baseball are allowed at 12 months.

Milestones for Progression to the Next Phase

- Less than 10% side-to-side deficit on isokinetic testing
- Less than 15% side-to-side deficit on hop test
- Patient-reported outcome studies at 52 weeks should be greater than 90% compared with preoperative scores.

Outcome Measures

Patient reported outcome scales should be implemented at the 12-month follow-up appointment. Scales that have been utilized in the literature for cartilage restoration procedures include:

- IKDC—International Knee Documentation Committee Subjective Knee Form
- SF12—Quality of life instrument
- KOOS—Knee injury and Osteoarthritis Outcome Score

Criteria for Return to Sport

General

- Full AROM in tibiofemoral and patella-femoral joint, no apprehension
- Minimum of 80% to 90% side-to-side symmetry on isokinetic testing
- Minimum of 15% side-to-side symmetry on hop test
- Quadriceps-hamstrings ratio that matches nonsurgical limb—isokinetic testing
- Correct hip and knee alignment during jump test and hop test, particularly when fatigued.

Sport-Specific

- Specific sports require specific functional demands of the athlete. The rehabilitation specialist needs to be familiar with sport-specific demands.
- A particular focus should be on working the patient to fatigue, because injury rates have been shown to increase when a patient is fatigued.

After Return to Sport

Continuing Fitness or Rehabilitation Exercises

- Total body fitness regime

Exercises and Other Techniques for Prevention of Recurrent Injury

- Ensure maintenance of lower limb strength, maintain surgical limb at 85% or better when compared to nonsurgical limb. The patient may be encouraged to consult with the rehabilitation specialist every 3 to 6 months in order to undergo repeat isokinetic testing and functional testing, such as the hop test.
- Continue neuromuscular control exercises to maximize core, hip, knee, and ankle stability and proprioception.
- Maintain cardiovascular endurance, balance, and proprioception, flexibility, strength, and endurance. Neglect of any of these areas may place the athlete at risk for reinjury.
- Consider limiting impact and joint loading except when it is necessary for sport-specific demands.

Modifications for Concomitant Surgeries

ACL-Patellar tendon or Hamstring Graft Reconstruction

- Weightbearing progression—Follow ACI protocol.
- Passive ROM follows ACI-patellofemoral guidelines

Meniscus Allograft

- Weight-bearing progression—Follow ACI protocol.
- Passive ROM
  - Week 1: 60 degrees
  - Week 2: 90 degrees
  - Week 5: 100 degrees
  - Week 8: 125 degrees
- No active flexion for 6 weeks (owing to hamstring attachment to the meniscus)
- Resisted hamstring strengthening, week 12

Tibial Tubercle Realignment (Fulkerson)

- Weightbearing progression—Follow ACI protocol.
- Passive ROM
  - Week 1: 60°
  - Week 3: 90°
  - Week 5: full 125°
- No short arc quads until week 8

High Tibial Osteotomy

- Weight-bearing progression—Follow ACI protocol.
- Passive ROM (limited by pain tolerance only)
  - Week 1: 90°
  - Week 3: 115°
  - Week 6: greater than 125°
- Discontinue brace at week 6 to 8 only

Distal Femoral Osteotomy

- Similar to high tibial osteotomy but important to emphasize passive knee flexion early because it can be harder to regain.
- Weightbearing progression—Follow ACI protocol.
- Passive ROM (limited by pain tolerance only)
  - Week 1: 90°
  - Week 3: 115°
  - Week 6: greater than 125°
- Discontinue brace at week 6 to 8 only

Multiple-Lesion ACI

- Slower progression in both weightbearing and ROM than standard ACI protocol

Clinical Pearl

Although protocols are excellent for providing basic timelines, individual patients will differ in their progression. Age, size of lesion, tissue quality, motivational level, and fear avoidance are some examples of factors that will alter the patient's progress. Base the patient's progression in rehabilitation on research findings of articular cartilage healing rates and the patient's ability to fulfill specific criteria before progressing to the next phase.

Evidence

Gillogly S, Myers T, Reinhold M: Treatment of full-thickness chondral defects in the knee with autologous chondrocyte implantation. *J Orthop Sports Phys Ther* 36(10):751–764, 2006.

This article discusses patients' selection for ACI, reviews ACI surgical options and techniques, details postoperative protocols, and summarizes clinical outcomes. (Level 4 evidence)

Kon E, Filardo G, Berruto M, et al: Articular cartilage treatment in high level male soccer players: A prospective comparative study of arthroscopic second-generation autologous chondrocyte implantation versus microfracture. *Am J Sports Med* 39(12):2549–2557, 2011.

This cohort study evaluated prospectively 41 male soccer players at 2 and 7.5 year mean follow-up. Twenty-one patients were treated with ACI, 20 with microfracture. Return to sport was 80% in microfracture, 86% in ACI. Return to playing a soccer game took 8 months (median) for the microfracture group and 12.5 months (median) for ACI. IKDC scores at 2 years were similar, but significantly better at final evaluation for ACI. In fact, microfracture results deteriorated over the long term. The study concluded that ACI patients will take longer to return to competition but ACI offers more durable clinical results. (Level 2 evidence)

Logerstetdt D, Snyder-Mackler L, Ritter R, et al: Knee pain and mobility impairments: Meniscal and articular cartilage lesions. *J Orthop Sports Phys Ther* 40(6):A1–A35, 2010.

Clinical practice guidelines detailing evidence-based recommendations for examination and diagnosis, rehabilitation interventions, and assessment of outcome. (Level of evidence not known)

Mithoefer K, Hambly K, Della Villa S, et al: Return to sports participation after articular cartilage repair in the knee: Scientific evidence. *Am J Sports Med* 37(Suppl 1):167S–176S, 2009.

A systematic review of 20 studies (1363 patients), with average follow up of 42 months. 73% return to sports, with highest rates after OATS. Time to return to sports varied from 7 to 18 months. Initial return to sports at the preinjury level was possible in 68% without significant differences between surgical techniques. Continued sports participation at the preinjury level was possible in 65%; ACI showed best durability. Factors that affected the ability to return to sport included: athlete's age, preoperative duration of symptoms, level of play, lesion size, and repair tissue morphology. (Level 3 evidence)

Peterson L, Vasiliadis HS, Brittberg M, et al: Autologous chondrocyte implantation: A long-term follow-up. *AM J Sports Med* 38(6):1117–1124, 2010.

Twenty years after the implantation (mean, 12.8 years), 74% of the patients reported their status as better or the same as the previous years. There were 92% who were satisfied and would have the ACI again. The average Lysholm score improved from 60.3 preoperatively to 69.5 postoperatively, the Tegner from 7.2 to 8.2, and the Brittberg-Peterson from 59.4 to 40.9. The KOOS score was on average 74.8 for pain, 63 for symptoms, 81 for activities of daily living, 41.5 for sports, and 49.3 for quality of life. The average Noyes score was 5.4. Patients with bipolar lesions had a worse final outcome than patients with multiple unipolar lesions. The presence of meniscal injuries before ACI or history of bone marrow procedures before the implantation did not appear to affect the final outcomes. The age at the time of the operation or the size of lesion did not seem to correlate with the final outcome. (Level IV case series.)

This paper provides an introduction to ACI surgery. (Level 4 evidence)

Multiple-Choice Questions

QUESTION 1. When should full PROM of tibiofemoral knee extension be established?

A. 0 to 2 weeks
B. 2 to 4 weeks
C. 4 to 6 weeks
D. Never

QUESTION 2. How many months does research indicate, for the surgical cartilage begin to become as durable as the surrounding healthy cartilage?

A. 3 months
B. 6 months
C. 9 months
D. 15 months

QUESTION 3. True/False

An ACI-Femoral condyle lesion will require a slower progression into weightbearing that an ACI-Patella-femoral lesion.

QUESTION 4. When can High impact sports be resumed following an ACI-femoral condyle procedure?

A. 3 months
B. 6 months
C. 9 months
D. 12 months

QUESTION 5. Which surgery allows the fastest return to sports?

A. Allograft OATS
B. Autograft OATS
C. ACI-femoral condyle
D. ACI-patella-trochlea

Answer Key

QUESTION 1. Correct answer: **A** (see Phase I)

QUESTION 2. Correct answer: **C** (see Healing Timeframes section)

QUESTION 3. Correct answer: **True** (see Table 31-3)

QUESTION 4. Correct answer **D** (see Return to sport section)

QUESTION 5. Correct answer **B** (see Table 31-3)

POSTOPERATIVE REHABILITATION AFTER OSTEOCHONDRAL ALLOGRAFT/AUTOGRAFT TRANSFER FOR CARTILAGE RESTORATION

Scott D. Gillogly, MD, FACS, and Kate McDonald, BSc PT, OCS, COMT

Indications for Surgical Treatment

Osteochondral Allograft Transfer

- Symptomatic full-thickness chondral defects (grade III to grade IV lesions) and osteochondritis dissecans (OCD) lesions of the femoral condyle
- Any osteochondral defect or OCD where native subchondral bone loss has occurred, especially bone loss greater than 7 to 8 mm in depth
- Medium to large focal chondral lesions typically larger than 20 mm in diameter and up to the width of the damaged femoral condyle

Osteochondral Autograft Transfer

- Limitations of this technique are related to the amount of tissue that can be safely or easily harvested from the patient's involved knee.
- Typically up to two 10-mm diameter plugs or three 6- to 8-mm diameter plugs can be harvested from the patient's knee.
- Therefore the indications are for smaller lesions that can be filled by this amount of autograft osteochondral tissue. Generally a lesion no bigger than 20 × 10 mm in size.

Brief Summary of Surgical Treatment

Osteochondral Allograft Transfer

- No biopsy is required, although sizing radiographs are obtained to allow size matching of the patients affected defect location with the allograft (cadaver) osteochondral tissue
- Osteochondral allograft transfer (Figure 31-41) is an open procedure requiring adequate exposure.

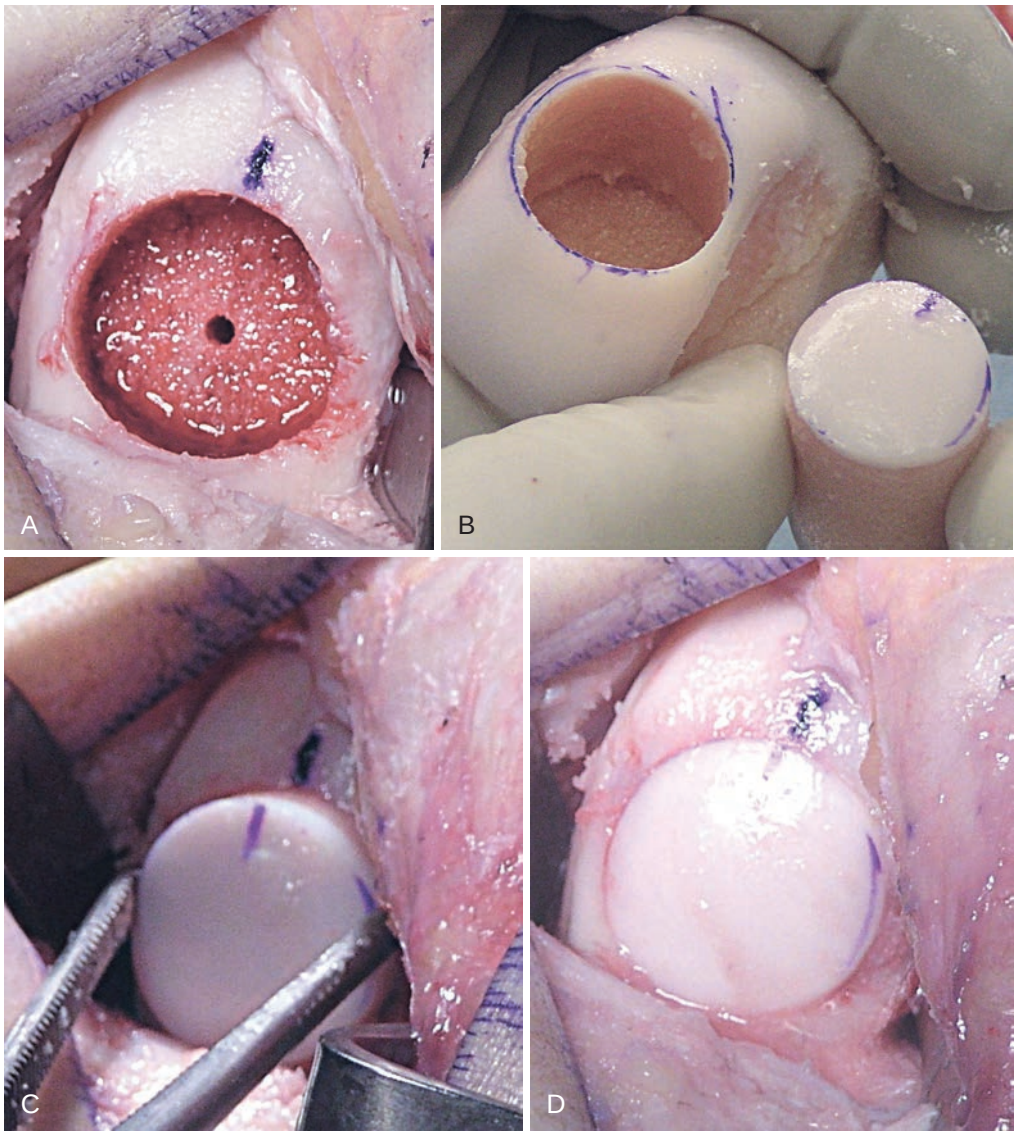

FIGURE 31-41. Osteochondral Allograft Transfer. **A,** The patient's defect has been reamed to remove all damaged cartilage and bone and create a socket for the transfer. **B,** Cylinder osteochondral plug is obtained from a corresponding anatomic site on the allograft condyle. **C,** After shortening the bony portion of the plug to match the depth of the patient socket, the transfer is oriented and inserted by "press fit." **D,** The surface of the transfer is congruous with the patient's surrounding articular cartilage.

- The chondral defect is sized with templates of various size circles, finding the size that will fully cover the defect.
- The defect is then reamed to create a socket for the osteochondral allograft transfer.
- Using the same sized template, the location of the patient defect is matched on the cadaveric donor.
- Using a circular cutting saw of the identical diameter, a cylinder of osteochondral allograft is obtained.
- The depth of the patients defect after preparation is then transferred to the osteochondral allograft, shortening the bony portion to just match the depth of the patient defect.
- The osteochondral cylinder plug is then "press fit" into the patients defect, leaving a surface of donor articular cartilage congruous with the patient's healthy remaining articular cartilage.
- Any concomitant procedures such as anterior cruciate ligament reconstruction, osteotomy, patellofemoral realignment, or meniscal transplantation are done prior to completing the osteochondral allograft transfer, which should be the last portion of the procedure
- The stability of the press fit insertion of the allograft allows for immediate range of motion during the rehabilitation process.

Osteochondral Autograft Transfer

- The procedure at times is performed arthroscopically, although the trend has been to do a mini open technique to insure that the plugs are placed perpendicular to the articular surface.

Table 31-4 Comparison of Osteochondral Allograft and Autograft Transfer Surgery

	Weightbearing	PROM Knee Flexion Goals	Return to Sport
Osteochondral Autograft Transfer	Less protection required for patient's own tissue 25% weight bearing Week1 50% weightbearing Week 2 100% weight bearing Weeks 3–4	Full PROM restored in first 3–6 weeks, restricted by pain only	4 months Low impact 6 months Moderate impact 7–8 months High impact
Osteochondral Allograft Transfer	50% weight bearing Week 2 75% weightbearing Weeks 3–4 100% weightbearing Weeks 6–8	PROM is restricted only by pain; the following are conservative numbers and can be progressed faster. 90° by Weeks 1–2 105° by Week 3 115° by Week 4 135° by Week 6	6 months Low impact 7–8 months Moderate impact 12 months High impact

- The most common harvest site is the superolateral femoral condyle, the non–weight-bearing, and nonarticulating area.
- The recipient site (patient's defect) is prepared for the one to two plugs and the transferred autograft plugs are put in place in a press-fit fashion. The stability of the press-fit insertion of the autograft tissue allows for immediate range of motion during the rehabilitation process.

Before Surgery: Overview of Goals, Milestones, and Guidelines[3]

- Prehabilitation is very important prior to cartilage restoration procedures. Postsurgical pain and immobility may be significant and result in fairly significant muscular atrophy. Obviously, the stronger the patient is prior to surgery, the easier it will be to maintain and regain muscle.
- One or two prehabilitation sessions of physical therapy should be sufficient to instruct the patient. Focus on the following specific areas:
  - Weight loss
  - Core strengthening (e.g., planks, side planks, abdominal roller, physioball exercises)
  - Hip abductor strengthening (side-lying abduction, single leg balance on wobble board, speedskaters [see Figure 31-39])
  - Quadriceps strengthening vastus medialis oblique holds (sit, maintaining good posture on a level surface, with both feet on the ground. Hold the surgical knee in static, active knee extension for five minutes. Once finished, slide back onto the bed so that it is not necessary to do open chain knee flexion). Sit-to-stands (similar to squats but patient sits on the low mat table and then stands again, without using arm support), leg presses.
  - General cardiovascular fitness
- In addition, it may be advisable to teach the patient the initial postoperative regime including crutch walking, heel prop, quad sets, ankle pumps, and hamstring and calf stretches during the prehabilitation sessions (refer to Phase I). This is necessary because the patient is often in significant pain and/or on strong analgesia at the initial postsurgery visit.

[3]*Prehabilitation, if appropriate, is described in the Nonoperative Rehabilitation section of this chapter.*

GUIDING PRINCIPLES OF POSTOPERATIVE REHABILITATION

- Appreciate the anatomic structures involved and their individual rates of healing.
- Appreciate stresses applied in different ranges of motions, with different activities.
- Determine location, size, depth, and number of lesions.
- Determine whether concomitant procedures have been performed. Follow the more conservative protocol.
- Respect ROM requirements and weight-bearing progressions. These will differ for the different surgical techniques and different locations (Table 31-4).
- The osteochondral autograft protocol is considerably less conservative than the osteochondral allograft protocol, due to the fact that a patient's own tissue requires a shorter integration period. The first 14 days of rehabilitation are identical for both procedures, after which the rehabilitation specialist can progress the osteochondral autograft more rapidly.

Phase I (days 0–14): Immediate Postoperative Period

Clinical Pearl

It is imperative to retain full passive knee extension immediately postoperative (e.g., by performing prone hangs or heel props [see Figures. 31-28 and 31-29] or using a passive extension device). The patient should additionally be educated against resting with a pillow under the knee. Educating the patient on the importance of this step is invaluable in gaining full compliance.

Goals

- Decrease pain and effusion.
- Protection from load and shear forces

- Immediate restoration of full passive knee extension
- Gradually increase passive knee flexion, limited by patient's pain only.
- Regain quadriceps control.
- Achieve safe crutch walking with full understanding of weight-bearing requirements.

Protection

- The patient may present to the clinic in a knee immobilizer. This may be utilized as long as the nerve block continues to be effective, because the patient will have very little active leg control.
- As soon as quadriceps control returns (the patient no longer has a quads lag), a hinged brace should be fitted.
- Lock the brace at the angle achieved in rehabilitation and increase range of knee flexion to mirror the patient's gains in passive knee flexion ROM achieved in rehabilitation.
- Weight bearing must be limited. Two crutches (two-point or three-point gait) should be used, and the patient is advised to use heel-toe gait on the affected side while only placing 10% to 20% of body weight on the surgical leg. Complete non–weight-bearing has been shown to negatively affect growing articular cartilage. Conversely, the controlled compression and decompression forces created through weight bearing are believed to nourish the growing articular cartilage and to provide the necessary signals to the tissues to allow matrix production that matches environmental need.
- A compression stocking should be utilized for edema control and to prevent blood clots in the first week. This should be followed by use of a lightweight, shorter compression stocking until edema subsides.

Management of Pain and Swelling

- A pain pump for continuous nerve block may be inserted during surgery.
- Oral pain medications
- Cryotherapy for pain and inflammation reduction
- Patient education: The patient should NEVER place a pillow under the knee in an effort to find a position of comfort—this will result in difficulty and pain in attempting to regain passive knee extension.
- The patient should sleep in the hinged knee brace.

TIMELINE 31-4: **Postoperative Rehabilitation After Osteochondral Autograft/Allograft Transfer**

PHASE I (weeks 1 to 2 postop)	PHASE II (weeks 2 to 6 postop)	PHASE III (weeks 6 to 10 postop)

• Hinged knee brace—locked at PROM flexion gains in rehab
• PT modalities
• Immediate motion Day 1
• ROM Passive knee extension—full PROM ASAP. Perform in 20 minute sessions 5 times per day.
• ROM Passive knee flexion—progress as per patient tolerance—3 times a day
• ROM Patella-femoral joint mobilization—3 times a day
• Weight bearing—10–20 lbs, heel-toe gait with 2 crutches
• Ankle pumps, quads sets, SLR with NMES
• Stationary bike when ROM allows
• Hamstring, calf, quadriceps stretching
	• Hinged knee brace
	• PT modalities
	• ROM—no precautions, full extension, increase PROM knee flexion as tolerated, PF mobs
	• PROM knee flexion goals:
	  • ACI-Femoral condyle lesion:
	  • 90° weeks 1–2,
	  • 105° by week 3,
	  • 15° by week 4
	  • 35° by week 6
	  • These are conservative and can be progressed faster.
	  • ACI-Patella-trochlea lesion
	  • 90° by weeks 2–3
	  • 105° by weeks 3–4
	  • 120°s by week 7
	• Weight bearing
	  • ACI-Femoral condyle lesion
	  • Continued restriction of weight bearing initially—10–20 lbs only
	  • 50% weight bearing at weeks 4–6
	  • ACI-Patella-trochlea lesion
	  • Weight bearing can be accelerated more quickly.
	  • 25% body weight week 2
	  • 50% weight bearing at week 4
	  • Full weight bearing at week 6
	• Ankle pumps, quads sets, SLR with NMES, short arc quads, TKEs
	• Manual rhythmic stabilization of trunk in sitting, nonsurgical leg single leg balance
	• Stationary bike
	• Hamstring, calf, quad (rectus fem) stretching
	• TBS/TAS/TLS activities as recommended and tolerated
	• Week 4—isometric leg press, aquatic treadmill walking
		• DC Brace at week 6
		• Passive Knee ROM
		  • ACI-Femoral condyle
		  • At least 135° PROM knee flexion
		  • ACI-Patella-trochlea
		  • 120° week 7
		  • 135° weeks 8–9
		  • Full PROM knee extension, PF mobs, gentle scar tissue mobilization
		• Weight bearing
		  • ACI-Femoral condyle lesion:
		  • 50% weight bearing with crutches at weeks 4–6
		  • 100% weight bearing at 6–8 weeks—earlier with permission from MD
		  • ACI-Patella-trochlea lesion
		  • 100% weight bearing weeks 6–8
		• Continue previous stretches, add pretzel, Thomas test stretch
		• Continue stationary bike, aquatic TM (lower water level), treadmill wks 8–9
		• TBS/TAS/TLS activities as recommended an tolerated
		• Week 6—isometric leg press, standing weightshifts, rocker board, physioball bridging and walkouts
		• Week 8—Mat squats, double-leg leg press, cup walking, heel raises (double leg), stationary minilunge with cable chops
		• Week 9—front step-ups, single leg rocker board
		• Week 10—elliptical, lateral step ups

- A continuous passive motion (CPM) machine can be used up to 4 hours a day (using ROM gained in PT). This can help with pain management and in regaining motion. Emphasis on full passive knee extension while using CPM should be encouraged from Day 1.
- A compression stocking is worn initially. When control is gained over edema, this can be replaced with a shorter, light compression stocking.

Techniques for Progressive Increase in Range of Motion

Manual Therapy Techniques

- Immediate motion from Day 1
- Maximize passive knee extension immediately. Use a patient-controlled passive knee extension device, heel prop or prone hangs.
- Perform in 20-minute sessions five times per day.
- Grade 2–3 anterior-posterior mobilizations (APs) to the tibiofemoral joint can be used to increase this range.
- Passive patella-femoral joint mobilization, both in the medial-lateral and cephalad-caudad directions, will prevent loss of patella-femoral ROM and resulting potential loss of tibiofemoral ROM three times a day.
- Passive knee flexion is progressed per patient tolerance. There is no limitation to this increase, except for the pain tolerance levels of the athlete. Perform three times a day.

Clinical Pearl

Passive knee flexion is limited only by patient tolerance. The increase in ROM is expected to be slower in patella-trochlea ACI patients than in femoral condyle ACI patients. It can be particularly beneficial to aim for an increase in ROM, even if it is just a few degrees, at each treatment session. It is discouraging for a patient to tolerate pain and then not make any gains. This range will always be limited by swelling. Make every effort to reduce swelling, including patient education. If you are not successful, always seek the orthopaedic surgeon's opinion, in case knee aspiration is necessary.

TIMELINE 31-4: **Postoperative Rehabilitation After Osteochondral Autograft/Allograft Transfer** (Continued)

PHASE IV (weeks 10 to 14 postop)	PHASE V (weeks 14 to 24 postop)	PHASE VI (weeks 24 to 52 postop)

• PROM—maintain full motion, joint mobilizations as needed
• Weight bearing 100%
• Continue lower limb stretches. Add Frog, Pretzel, modified Thomas test stretch
• Stationary bike, treadmill walking, elliptical, StairMaster
• TBS/TAS/TLS activities as recommended an tolerated
• CKC: High step-ups, backward stationary lunges, double leg squats, leg press, heel raises (double and single-leg); week 12, single leg leg press
• OKC: speedskaters, open chain knee extension 0°–20°, leg curls
• Single leg balance, walking agility drills
• *If the osteochondral autograft athlete is demonstrating faster progression, it is reasonable, at this stage, to accelerate the time frames in the upcoming phases.*
	• PROM—maintain full motion
	• Weight-bearing status—aquatic TM run 24 weeks
	• Continue lower limb stretches. Add Frog, Pretzel, modified Thomas test stretch
	• Stationary bike, treadmill/road walking, elliptical, StairMaster
	• PNF lower limb and/or trunk in supine or sitting
	• TBS/TAS/TLS activities as recommended and tolerated
	• CKC: Progress height of high step-up, backward lunge walking, forward lunge walking, single leg squats (vary surface, add perturbations)
	• OKC: speedskaters on proprioceptive equipment, cable kicks in PNF patterns
	• Walking agility drills—increase complexity
		• Previous levels of functional activities
		• End range sustained stretches
		• Single leg stand/squat on balance device. Increase complexity
		• PNF lower limb patterns in standing and supine
		• PNF upper limb/trunk in tall kneeling, half kneeling, single leg stand on rocker board
		• Physioball ex: bridge back on ball with leg extensions, bridge back on floor, single leg curls
		• CKC: lunges on 2 BOSU, LSU
		• OKC: open chain knee ext 0°–20°, open chain kicking
		• 6 mo—pool run, 7 mo—treadmill run, increase distance on bike, elliptical, StairMaster
		• Agility drills—fast walk
		• Single leg cone touches, single leg deadlifts
		• 4–7 mo—upper body plyometrics, static stance lower body
		• 7–8 mo—box jump—progress direction, number, single leg
		• 8–9 mo—single leg hop agility drills
		• Sports—Osteochondral autograft
		  • 4 mo—Low impact: golf, swimming, skating, rollerblading, cycling
		  • 6 mo—Moderate impact: light running, aerobics
		  • 7–8 mo—High impact: tennis, volleyball, basketball, football, baseball
		• Sports—Osteochondral allograft
		  • 6 mo—Low impact: golf, swimming, skating, rollerblading, cycling
		  • 7–8 mo—Moderate impact: light running, aerobics
		  • 12 mo—High impact: tennis, volleyball, basketball, football, baseball

Soft Tissue Techniques

- Gentle effleurage to decrease edema in the calf area can be beneficial. Avoid the surgical area during this phase.
- Stretching/flexibility techniques for the musculotendinous unit
- Gentle hamstring and calf stretching will help improve patient comfort and prevent future soft tissue restrictions.

Other Therapeutic Exercises

- As soon as the patient is ready for cardiovascular exercise, an upper body ergometer can be used.
- As soon as patient gains sufficient passive knee flexion, the patient should begin stationary cycling for limited periods (10 to 15 minutes).

Activation of Primary Muscles Involved in Injury Area or Surgical Structures

- Immediate ankle pumps are advised to aid in edema control and prevent blood clots.
- Quad sets are taught as soon as the patient regains limb control (i.e., once nerve block wears off). Neuromuscular electrical stimulation (NMES) should be utilized.
- Active assisted straight leg raise is added Day 4. Progress to 4-way SLR as the patient's tolerance increases.
- Crutch walking should be reviewed. This is difficult initially because the patient has to be completely non–weight-bearing while the nerve block remains effective. Actual gait training should be repeated when leg control returns—10% to 20% of body weight heel-toe weight bearing, two crutches, and lace-up shoes. Teach the patient how to ascend and descend stairs.
- Week 2—Introduce terminal knee extensions (see Figure 31-30); patient must use crutches for support. Maximum supervision required.

Phase II (weeks 2 to 6 postoperative)

Goals

- Decrease pain and effusion.
- Maintenance of full passive knee extension
- Continued restoration of passive knee flexion
- Regain quadriceps control.
- Gradually increase strengthening and cardiovascular demand.
- Encourage correct heel-toe gait with crutches (being mindful of the appropriate weight-bearing allowances).

Protection

- Continued use of hinged knee brace. Increase the range of motion in the brace as the patient gains ROM in rehabilitation.
- Osteochondral allograft
  - 25% weightbearing week 2
  - 50% weightbearing week 4
- Osteochondral autograft
  - Less protection required for patient's own tissue
  - 50% weightbearing week 2
  - 100% weightbearing weeks 3 to 4

Management of Pain and Swelling

- Oral pain medication may remain necessary, particularly at night and for rehabilitation sessions.
- Continued use of cryotherapy (three times per day), elevation of the limb, ankle pumps
- Continued use of a compression sleeve (lightweight)
- Continued use of CPM, ROM to mirror gains in rehabilitation

Techniques for Progressive Increase in Range of Motion

Manual Therapy Techniques

- ROM precautions: None
- PROM: Manual ROM of the patella-femoral joint—medial/lateral and cephalad/caudad.
- PROM: Continue to maintain tibiofemoral extension. Every effort should be made to mirror the patient's opposite limb extension ROM.
- PROM knee flexion goals
  - OATS Autograft
    - Full ROM restored in first 3 to 6 weeks, restricted by pain only
  - OATS Allograft
    - PROM is restricted only by pain; the following are conservative numbers and can be progressed faster.
    - 105° by week 3
    - 115° by week 4
    - 135° by week 6

Clinical Pearl

At this stage, consider performing passive knee flexion with the hip in extension. This is most easily achieved with the patient in side-lying, with the involved leg on the table. This will help to prevent loss of extensibility of the rectus femoris muscle—a two joint muscle. This position also provides the rehabilitation specialist with excellent leverage (see Figure 31-31).

Stretching and Flexibility Techniques for the Musculotendinous Unit

- Maintain gastroc/soleus ROM—passive stretching in supine, on table
- Maintain or improve hamstring ROM; angle of stretch can be varied to include the iliotibial band or adductor group.

Other Therapeutic Exercises

- Upper extremity exercises during this phase may include upper-body ergometer (UBE) and general weight equipment (such as lat pulldowns, pec deck, tricep pushdowns, biceps curls, scaption). Perform all exercises in a seated position.

- Core exercises may include single leg planks, single leg pushups, and reverse planks. Reverse planks are similar to regular planks, except that the patient performs them belly-up (supine), instead of belly-down (prone) like a regular plank. As in regular planks, the patient can weight bear on the hands or on the forearms. In all these exercises, the surgical leg is non–weight-bearing and held off the ground.

Activation of Primary Muscles Involved in Injury Area or Surgical Structures

- Ankle pumps, ankle alphabet exercises
- Quads sets with NMES or biofeedback
- SLR—4-way with NMES or biofeedback
- Short arc quads with NMES or biofeedback
- Stationary bike
- Isometric leg press at week 4
- Aquatic treadmill walking at week 4
- Nonsurgical leg exercises are begun
- No open chain knee extension for 4 months. This precaution may be necessary because patients often complain of patella-femoral joint symptoms following the surgery. This temporary complaint is suspected to be a result of quad weakness and remedies itself as the patient's quad control returns.

Clinical Pearl

Side-lying abduction is very important. Limited weight bearing may cause muscular atrophy of the gluteal group. Ensure that the patient is in the correct side-lying position with lower limb slightly extended to ensure maximal gluteus medius recruitment (see Figure 31-32).

Sensorimotor Exercises

- Begin active angular replication exercises, for motor control. These can be introduced during the SLR exercises.

Techniques to Increase Muscle Strength, Power, and Endurance

- Upper body strengthening
- UBE
- Stationary bike
- Aquatic treadmill at week 4. Remember that chest-high water level is 25% weight bearing, waist-high water level is 50% weight bearing.

Neuromuscular Dynamic Stability Exercises

- Manual rhythmic stabilization of trunk and core, performed in sitting
- Nonsurgical leg single leg balance retraining

Functional Exercises

- Gait training
- Single leg bridging to increase ease of transitioning
- Ensure that the patient is lifting the surgical leg independently when getting on and off table.

Phase III (weeks 6 to 10 postoperative)

Goals

- Achieve full PROM of knee flexion.
- Maintain full PROM knee extension.
- Gradually improve quadriceps strength and endurance. Focus on eccentric quadriceps control.
- Progress functional activities during this period.
- Maintain cardiovascular fitness and upper body strength.

Protection

- Brace is discontinued at week 6—Ensure quad lag is eliminated before discontinuing brace.
- Osteochondral autograft: Full weightbearing, no restrictions
- Osteochondral allograft: 100% weightbearing by weeks 6 to 8

Management of Pain and Swelling

- Oral analgesic use is continued as needed.
- NSAID use may be prescribed for persistent pain.
- Cryotherapy is used post therapy to mitigate postexercise inflammation and soreness.

Techniques for Progressive Increase in Range of Motion

Manual Therapy Techniques

- No knee ROM precautions
- Maximize PROM knee flexion (at least 135°), maintain full PROM of knee extension.
- Continue patella-femoral joint mobilization—cephalad/caudad direction important for assisting in tibiofemoral ROM
- Maintain hip joint mobility—Consider Hip PAs performed in prone or slight hip extension, add hip ER/IR, being cautious of the possible effects of torque on the knee joint.
- Assess PROM of ankle dorsiflexion—Compare to contralateral limb.

Soft Tissue Techniques

- Gentle scar tissue mobilization can be introduced at this stage.
- Soft tissue techniques may be applied to the quadriceps, hamstrings, and calves—Avoid the knee joint.

Stretching and Flexibility Techniques for the Musculotendinous Unit

- Continue to focus on gastrocnemius/soleus (now performed in standing), hamstrings, and quadriceps stretches.

- Add Pretzel (piriformis/glutes) stretch, if knee can tolerate (see Figure 31-38).
- Thomas test stretch with added PROM knee flexion to improve flexibility of the rectus femoris muscle (see Figure 31-33).

Other Therapeutic Exercises

- Cardiovascular—UBE, stationary biking
- Week 8—Introduce elliptical training and Stairmaster. Gradually build up tolerance.
- Aquatic treadmill walking—Gradually lower water level to tolerance and with respect to the appropriate weight-bearing requirements.
- Weeks 9 to 10—Treadmill walking
- Upper body strengthening can be progressed to preoperative levels.
- Consider combination exercises involving the core and upper body at this stage (e.g., physioball walkouts: roll prone on ball, walk on hands), and consider adding push-ups or serratus hunches.

Activation of Primary Muscles Involved in Injury Area or Surgical Structures

- Basic surgical limb strengthening includes four-way straight leg raises with increased resistance. Quad lags should be completely eliminated at this stage. Discontinue use of NMES when quads lag is eliminated.
- Terminal knee extensions in standing; increase resistance
- Week—isometric leg press
- Week 8—stationary minilunge with cable chop. The cable chop involves holding a Thera-Band or attachment to a cable machine and performing a D1 or D2 PNF pattern. All effort is made to maintain core stability.
- Week 8—mini-squats 0° to 45° using correct biomechanics. Avoid genu valgum and prevent knee over toes.
- Week 8—Begin double leg leg press through as much ROM as machine will allow
- Week 8—double leg heel raises
- Week 9 front step ups.
- Week 10 lateral step up—Target eccentric quadriceps and hip abductor control.

Clinical Pearl

The weightshift exercise in standing encourages the patient to weight bear in an equal distribution over the bilateral limbs. It targets hip, knee, and ankle proprioception, which encourages improved joint position awareness, increased joint stability, and decreased patient apprehension.

Begin training with the patient shifting laterally, feet hip distance apart. The patient should avoid sideflexion of the trunk and a Trendelenburg at the hip. The patient should shift 90% of weight onto the right leg and then shift 90% of weight onto the left. Scales can be utilized in order to perform this accurately. In the clinical setting, the rehabilitation specialist can instruct the patient to shift 90% of weight onto the one leg, while keeping the toes of the opposite leg on the floor. This ensures safety when this exercise is first introduced. As weight-bearing tolerance is allowed to progress, this exercise can be further modified in order to allow full single-leg weightbearing. It is therefore an excellent tool to use in the clinic (see Figure 31-34)

When the patient can achieve this rhythmically and comfortably, progress to stride standing, shifting weight forward onto the front leg (90% weight bearing) and backward onto the back foot (90% weight bearing) rhythmically (see Figure 31-35).

Again, as patient tolerance allows progress to stepovers—the surgical leg stays fixed on the floor and the patient steps forward and backward with the nonsurgical leg, replicating the stance phase of the gait pattern.

These can be initiated at week 8, and progressed according to weight-bearing tolerance.

Sensorimotor Exercises

- Weightshift exercise in standing
- Rocker board balance retraining. Begin doubleleg AP direction, progress to lateral. Progress to single leg AP at weeks 8 to 9.
- Progress to wobble board—circles, right-left, front-back, balance on double leg. Progress to single leg at weeks 8 to 9.
- Active joint positioning of knee and hip
- Balance equipment (such as the BOSU, Dynadisc) can be incorporated at this stage. Progress patient as appropriate, keeping the exercises challenging.
- Use of physioball—bridging with back on floor, single leg and double leg; bridging with back on ball, add leg extensions and physioball walkouts with single leg extension.

Open and Closed Kinetic Chain Exercises

- Closed chain proprioception activities: rocker board, wobble board, BOSU, etc. utilizing double leg and single leg stance
- Closed chain strengthening exercises: At week 8 introduce leg press, mat squats (double leg), forward step-ups, lateral step-ups—progress resistance.
- Open chain strengthening exercises: short arc quads, VMO holds

Techniques to Increase Muscle Strength, Power, and Endurance

- Progress bike endurance.
- Introduce elliptical training at weeks 7 to 8.
- Aquatic treadmill—Continue walking program

Neuromuscular Dynamic Stability Exercises

- It is safe, and indeed advisable, to progress proprioceptive challenge on balance equipment as cartilage healing

progresses. Consider adding complexity challenges to the exercises (e.g., add perturbations, utilize multijoint exercises such as scaption PREs while balancing single leg on the rocker board).

Plyometrics

- Lower limb plyometrics should be avoided at this stage of critical cartilage repair.

Functional Exercises

- Gait correction is vital at this stage. Consider cup walking (see Figure 31-36) at week 7 to 8. Cup walking was originally utilized in prosthetic gait training. It encourages a reciprocal gait pattern, full weight bearing over the surgical side, and forces the patient to pull the foot and knee up in order to clear the cups. Even gait cadence should be emphasized.
- Ensure that the patient is walking up stairs reciprocally by weeks 8 to 9. Descending stairs reciprocally will lag behind ascending because of the slower recovery of eccentric quadriceps control.
- Ensure that patient weight bears equally through both lower limbs when transitioning from sit to stand. This can be measured by using scales or by closely observing the lower limb kinetic chain and ensuring that each hip lines up with the respective knee and ankle. Additionally, ensure that the feet are placed in a straight line in the frontal plane, otherwise the foot that is placed further back will be the one bearing most weight.
- Throwing athletes may incorporate the Throwers 10 program for the upper limbs.

Sport-Specific Exercises

- This is only appropriate for upper body training during this time period.

Phase IV (weeks 10 to 14 postoperative)

If the osteochondral autograft athlete is demonstrating faster progression, it is reasonable, at this stage, to accelerate the time frames in the upcoming phases.

Goals

- Improve muscle strength and endurance.
- Progress functional activities.
- Encourage continued compliance. The patient must respect that overuse of the limb will have a detrimental effect on short-term healing and long-term cartilage integrity.

Techniques for Progressive Increase in Range of Motion

Manual Therapy Techniques

- Maintain full PROM of both the tibiofemoral and patella-femoral joints.
- Hip mobilizations—maintain or regain full ROM.
- Maintain full ankle dorsiflexion ROM.

Soft Tissue Techniques

- Soft tissue release of the quadriceps, hamstrings, gastroc/soleus complex and glutes. This is not always necessary. However, occasionally, a patient may be aware of significant muscle pain, usually in the quadriceps muscle. The possibility of a DVT should always be ruled out. Please consult with the referring physician immediately, if you have any concerns. Effleurage-type massage may be effective in decreasing edema and improving patient comfort.
- Continue gentle scar tissue mobilization.

Stretching/Flexibility Techniques for the Musculotendinous Unit

- Maintain/achieve sufficient flexibility of the lower limb muscles.
- Progress to targeting hip ER and IR ROM—frog stretch (see Figure 31-37) and pretzel stretch (see Figure 31-38)
- Continue to focus on iliopsoas and rectus femoris length by performing the modified Thomas test stretch.

Other Therapeutic Exercises

- Progress upper body strengthening exercises.
- Progress core recruitment exercises.
- Treadmill walking, elliptical, Stairmaster, stationary bike

Activation of Primary Muscles Involved in Injury Area or Surgical Structures

- As before with progressive resistance
- Increase leg press through full range; add resistance; aim for equal weight distribution when using both legs. Sophisticated digitized leg press machines are able to calculate weight distribution. In the absence of such machines, carefully observe the patient and encourage the patient to avoiding protecting the surgical leg. Ensuring alignment of the feet, ankles, and knees can aid in this goal. As the patient gains strength and confidence, and as pain decreases, she/he should be encouraged to gradually progress to equal weight distribution between both legs.
- Progress to single leg at week 12.
- Add leg curls.
- Single leg heel raises—extended (gastrocnemius) and flexed (soleus) knee

Open and Closed Kinetic Chain Exercises

- CKC
  - High step-ups—Progress to waist height.
  - Backward stationary lunges
  - Double leg squats
  - Athletes are encouraged to avoid locking out the tibiofemoral joint. Stance used should be hip width apart with careful focus on maintaining correct joint mechanics.

- OKC
  - Speedskaters (see Figure 31-39)
  - Open chain knee extension 0° to 20°

Techniques to Increase Muscle Strength, Power, and Endurance

- Advance endurance sets to strength exercises (fewer repetitions 6 to 8).

Neuromuscular Dynamic Stability Exercises

- Progress use of balance equipment. Focus predominantly on single leg exercises and compare sides to judge progress. Time how long patient can stand on a single leg without support on various pieces of balance equipment, such as the rocker board, wobble board, and BOSU. Aim to get the surgical leg to balance for as long as the nonsurgical side. Observe that the patient does not use incorrect hip, knee, or ankle strategies, such as foot pronation or knee genu valgum.

Functional Exercises

- Lower limb agility drills can be performed utilizing fast walking without sudden changes in directions or pivoting.

Sport-Specific Exercises

- The running athlete must still avoid any lower body impact exercises at this stage.

Milestones for Progression to the Next Phase

- Full range of motion
- Acceptable strength level
  - Hamstrings within 10% of contralateral leg—isokinetic testing
  - Quadriceps within 10% to 20% of contralateral leg—isokinetic testing
- Balance testing within 30% of contralateral leg—Again, sophisticated balance testing machines are available. However, in the absence of such equipment, measure single leg balance time on the wobble board without allowing the edge of the board to make contact with the ground. Compare sides.
- Able to walk 2 miles or bike for 20 minutes
- 50 lateral step-ups (8 inch height). This is an easily measurable activity, which ensures that sufficient eccentric quad control has been achieved in order to progress to Phase V.

Phase V (weeks 14 to 24 postoperative)

Goals

- Improve muscle strength and endurance.
- Progress functional activities.
- Encourage continued compliance. The patient must respect that overuse of the limb will have a detrimental effect on short-term healing and long-term cartilage integrity.
- Hamstrings and quadriceps strength within 10% of contralateral leg
- Balance testing within 10% of contralateral leg

Techniques for Progressive Increase in Range of Motion

Manual Therapy Techniques

- Maintain full PROM of both the tibiofemoral and patella-femoral joints.
- Continue hip and ankle mobilizations if necessary.

Soft Tissue Techniques

- Assess the need for soft tissue release of the quadriceps, hamstrings, gastroc/soleus complex, and glutes. This is only necessary if the patient continues to complain of specific muscle pain. Trigger points can be assessed and treated. Any edema can be addressed with effleurage massage. Again, always rule out the possibility of DVTs.
- Continue gentle scar tissue mobilization.

Stretching/Flexibility Techniques for the Musculotendinous Unit

- Maintain/ achieve sufficient flexibility of the lower limb muscles.
- Continue to focus on iliopsoas and rectus femoris length by performing the modified Thomas test stretch.

Other Therapeutic Exercises

- Progress upper body strengthening exercises.
- Progress core recruitment exercises.

Activation of Primary Muscles Involved in Injury Area or Surgical Structures

- As before with progressive resistance
- Progress to single leg leg curls and leg extensions at week 14; increase resistance.
- Avoid open chain knee extensions if they increase patient discomfort.

Sensorimotor Exercises

- PNF lower limb patterns performed in supine. Be sure to add knee flexion and extension into the patterns to recruit the primary operative muscles. PNF upper limb and trunk patterns in half kneeling and static lunge position

Open and Closed Kinetic Chain Exercises

- CKC
  - High step ups—Progress to waist height.
  - Backward lunges—Progress to backward lunge walking; progress to forward lunge walking.
  - Double leg squats—Progress to single leg squats. Vary surface, add perturbations, add upper body/ trunk motion.

  - Athletes are encouraged to avoid locking out the tibiofemoral joint. Stance used should be hip width apart, with careful focus on maintaining correct joint mechanics.
- OKC
  - Speedskaters—Increase resistance; the patient can stand on a BOSU or rocker board
  - Cable kicks in PNF patterns

Techniques to Increase Muscle Strength, Power, and Endurance

- Advance endurance sets to strength exercises (fewer repetitions 6 to 8).
- Alternately focus on endurance (16 to 20) sets and hypertrophy (6 to 8) resistance training.

Neuromuscular Dynamic Stability Exercises

- Progress use of balance equipment. Focus predominantly on single leg exercises and compare sides to judge progress. Here again, single leg balance on the wobble board, whereby the edge of the board is not allowed to make contact with the floor, is an effective comparison tool. This same principle can be applied to other balance equipment.
- Add sport-specific drills (e.g., a baseball pitcher can perform trampoline pitching while balancing single leg on a BOSU; a soccer player can replicate kicking with band resistance balancing on a balance board).

Plyometrics

- Plyometrics are still not introduced at this stage, in order to protect the cartilage repair.

Functional Exercises

- Lower limb agility drills can be performed utilizing fast walking. Increase unpredictability of training by throwing balls and calling direction changes.
- Increase walking distance, speed, and inclines as time progresses.

Sport-Specific Exercises

- Gradual reintroduction of impact exercises toward the end of this stage

Phase VI (weeks 24 to 52 postoperative)

Goals

- Prepare patient for return to sport.

Management of Pain and Swelling

- Cryotherapy application post exercise

Techniques for Progressive Increase in Range of Motion

- Full AROM and PROM must be achieved by 4 months.
- Ensure maintenance of patella-femoral ROM.

Soft Tissue Techniques

- Seldom necessary at this stage.

Stretching and Flexibility Techniques for the Musculotendinous Unit

- Full, passive knee extension ROM remains critical. Most patients will be easily able to maintain this, especially if their gait pattern is optimal and, as a result, they use knee extension with every step that they take. The occasional patient may continue to struggle. Regular hamstring and gastrocnemius stretching remains useful in these cases. Use of low-load, long-duration passive knee extension may still be required on a daily basis.

Other Therapeutic Exercises

- Continue and progress multijoint exercises.

Activation of Primary Muscles Involved in Injury Area or Surgical Structures

- Aim to return to preinjury levels of function toward the end of this phase.

Sensorimotor Exercises

- Single leg standing on wobble board (or similar device). Increase complexity by adding ball toss, close eyes, add perturbation of board or trunk, and initiate single leg squats.
- PNF lower limb patterns performed in supine and standing. Be sure to add knee flexion and extension into the patterns to recruit the primary operative muscles. PNF upper limb and trunk patterns in half kneeling and static lunge position
- Continued use of physioball—continue increasing challenge and complexity of exercises (e.g., sitting on physioball with single leg support), perform cable PNF with upper limbs and maintain balance. Perform with eyes closed.

Open and Closed Kinetic Chain Exercises

- Advance the previous exercises in accordance with sport-specific demands.
- CKC progression includes:
  - Single leg squats standing on a wobble board
  - Lunges on two BOSU surfaces, increasing resistance and decreasing support
  - Lateral step-ups with trunk perturbations.
- OKC
  - Restrict open chain knee extensions to 0° to 20°.
  - If patient participates in a kicking sport, open chain kicking agility exercises can be incorporated.

Techniques to Increase Muscle Strength, Power, and Endurance

- Pool running can be introduced at the 6-month mark.
- Treadmill running can be introduced at the 7-month mark.
  - Carefully observe the patient's running pattern. Ensure an even rhythm, light grading, equal weight bearing, correct use of upper limbs, and core recruitment.
- Increase endurance on the elliptical, bike, and StairMaster. It is usually preferable to increase distance before speed/intensity but individual preference must be respected.

Clinical Pearl

Use pain and/or swelling to monitor whether you are progressing too quickly. It is an accurate sign of overuse and should be respected accordingly.

Neuromuscular Dynamic Stability Exercises

- Agility drills—cariocas and cone drills can only be performed at a fast walking pace until the 7-month mark, when light running can be added. Speed and complexity can be progressed at that stage.
- Cone touches—Place two cones slightly more than hip distance apart. Stand on one leg in between them. Reach left hand to right cone and reverse, repeat for 20 reps (Figure 31-40).
- Single leg deadlifts (patient holds PVC pipe vertically behind back. Patient performs a single leg deadlift maintaining contact of the PVC pipe against the occiput and tailbone throughout the motion.)
- Deep knee bends (full range, good mechanics) can be introduced to teach efficient eccentric quadriceps release.
- Always challenge the patient.

Plyometrics

- Month 4 to 7—Consider upper body plyometrics while utilizing static stance for lower body (e.g., hold static squat position while throwing ball against wall, physioball bridge with back on ball while performing overhead ball toss and crunches).
- Months 7 to 8—Teach box jumping. Monitor patient's level of discomfort during and after the exercise. Ensure patient learns to land with light grading ("light, like a panther") and maintains correct joint positioning (do not allow the knees to go forward over the toes, keep the knees apart and avoid genu valgum) throughout the movement. As time progresses, advance from double leg jumps forward to double leg jumps sideways to double leg jumps over the box. Continue the progression to single leg jumps forward to single leg jumps sideways. For safety, do not allow the patient to become overly fatigued. The patient should be allowed to rest often. The exercises should be discontinued immediately as soon as the patient is no longer able to maintain correct form.
- Month 8 to 9—Progress to single leg hopping agility drills.

Sport-Specific Exercises

Osteochondral Autograft

- Low impact sports such as golf, swimming, skating, rollerblading, and cycling are permitted at 4 months.
- Moderate impact sports such as running and aerobics may be performed at 6 months.
- High impact sports such as tennis, volleyball, basketball, football, and baseball are allowed at 7 months.

Osteochondral Allograft

- Low-impact sports such as golf, swimming; skating, rollerblading, and cycling are permitted at 6 months.
- Moderate impact sports such as running and aerobics may be performed at 7 to 8 months.
- High-impact sports such as tennis, volleyball, basketball, football, and baseball are allowed at 12 months.

Milestones for Progression to the Next Phase

- Less than 10% side-to-side deficit on isokinetic testing
- Less than 15% side-to-side deficit on hop test
- Patient reported Outcome Studies at 52 weeks should be greater than 90% compared with preoperative scores.

Outcome Measures

Patient reported outcome scales should be implemented at the 12-month follow-up appointment. Scales that have been utilized in the literature for Cartilage Restoration Procedures include:

- IKDC—International Knee Documentation Committee Subjective Knee Form
- SF12—Quality of life instrument
- KOOS—Knee injury and Osteoarthritis Outcome Score

Criteria for Return to Sport

General

- Full AROM in tibiofemoral and patella-femoral joint, no apprehension
- Minimum of 80-90% side-to-side symmetry on isokinetic testing.
- Minimum of 15% side-to-side symmetry on hop test.
- Quadriceps-hamstrings ratio that matches non-surgical limb, based on isokinetic testing results.
- Correct hip and knee alignment during jump test and hop test—particularly when fatigued.

Sport-Specific

- Specific sports require specific functional demands of the athlete. The rehabilitation specialist needs to be familiar with sport-specific demands.
- A particular focus should be on working the patient to fatigue, because injury rates have been shown to increase when a patient is fatigued.

After Return to Sport

Continuing Fitness or Rehabilitation Exercises

- Total body fitness regime

Exercises and Other Techniques for Prevention of Recurrent Injury

- Ensure maintenance of lower limb strength, maintain surgical limb at 85% or better when compared with nonsurgical limb. The patient may be encouraged to consult with the rehabilitation specialist every 3 to 6 months in order to undergo repeat isokinetic testing and functional testing, such as the hop test.
- Continue neuromuscular control exercises to maximize core, hip, knee, and ankle stability and proprioception.
- Maintain cardiovascular endurance, balance and proprioception, flexibility, strength, and endurance. Neglect of any of these areas may place the athlete at risk for reinjury.
- Consider limiting impact and joint loading except when it is necessary for sport-specific demands.

Evidence

Gudas R, Kalesinskas RJ, Kimtys V, et al: A prospective randomized clinical study of mosaic osteochondral autologous transplantation versus microfracture for the treatment of osteochondral defects in the knee joint in young athletes. *Arthroscopy* 21(9):1066–1075, 2005.

A prospective, randomized clinical study compared 60 athletes. At an average of 37.1 months (range, 36 to 38 months) follow-up, the OATS procedure demonstrated significant superiority over microfracture. Only 52% of microfracture athletes could return to sports at the preinjury level, as compared with 93% of the OATS athletes. (Level 2 evidence)

Logerstetdt D, Snyder-Macker L, Ritter R, et al: Knee pain and mobility impairments: Meniscal and articular cartilage lesions. *J Orthop Sports Phys Ther* 40(6):A1–A35, 2010.

Clinical practice guidelines detailing evidence-based recommendations for examination and diagnosis, rehabilitation interventions, and assessment of outcome. (Level of evidence not known)

Mithoefer K, Hambly K, Della Villa S, et al: Return to sports participation after articular cartilage repair in the knee: Scientific evidence. *Am J Sports Med* 37(Suppl 1):167S–176S, 2009.

A systematic review of 20 studies (1363 patients), average follow-up of 42 months. 73% return to sports, with highest rates after OATS. Time to return to sports varied from 7 to 18 months. Initial return to sports at the preinjury level was possible in 68% without significant differences between surgical techniques. Continued sports participation at the preinjury level was possible in 65%; ACI showed best durability. Factors that affected the ability to return to sport included: athlete's age, preoperative duration of symptoms, level of play, lesion size, and repair tissue morphology. (Level 3-x evidence)

Multiple-Choice Questions

QUESTION 1. When should full PROM of tibiofemoral knee extension be established?

A. 0 to 2 weeks
B. 2 to 4 weeks
C. 4 to 6 weeks
D. Never

QUESTION 2. Why is it preferable to stretch the knee into passive flexion in prone or side lying rather than supine, with the hip in flexion?

A. It is more comfortable for the patient.
B. It allows the patient to gain passive ROM more quickly.
C. It addresses all four quadriceps muscles, including the all-important rectus femoris—the flexibility of which needs to be addressed post surgery.
D. It allows the patient to return to high impact sports more quickly.

QUESTION 3. Which surgery allows a faster return to sports?

A. Osteochondral allograft transfer
B. Osteochondral autograft transfer

QUESTION 4. Which criterion does not apply when evaluating whether a patient is ready to progress to Phase V of the rehabilitation process?

A. Full range of motion
B. Balance testing within 30% of contralateral leg
C. Ability to hop 50 paces
D. Ability to walk 2 miles or bike for 20 minutes

Answer Key

QUESTION 1. Correct answer: **A** (see Phase I)

QUESTION 2. Correct answer: **C** (see the Clinical Pearl in Phase II)

QUESTION 3. Correct answer: **B** (see Table 31-3)

QUESTION 4. Correct answer: **C** (see Milestones for Progression to the Next Phase [Phase V])

BEYOND BASIC REHABILITATION: RETURN TO BASKETBALL AFTER OSTEOCHONDRAL ALLOGRAFT TRANSPLANTATION

Daphne R. Scott, PT, DSc, FAAOMPT, OCS, Wendell M.R. Heard, MD, Andrew S. Lee, MD, Bryan M. Saltzman, MD, and Brian J. Cole, MD, MBA

ASPECTS OF BASKETBALL THAT REQUIRE SPECIAL ATTENTION IN REHABILITATION

- Hennig[1] summarized four categories for consideration regarding decisions to return an athlete to her or his chosen sport: medical, socioeconomic, political, and legal.
- Most athletes pursue surgery for a medical condition with the full intention of returning to his or her chosen sport.
  - The goal of the sports medicine healthcare provider is to return the athlete to the particular sport.
  - The provider hopes to allow the athlete to maximize his or her abilities, without compromising their safety and the safety of others, and prevent reinjury.
- With recent advances in the recognition and surgical treatment of chondral defects in the knee,[1,2] there is a similar lack of proven standards for returning an athlete to sport and in particular, to basketball, following an osteochondral allograft transplantation (OA graft) procedure.

Introduction

- Cartilage repair procedures yield less predictable outcomes in this population given the inherent demands placed upon their reconstructed joints and the inability to completely reduce or eliminate pain to the point where athletic performance is not compromised.
  - Added to this complexity is the concern that once a patient achieves his or her desired degree of pain relief and functional return, there is the inherent risk of sport and athletic injury similar to the risk that may have contributed to the initial joint failure.
- Postoperative return to sports presents the most significant measure of a successful outcome for the injured athlete and the healthcare provider.
  - Because of the multifactorial nature of this decision, guidelines are best employed to encompass each individual athlete's needs and goals at appropriate intervals.
- Decision making is both based upon evidence-based medicine reporting outcomes as well as an "economic" argument that considers risk versus benefit. Ultimately, it becomes the patient's decision as to whether he or she will knowingly expose themselves to these risks, assuming they achieve their desired outcome.
- It is always best to correct extraarticular aspects contributing to their pathology and symptoms.
  - In a setting of clinically relevant malalignment, performing an osteotomy even without an intraarticular cartilage repair procedure may yield an acceptable clinical result without the additional risk of future injury to transplanted cartilage repair tissue, assuming that an acceptable amount of symptom relief and associated functional return are achieved.
- Some factors identified that can delay the return to sport participation following chondral repair of the knee:
  - Age of the athlete
  - Preoperative duration of symptoms, size of lesion
  - Recreational versus professional playing level
  - Morphology of the tissue repair and the nature of the concomitant co-morbidities addressed at the time of the cartilage repair procedure[3–7]

Literature

- Many factors have been identified to affect full return to sport following any chondral repair in the knee; overall results for those who choose to return to sport are promising.[8,9]
- Flanigan et al.[10] report the prevalence of full-thickness chondral injuries in the athletic population to be 36% and significantly higher than those found in the general population.
- Chondral injuries of the knee are also noted to occur in association with other knee injuries, and in particular anterior cruciate ligament tears.[11–13]
- It is estimated that up to 50% of athletes undergoing anterior cruciate ligament (ACL) reconstructions will have an associated chondral injury.
  - The current reported incidence of ACL injuries each year is approximately 200,000, which may indicate that there are 100,000 associated chondral injuries as well.[14,15]

Advanced Rehabilitation Program

- A key component of this return to sport program is the addition of functional testing to determine the athlete's readiness to return to basketball safely. This far exceeds the relevance of any rehabilitation program and is also significantly overlooked in the current literature, especially when considering this condition.

Measurement of Skills and Movement

- The most important aspect for the final return to sport is the functional progression and transition of the

athlete to proficient performance of high-demand sporting activities. In contrast, one of the greatest limitations for professional determination of an athlete's ability to return to sport is the lack of objective criteria and physical performance measures that coincide with the functional demands of the sport in question.

- Without specific functional performance measures, the rehabilitation provider may be left with only subjective input from the athlete as to readiness and therefore, miss crucial impairments that could expose the athlete to further risk of injury, and allow the athlete to return without adequate preparation. This may also force the clinician to justify delay in returning to sport with little objective criteria.
- Standardized approaches for functional movement testing are not necessarily established for determining an athlete's ability to return to basketball following an OA graft procedure. However, based on previous literature concerning successful rehabilitation of ACL reconstruction, there are appropriate criteria that address the relevant needs of the basketball athlete and support decisions made by physicians and therapists in allowing the athlete to return to basketball.
- As well, these criteria are also appropriate to guide further strengthening and conditioning for the athlete beyond basic rehabilitation to allow for successful return to sport.

Functional Testing

- Identifying specific functional testing and establishing baseline values for the athlete can be particularly helpful by not only identifying functional deficits but also establishing goals for the athlete to prepare for a full return to sport.
- However, the return to sport phase in many rehabilitation programs for athletes is not well established and this is particularly evident when looking for protocols to return the basketball athlete to sport following an OA graft procedure.
- Common testing that may be utilized to assess functional movement typically involves cutting and pivoting drills that include bilateral functional movements.
- One of the limitations of these activities is that unilateral strength deficits can be missed during these tests. Deficits during actual sporting activities can also be missed for the same reason, as most sport demands are bilateral in nature.
- As an example, studies have documented continued asymmetrical strength deficits in quadriceps strength in those athletes who have received ACL reconstructions.[16]
- More importantly, athletes have returned to sport even when deficits were still present in the surgical extremity compared with the nonsurgical extremity via unilateral functional activities such as single leg hop for distance testing.[16]
- Several studies have also documented continued functional deficits and asymmetries in performance-based testing as well as decreased quadriceps strength in athletes who have undergone ACL reconstruction, even after athletes have been returned to sport for 18 to 24 months.[17]
- It is likely that this same presentation would be evident in the athlete who had undergone a chondral repair, especially when combined with the previous knowledge of the incidence of chondral injuries associated with ACL tears in the athletic population.
- Myer and colleagues provide some guidance to fulfill this deficit in the literature regarding unilateral functional lower extremity testing.[17] In a 2011 study the investigators utilize modified NFL combine testing methodology to test functional deficits in athletes following ACL reconstruction after release to sport against a group of controls who had not undergone ACL reconstruction. The tests compare single leg functional tasks with double leg tasks to distinguish deficits between the two groups.
- Functional testing includes the broad jump, vertical jump, modified long shuttle, modified pro shuttle, modified agility t-test, timed hop, triple hop, single hop, and crossover hop tests. The results of this study confirm that athletes who had undergone ACL reconstruction and who had been returned to sport continue to demonstrate unilateral functional testing deficits that were not evident when double-limb performance activities were utilized.[17]
- The authors also state that isolated single-limb performance tasks such as the single leg hop for distance, triple hop for distance, and crossover hop for distance are able to demonstrate functional deficits in athletes who had undergone ACL reconstruction when compared with controls.
- Although this chapter is concerned with those athletes who have undergone an OA graft procedure, it is highly likely that owing to the nature of the length of symptoms and postoperative restrictions following a chondral repair, many of the same functional deficits will be evident in this patient population, therefore making these functional tests appropriate for use with the athlete who has undergone surgical chondral repair.
- Second, these activities are consistent with sport demands and therefore it is recommended that athletes should be able to complete these tests before returning to sport.
- The authors recommend that the surgically repaired leg should perform at 90% of the uninjured leg before return to sport is considered. Measuring this difference in limbs is referred to as the limb symmetry index (LSI), which is calculated by dividing the distance hopped on the involved lower extremity by the distance hopped on the uninvolved lower extremity and then multiplying this number by 100% (involved side performance/uninvolved side performance × 100%) (Figure 31-42).[16] These tests will be reviewed to guide the sports medicine professional in specific unilateral functional testing of the lower extremity.
- Single-leg hop for distance
  - The athlete begins this test standing on the involved extremity in a prejump stance with the knee partially bent. The athlete is then instructed to initiate the hop by swinging the arms forward and then hopping forward as far as possible while being able to land safely and controlled on the same limb. The athlete also maintains the landing stance for one second to

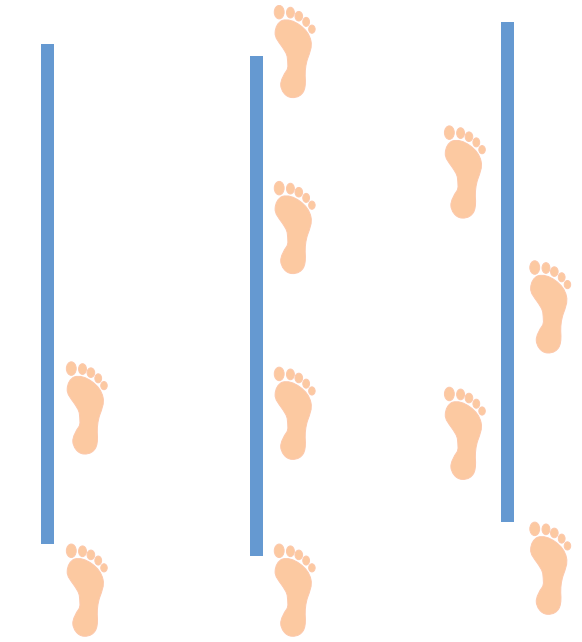

FIGURE 31-42. Lower limb symmetry index test.

have a successful trial. The distance hopped is measured in centimeters. Each leg will perform two trials with the best trial of each lower extremity chosen for calculation.

- Crossover hop for distance
  - The starting position for this test begins with the athlete standing on the involved lower extremity in a prehop position with a line that is placed medial to the standing foot. The athlete is then instructed to hop forward as far as possible and land on the same leg while crossing over the line with each subsequent hop. The athlete is allowed to use the arms as previously described in the single leg hop for distance test. The athlete maintains the last jump for one second for a successful trial. The distance hopped is measured in centimeters. Each leg will perform two trials with the best trial of each lower extremity chosen for calculation.
- Triple hop for distance
  - The starting position for this test begins with the athlete standing on the involved lower extremity in a prehop position with the knee slightly bent. The athlete is then instructed to hop forward as far as possible on the same leg and to then immediately complete two more hops as far as possible and holding the third hop for one second to complete the trial. The distance hopped is measured in centimeters. Each leg will perform two trials with the best trial for each lower extremity chosen for calculation.

Analysis of Testing

- Each of these tests takes into consideration the athlete's ability to generate functional power, attenuate force, and control postural stability as it relates specifically to demands that may occur during sport. The ability of the athlete to maintain and generate single-limb power and control the redirection of motion may be significant in reducing further injury. Once each of these tests is completed, the provider will have objective measures of potential unilateral limb asymmetries that can guide the decision to return the athlete to sport. The sports medicine provider will also be able to apply the appropriate intervention regarding strengthening, coordination, and flexibility training, which may all influence an athlete's ability to return to sport and participate safely without risking further injury. It should be noted that these three functional tests might not be the only tests that can or will be utilized with an athlete to determine sport readiness and also do not take into account the ability to evaluate the overall quality of movement while performing the tests.

Phase I (weeks 16 to 24 postoperative): Advanced Strength and Conditioning Programs

- Establish baseline measurements prior to beginning phased rehabilitation for return to sport.
- Baseline testing is conducted at the conclusion of the 12- to 16-week initial post-rehabilitation program following surgical procedure. Recommendations for full return to impact activities are imposed at 8 months postoperative.
  - Cardiovascular: Establish baseline cardiovascular endurance via cycle ergometry.
  - 1 to 3 RM power clean: Evaluates the athlete's total body explosiveness. The technique for performing should be standardized and athlete instructed.
  - 1 to 3 RM bench press and back squat: Evaluates upper and lower body maximum strength
  - 1 to 3 RM leg press: performed at regular knee angles
  - 1-minute crunch and situp test: legs held down
  - Flexibility testing: hamstrings via sit-and-reach test
  - Specific functional performance measures as described: Single leg hop for distance, cross-over hop for distance, and triple hop for distance testing. Determine limb symmetry index (see previous).

Periodization

- Linear: preseason, in-season and postseason training

Program Design/Performance Training Program

Sport-Specific Concepts of Integrated Training

- Recommend this approach begin no sooner than 12 to 16 weeks post rehabilitation program (Table 31-5)
- Proprioception training via single leg balance and non-impact agility drills. Include sport-specific basketball coordination drills.
- Emphasis on return of cardiovascular function via cycling and initial strength training phases for endurance of lower extremity and trunk musculature performed in straight planes of movement

Table 31-5 Four-Month Plan (following completion of Acute Rehab Phase) for Return to Basketball After Osteochondral Allograft Transplantation

Month 1	Month 2	Month 3	Month 4 (approx. 8 months post surgical date)
Proprioception training via single leg balance and nonimpact agility drills. Include sport-specific basketball coordination drills. Emphasis on return of cardiovascular function via cycling and initial strength training phases for endurance of lower extremity and trunk musculature performed in straight planes of movement. Recommended strength training occurring 3 days per week. Monitor response at the knee for any adverse effects.	Retest all variables as conducted during baseline testing. Establish goals with athlete. Emphasis on core strengthening. Incorporate diagonal patterns of movement during single leg stance activities. Continue LE strengthening and progress resistance as appropriate. If available, introduce swimming for cardiovascular endurance. Increase cycle intensity to address endurance.	Retest all variables conducted during baseline testing. Establish new goals based on results. Based on results, modify strengthening or power emphasis as needed. Introduce snatch pulls and pressing snatch for balance and core stability/power training. Monitor knee response. Begin nonimpact pivot drills with basketball. Continue to progress lateral strengthening of the lower extremities.	Retest all variables conducted during baseline testing. Establish new goals based on results. Modify strengthening or power emphasis as needed and continue to increase resistance. Retest all variables with special emphasis on LSI index. If all criteria are met, consider return to full sport following the introduction of running, sprinting, cutting, and pivoting drills.

- Recommended strength training occurring 3 days per week. Monitor response at the knee for any adverse effects.

Training Principles Used in the Design of the Program

- Principle of progression
- Principle of individualization
- Principles of specificity—specific adaptation to imposed demands (SAID)

Application of Acute Training Variables

- Repetitions: used in this phase to increase endurance and therefore range in the higher numbers per set, as 10 to 12 repetitions
- Sets: used in this phase to increase endurance so greater number of sets at 3 per exercise
- Rest interval: Allow full recovery before beginning next set or exercise.
- Intensity: Lower intensity to allow return of endurance.
- Repetition tempo: slow
- Training frequency: recommend strengthening at 3 times per week in this phase with cardiovascular conditioning
- Training duration: based on athlete's individual ability
- Specific exercises used in the training: upper body strengthening, core strengthening, and lower extremity to include squats and general exercises.

Phase II (weeks 24 to 28 postoperative): Performance Enhancement Training Techniques

Periodization

- This phase begins at month 2 following the 12 to 16 week initial rehabilitation program and to continue with progression through month 3.
- Retest all variables as conducted during baseline testing. Establish new goals with the athlete and physician. Emphasize core strengthening and lower extremity strengthening.
- Linear

Program Design/Performance Training Program

Sport-Specific Concepts of Integrated Training

- Month 2: Begin diagonal patterns of movement during single leg stance activities. Continue LE strengthening and progress resistance as appropriate. If available, introduce swimming for cardiovascular endurance. Increase cycle intensity to address emphasis on power.
- Month 3: Based on results, modify strengthening or power emphasis as needed. Introduce snatch pulls and pressing snatch for balance and core stability/power training. Monitor knee response. Begin nonimpact pivot drills with basketball. Continue to progress lateral strengthening of the lower extremities.

Training Principles Used in the Design of the Program

- Principle of progression
- Principle of variation
- Principle of individualization
- Principles of specificity—(SAID)

Application of Acute Training Variables

- Repetitions: At month 3 begin decreasing repetitions as weight resistance is increased with strengthening to begin improving overall strength and power.
- Sets: Decrease sets by beginning to bring the muscles to fatigue with increased resistance.
- Rest interval: At month 3 begin decreasing rest intervals with cycle ergometry to introduce anaerobic training.
- Repetition tempo: quicker but controlled
- Training frequency: At month 3 increase to 4 days per week with strengthening remaining at three times per week.

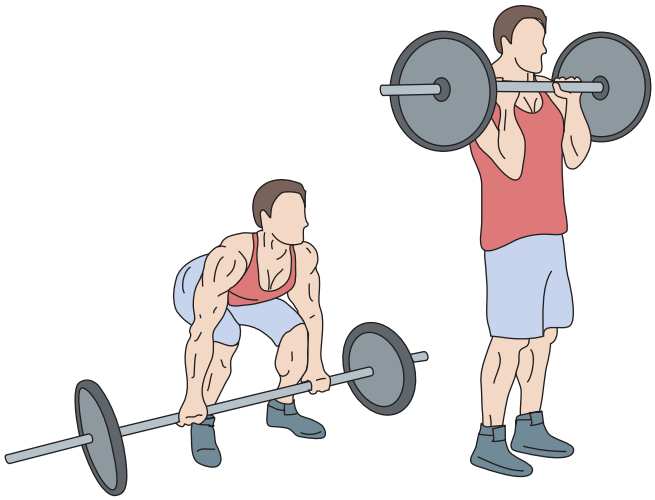

FIGURE 31-43. Power clean.

- Training duration: 60 minutes per session with intervals beginning at month 3
- Training volume
- Specific exercises used in the training: squats, single leg press, hamstring curls, bicep curls, tricep extensions; at month 3 begin power cleans (Figure 31-43), clean and jerks.

Phase III (weeks 28 to 32 postoperative): Sport-Specific Training

- Retest all variables conducted during baseline testing. Establish new goals based on results. Modify strengthening or power emphasis as needed and continue to increase resistance.
- Retest all variables with special emphasis on LSI. If all criteria are met, consider return to full sport following the introduction of running, sprinting, cutting, and pivoting drills.

Periodization

- Linear

Program Design/Performance Training Program

Sport-Specific Concepts of Integrated Training

- Neuromuscular dynamic stability exercises
- Training for speed, agility, quickness
- Plyometric training
- Functional training
- Sport-specific training

Olympic Lifts Used in the Training Program

- Snatch
- Clean and jerk
- Power clean

Training Principles Used in the Design of the Program

- Principle of overload
- Principle of individualization
- Principles of specificity—(SAID)

Application of Acute Training Variables

- Repetitions: to fatigue; lower reps 6 to 8 per set
- Sets: one to two sets per exercise to fatigue

TIMELINE 31-5: **Return to Basketball After Osteochondral Allograft Transplantation**

Phase I Initial Postrehabilitation Program (weeks 0 to 16 postoperative)			
Weeks 0 to 6	**Weeks 6 to 8**	**Weeks 8 to 12**	**Weeks 12 to 16**

• Non–weight-bearing
• Bracing
  • Week 0–1: Locked in full extension (remove only for CPM and exercises)
  • Week 2–4: Gradually open brace in 20 degree increments as quadriceps control is gained; discontinue when no quad lag is present with a straight leg raise
• ROM: CPM use for 6–8 hours per day; begin at 0–40°, increasing by 5–10° daily per patient comfort; gain 100° by week 6
• PROM/AAROM to tolerance
• Manual therapy: patellar and tibiofibular joint mobilizations (grades I/II)
• Strengthening: hamstring and gluteal sets, SLR
• Flexibility: hamstrings
	• Partial weight bearing (25%)
	• No brace
	• ROM: Gradually increase flexion; patient to have 130° of flexion
	• Active exercise: stationary bike for ROM, advance LE strengthening with WB precautions
	• Manual therapy: scar and patellar mobilizations
		• Gradually return to full weight bearing
		• ROM: progress to full and pain free AROM and PROM
		• Proprioception: Begin gait training.
		• Exercise: Begin closed chain activities (wall sits, shuttle leg press, mini-squats, calf raises, begin unilateral stance activities).
			• Weight bearing normal with normal gait pattern
			• ROM: full and pain free
			• Strengthening: Advance strengthening and exercise as tolerated.
			• Begin consideration of return to sport training as appropriate.

- Rest interval: no more than 30 seconds between exercises/drills
- Intensity: high
- Training frequency: 4 to 5 days per week with plyometrics introduced one day per week
- Training duration: 2 hours
- Specific exercises used in the training: Olympic style lifts, sprints, cutting and pivoting drills, specific basketball agility drills

Sports Performance Testing

General Information

- General history
- Subjective questionnaires
- Medical history
- Sports injury history
- Surgical history
- Chronic conditions/medication

Specific Tests

- Specific lower extremity functional testing that specifically includes single leg activities should be included once the athlete is cleared to begin single leg plyometric activity

Objective Tests

- Physiological assessments
- Body composition tests
- Static/dynamic postural assessments
- Dynamic muscle performance testing
- Movement performance testing
- Sport-specific testing: single leg hop for distance, triple hop for distance, crossover hop for distance

Specific Criteria for Progression to the Next Stage to Determine Readiness for Basketball

- Weekly evidence of improvement across all variables of strength, endurance and flexibility

Specific Criteria for Release to Unsupervised Complete Participation in Basketball

- The surgically repaired leg should perform at 90% of the uninjured leg on three tests before return to sport is considered: the single leg hop for distance, the triple hop for distance, and crossover hop for distance. Measuring this difference in limbs is referred to as the limb symmetry index.

Recommended Ongoing Exercises

- Strengthening of the lower extremities with periodized plyometric activity

Evidence

Blazevich AJ, Jenkins D: Physical performance differences between weight-trained sprinters and weight trainers. *J Sci Med Sport* 1(1):12–21, 1998.

Tests of strength and power are also included in most basketball conditioning programs, as resistance training has an important role in improving athletic power production. The use of Olympic style lifts is consistent with existing literature

TIMELINE 31-5: **Return to Basketball After Osteochondral Allograft Transplantation** (Continued)

PHASE I (16 to 24 weeks postoperative)		PHASE II (weeks 24 to 28 postoperative)	PHASE III (weeks 28 to 32 postoperative)
Weeks 16 to 20	**Weeks 20 to 24**		
• Initiate specific baseline testing with emphasis on functional strength testing of the lower extremities. • Proprioception training with unilateral stance • Nonimpact agility drills including sport specific basketball coordination drills • Cycle ergometry to improve endurance • Double leg and single leg strengthening, upper body and core strengthening in straight planes of movement	• Retest all baseline variables. • Core strengthening, incorporate diagonal patterns of movement during single leg stance activities, progress LE strengthening, increase cardio intensity, and begin anaerobic intervals with cycling	• Retest all baseline variables; LE strength improving to 70% of noninvolved LE with single leg hop tests. • Begin emphasis on power; introduce Olympic style lifts for LE strength. • Power cleans, clean and jerk, snatch pulls • Emphasis on balance and core strength with power • Begin nonimpact pivot drills with basketball. • Progress lateral strengthening with cutting and pivoting. • Begin double leg/single leg jump drills.	• Retest all variables; LE strength at or approaching 90% of noninvolved LE with single leg hop tests • Emphasize any specific areas that require further training in strength, power, or proprioception. • Begin full running, pivoting, and sprinting drills.

relating to the large anaerobic and power components needed for basketball performance. (Level 3 evidence)

Ebben WP, Blackard DO: Strength and conditioning practices of National Football League strength and conditioning coaches. *J Strength Cond Res* 15(1):48–58, 2001.

Variations of Olympic lifts and squats remain the most commonly used strengthening exercises, consistent with what has been previously reported in surveys of professional athletes. (Level 5 evidence)

Fleck S: Periodized strength training: A critical review. *J Strength Cond Res* 13(1):82–89, 1999.

Periodization of conditioning programs is also employed to allow progressive cycling of various aspects of training in regard to intensity and frequency of training. The main aim of periodization is to allow peak training effects to occur at a critical time in the sport season. (Level 4 evidence)

McInnes SE, Carlson JS, Jones CJ, et al: The physiological load imposed on basketball players during competition. *J Sports Sci* 13(5):387–397, 1995.

McInnes and colleagues demonstrate that basketball is comprised of approximately 1000 changes of movement patterns occurring on average every 2 seconds. As well, 30% of these total movements occur in a lateral fashion with another 10% being short, direct sprints. The specific position of the player should be taken into consideration as forwards or centers may jump slightly more than those in the position of guard who typically may not spend as much time under the basket retrieving rebounds. (Level 4 evidence)

Mithoefer K: High-impact athletics after knee articular cartilage repair: A prospective evaluation of the microfracture technique. *Am J Sports Med* 34(9):1413–1418, 2006.

Mithoefer et al. completed a systematic analysis of the literature for athletes who had undergone articular cartilage repair, with results stating a return to sport was possible in 73% of the athletes who were reviewed with a 65% preinjury participation level. The overall time to return to sport varied from 7 to18 months and was dependent on the type of chondral repair performed. (Level 4 evidence)

Mithoefer K, Hambly K, Della Villa S, et al: Return to sports participation after articular cartilage repair in the knee: Scientific evidence. *Am J Sports Med* 37:167–175, 2009.

Mithoefer et al. conducted a systematic review of twenty studies describing 1363 patients with the time for return to sport between 7 and 18 months. However, it should be noted that this review included techniques such as microfracture, autologous chondrocyte transplantation, and osteochondral autograft transfer. The average length of time for return following osteochondral autograft transfer was 7 ± 2 months in this study. The longest amount of time before full return to sport for the osteochondral autograft transfer was found to be 18 ± 4 months. It should also be noted that of the factors, age demonstrated the greatest effect on full return to preinjury level sport participation, with 90% of athletes younger than 30 years of age returning to full participation, whereas only 23% of older athletes were able to return to preinjury levels. (Level 2 evidence)

Myer GD, Schmitt LC, Brent JL, et al: Utilization of modified NFL combine testing to identify functional deficits in athletes following ACL reconstruction. *J Orthop Sports Phys Ther* 41(6):377–387, 2011.

Myer and colleagues provide some guidance to fulfill this deficit in the literature regarding unilateral functional lower extremity testing. In a 2011 study the investigators utilized modified NFL combine testing methodology to test functional deficits in athletes following ACL reconstruction after release to sport against a group of controls who had not undergone ACL reconstruction. The tests compared single leg functional tasks with double leg tasks to distinguish deficits between the two groups. Functional testing included the broad jump, vertical jump, modified long shuttle, modified pro shuttle, modified agility t-test, timed hop, triple hop, single hop, and crossover hop tests. The results of this study confirmed that athletes who had undergone ACL reconstruction and who had been returned to sport continued to demonstrate unilateral functional testing deficits that were not evident when double-limb performance activities were utilized. (Level 3 evidence)

Noyes FR, Barber SD, Mangine RE: Abnormal lower limb symmetry determined by function hop tests after anterior cruciate ligament rupture. *Am J Sports Med* 19:513–518, 1991.

Noyes recommends that the surgically repaired leg should perform at 90% of the uninjured leg before return to sport is considered. Measuring this difference in limbs is referred to as the limb symmetry index (LSI), which is calculated by dividing the distance hopped on the involved lower extremity by the distance hopped on the uninvolved lower extremity and then multiplying this number by 100% (involved side performance/uninvolved side performance × 100%). (Level 3 evidence)

Simenz CJ, Dugan CA, Ebben WP: Strength and conditioning practices of National Basketball Association strength and conditioning coaches. *J Strength Cond Res* 19(3):495–504, 2005.

In an article published by Simenz in 2005, the basic practices of strength and conditioning coaches were investigated in the National Basketball Association. Twenty-nine strength and conditioning coaches were surveyed with a return rate of 68.9%. This study demonstrates that strength and conditioning coaches assess an average of 7.3 parameters of fitness, with body composition being one of the most common. All coaches used a variety of flexibility development strategies. 95% of coaches in this study indicated that their athletes used Olympic-style lifts, whereas all coaches used plyometric exercises with their athletes. Seventeen of 20 coaches used a periodization model to train their athletes across all parameters necessary for top conditioning. (Level 5 evidence)

Multiple-Choice Questions

QUESTION 1. What are the limitations of bilateral functional testing for athletes?

A. Length of time to complete tests
B. Strength deficits are not evident
C. Too many tests to consider
D. Tests are too hard for athletes to perform.

QUESTION 2. One of the most important considerations for returning an athlete to basketball following an OA procedure is:

A. The athlete's motivation to return to sport
B. The demands of the coach
C. The athlete's ability to perform sport specific demands safely
D. The current status of the repair

QUESTION 3. A recommended level of performance of the involved extremity with single leg hop functional tests is

A. 65% of the distance of the non-involved lower extremity.
B. 85% of the distance of the non-involved lower extremity.
C. a one-second hold being maintained on the involved lower extremity.
D. 90% of the distance of the noninvolved lower extremity.

QUESTION 4. The most significant measure of outcome for an OATs procedure in the basketball athlete is:

A. No knee pain when using stairs
B. Being able to run pain free
C. Jumping without knee pain or swelling
D. Full return to basketball

QUESTION 5. The limb symmetry index is a measure of what?

A. Girth of the quadriceps musculature
B. A measurement of strength
C. Measure of one leg to hop the same distance as the other
D. An index of limitations in leg balance

Answer Key

QUESTION 1. Correct answer: B (Review section on functional testing)

QUESTION 2. Correct answer: D (Review section on postoperative recommendations)

QUESTION 3. Correct answer: D (Review section on functional testing)

QUESTION 4. Correct answer: D (Review section on measurement of skills and movement)

QUESTION 5. Correct answer: C (Review section on functional testing)

Chapter 32

Anterior Cruciate Ligament Injuries

INTRODUCTION

J. Martin Leland, MD

Epidemiology

- Anterior cruciate ligament (ACL) ruptures are common athletic injuries with over 100,000 reconstruction surgeries performed annually in the United States
- ACL ruptures most commonly occur in cutting/pivoting sports, such as soccer, basketball, volleyball, and football
- The most common mechanism for ACL ruptures is a noncontact valgus rotational injury to the knee
- Women, especially those participating in soccer and basketball, are three times more likely to rupture their ACL than their male counterparts
- Athletes of any age can rupture their ACL. While ACL ruptures are most commonly seen in the second and third decades of life, this is most likely as a result of the more aggressive nature of athletic participation in younger athletes.

Pathophysiology

Intrinsic Factors

- Numerous intrinsic factors have been postulated for increasing the risk of ACL rupture including:
  - Deconditioned athletes
    - Do not have proper muscular co-contraction (normally aides in stabilization of the knee)
  - Athletes with poor jumping mechanics
    - Those who land with knees in a valgus position—most often encountered in female athletes
    - Risk may be decreased by participating in programs focused on neuromuscular training and ACL injury prevention, such as Cincinnati sportsmetrics and PEP (prevent injury enhance performance)
  - Knees with:
    - Intercondylar notch stenosis
    - Increased posterior tibial slope
    - Increased quadriceps (Q) angle
  - Estrogen's effect on increasing soft tissue laxity in female athletes

Extrinsic Factors

- Any sporting equipment that does not allow the foot to slide out when an athlete begins to fall and instead, transmits the forces through the knee
  - First generation AstroTurf (high coefficient of friction)
  - More cleats, larger cleats, and dry climates
  - Ski bindings that do not release properly
- "Chop blocking" (blocking below the knees) in football

Traumatic Factors

- Noncontact injuries (approximately 70%)
  - Deceleration combined with a sudden change in direction over a planted foot
  - Valgus rotational injury to the knee
  - Knee hyperextension
- Contact injuries (approximately 30%)
  - Direct blow to the knee

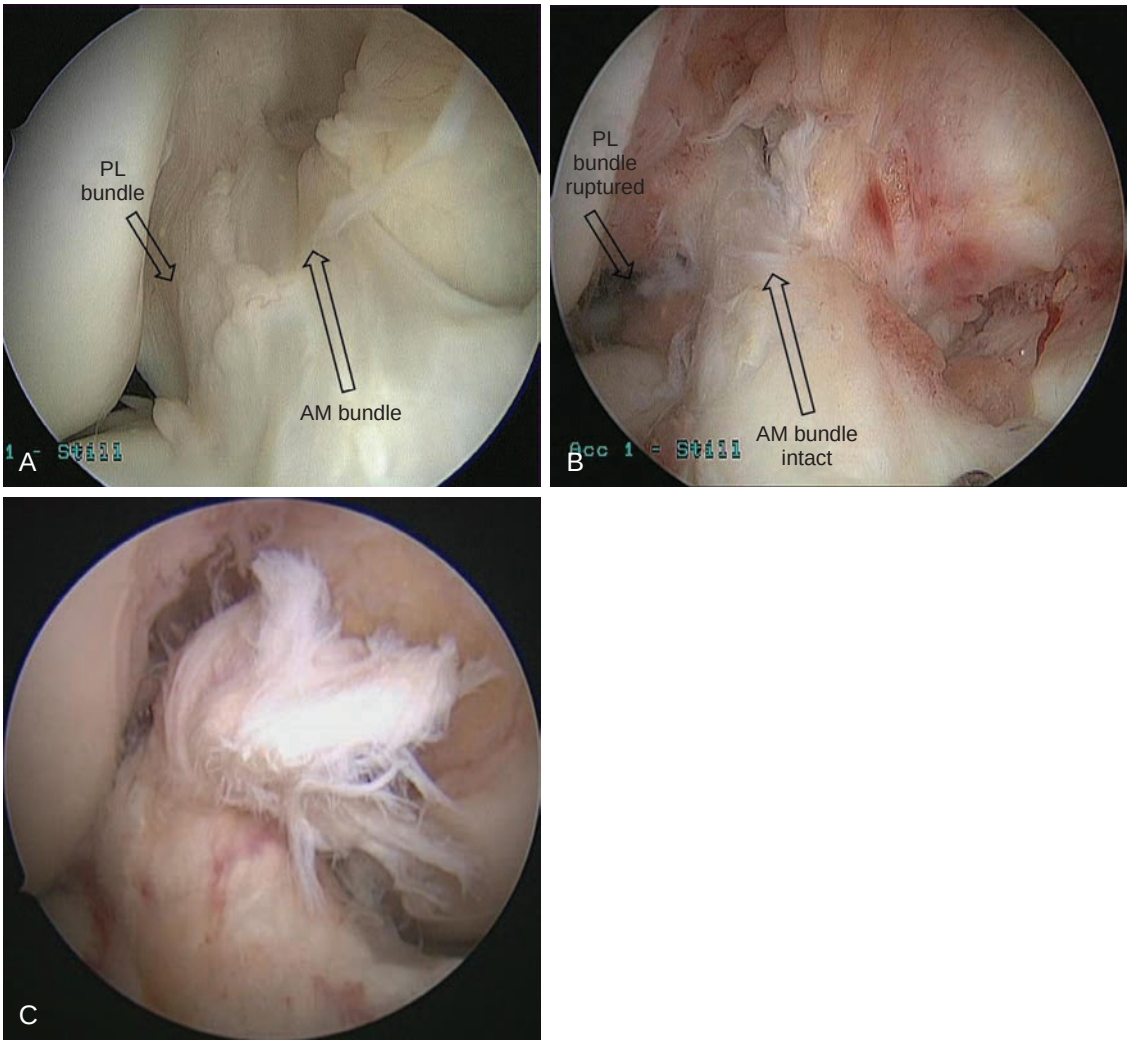

FIGURE 32-1. Arthroscopic images of an intact anterior cruciate ligament (ACL), single-bundle rupture, and complete rupture. (**A**) Intact, native ACL. The anteromedial (AM) and posterolateral (PL) bundles are labeled and have arrows running in the direction of the fibers of the individual bundles. (**B**) Posterolateral single-bundle ACL rupture. The anteromedial bundle is intact. (**C**) Complete rupture of the ACL (both bundles are ruptured). In this case, the ACL was ruptured at its femoral insertion.

Classic Pathological Findings

- The pathological findings of this injury include a partial or complete rupture of one bundle (anteromedial or posterolateral) or both bundles of the anterior cruciate ligament (Figure 32-1).
- Lateral-sided, direct injuries may lead to a Terrible Triad of the knee: ACL rupture, MCL rupture, and lateral meniscal tear
  - Lateral meniscal tears are more common in acutely-torn ACL injuries
  - Medial meniscal tears are more common in chronically-torn ACL injuries
- Other concomitantly-torn ligaments in the knee, in order of decreasing frequency:
  - Medial collateral ligament (MCL)
  - Posterior cruciate ligament (PCL)
  - Lateral collateral ligament (LCL)
- Other concomitant injuries can include:
  - Meniscal injuries (as mentioned above)
  - Cartilage injuries
  - Capsular injuries
  - Patellar dislocations

Clinical Presentation

History

- While there is a wide variety of presentations following ACL injury, typical complaints include:
  - Recollection of a specific contact or noncontact injury to the knee, frequently associated with pivoting on the knee or landing from a jump
  - Report of having heard a pop or felt the knee buckle
  - Immediate difficulty bearing weight on the injured knee and inability to continue athletic participation
  - Development of a large effusion of the knee 2 to 12 hours after injury
  - Knee stiffness for 1 to 2 weeks following injury (a result of the effusion)

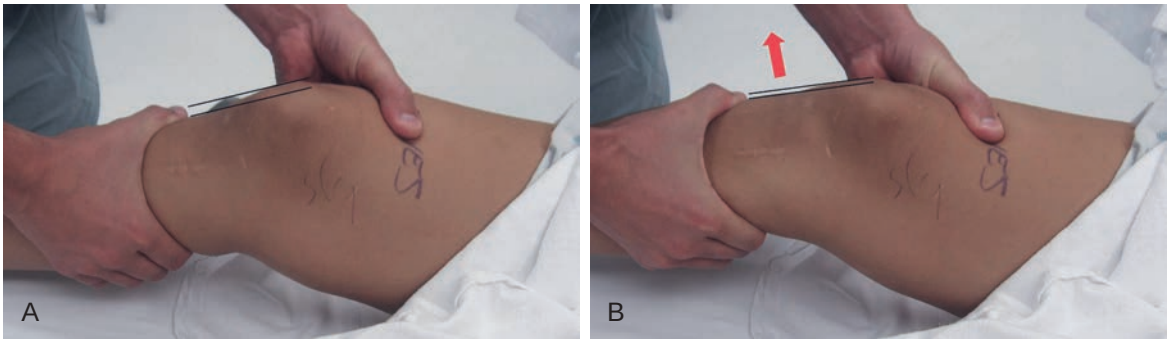

FIGURE 32-2. Positive Lachman test. (**A**) No forces are being applied. (**B**) The tibia is being pulled anteriorly. The black lines represent the relationship between the anterior aspect of the tibia and the anterior aspect of the patella (used as a consistent landmark between the two images). Note how the black lines show the tibia moves anteriorly in relation to the patella (and, therefore, the femur).

- After primary injury, recurrent instability or swelling with pivoting activities

Physical Examination

Abnormal findings

- Present if examined within a week of injury
  - Large knee hemarthrosis
  - Stiffness of the knee, lacking terminal flexion and extension
- Present if a relaxed examination of the knee is possible
  - Positive Lachman test (Figure 32-2)
  - Positive anterior drawer
  - Positive pivot shift

Pertinent normal findings

- Negative valgus and varus stress tests
- Negative posterior drawer
- Negative patellar apprehension
- Painless arc of motion (normally from approximately 25° to 75° of flexion)
- Ability to hold leg extended against gravity
- No palpable defects or crepitus

Imaging

- Radiographs
  - Should be negative
    - No subluxations/dislocations evident
    - No fractures
  - Positive findings
    - Effusion
    - Segond fracture: Anterolateral tibial capsular avulsion highly associated with ACL injuries (Figure 32-3)
    - Anterior tibial spine avulsion: ACL tibial avulsion (Figure 32-3)
- Magnetic resonance imaging (MRI)
  - Confirm ACL rupture
    - Disruption of ACL fibers (Figure 32-4) or tibial avulsion
    - Bone bruises (subcortical microfractures) commonly present in central aspect of lateral femoral

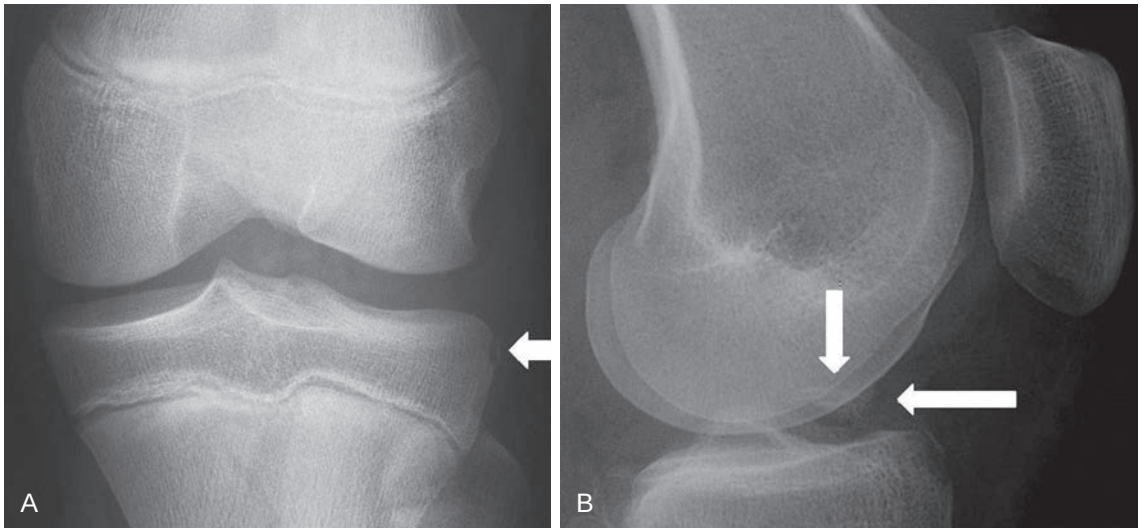

FIGURE 32-3. Radiographs of a Segond fracture and an anterior tibial spine avulsion. (**A**) Anteroposterior radiograph of a skeletally immature knee showing an anterolateral tibial capsular avulsion marked with a white arrow (Segond fracture). These avulsions are highly associated with anterior cruciate ligament (ACL) injuries. (**B**) Lateral radiograph of a skeletally mature knee showing an anterior tibial spine avulsion marked with white arrows. These avulsions occur when the ACL avulses a tibial fragment instead of rupturing midsubstance.

FIGURE 32-4. MRI of an ACL rupture. Sagittal, nonfat suppressed T2-weighted MRI showing a ruptured ACL marked with white arrows.

condyle and posterior aspect of lateral tibial plateau
- Diagnose other concomitant injuries (as listed above)

Differential Diagnosis

- Isolated meniscal tear: small effusion; negative Lachman/anterior drawer/pivot shift; tenderness over medial or lateral joint line; positive McMurray test
- Patellar dislocations: report of having observed patella dislocated laterally and subsequent reduction; increased lateral patellar translation; positive patellar apprehension
- Medial collateral ligament injuries: medial-sided pain and swelling; pain or instability with valgus stress test at 30°
- Posterior cruciate ligament injuries: positive posterior drawer; positive tibial sag sign
- Posterolateral corner injuries: lateral-sided pain and swelling; pain or instability with varus stress test at 30°; positive dial test at 30°; possible fibular head avulsion seen on radiographs
- Fractures of the patella, distal femur, or proximal tibia (including osteochondral injuries): positive crepitus or palpable deformity; pain with any range of motion of knee; fracture seen on radiographs
- Patellar tendon/Quadriceps tendon rupture: inability to hold leg extended against gravity; palpable defect in tendon

Treatment

Nonoperative Management

- Rest/ice/compression/elevation (RICE) and NSAIDs to help with acute pain and effusion
- Range of motion exercises to regain motion
- Quadriceps and hamstring strengthening exercises (focus on hamstrings to pull tibia posteriorly)
- ACL-deficient bracing may be helpful in stabilizing the knee during moderate- or low-intensity activities

Guidelines for Choosing among Nonoperative Treatments

- All patients should be initially treated with nonsurgical options to decrease pain and swelling and increase range of motion
  - Patients who undergo ACL reconstruction while their knee has an effusion and limited range of motion generally have more difficulty regaining motion postoperatively
- Patients unwilling or unable to undergo ACL reconstruction should proceed with nonsurgical treatment

Surgical Indications

- There are no absolute indications for ACL reconstruction
- Relative indications:
  - High activity level athletes
  - Recurrent instability
  - Concomitant ligament injury
  - Concomitant unstable, vertical meniscal tears
- Contraindications:
  - Infection
  - Fracture (other than tibial spine avulsion or osteochondral fragment)
  - Neurovascular compromised extremity
  - Unstable medical comorbidities
  - Open wounds around the knee
  - Unwilling/unable to follow postoperative rehabilitation protocols

Aspects of History, Demographics, or Exam Findings that Affect Choice of Treatment

- Age and activity level
  - Younger, higher-demand athletes, and those who tear their ACL during sport participation usually require ACL reconstruction in order to return to high-level activities
  - Older, lower-demand individuals usually do not require ACL reconstruction to return to low-demand activities. ACL is required for rotational stability of the knee and is not necessary for walking, stair-climbing, and low-demand in-line activities
- Willingness to modify activities
  - Individuals willing to modify their level of activity to moderate or lower levels may successfully be treated with nonoperative therapy
- Degree of instability of the knee
  - Recurrent instability with lower levels of activity, such as light dancing, may require ACL reconstruction in order to continue such activities
- Concomitant injuries
  - Large, unstable vertical meniscal tears
    - Meniscal repairs performed in ACL-deficient knees have a high incidence of reinjury. Options include meniscal repair in association with ACL reconstruction or meniscectomy.

- Multiligament injured knee
  - Knees with multiple injured ligaments are often more unstable and frequently require multiligament reconstruction

Aspects of Clinical Decision-Making When Surgery is Indicated

- Graft use
  - Autograft options: patellar tendon, hamstrings, quadriceps tendon
    - Increased pain postoperatively from donor site
  - Allograft options: patellar tendon, hamstrings, Achilles, anterior tibialis, posterior tibialis
    - Risk of disease transmission

    HIV: approximately 1 in 1.5 million

    Hepatitis C: approximately 1 in 150,000
    - Recent literature has shown higher re-rupture rates following allograft ACL reconstruction in patients under 25 years old
- Tunnel placement
  - Anatomic versus nonanatomic
    - Current literature supports anatomic tunnel drilling to increase rotational stability of the knee and improve functional results
- Single bundle versus double bundle reconstruction
- Method of graft fixation
  - Cortical: suspensory button; cross-pin; screw and washer; staple
  - Aperture: interference screw

Evidence

Ferretti M, Ekdahl M, Shen W, et al: Osseous landmarks of the femoral attachment of the anterior cruciate ligament: an anatomic study. *Arthroscopy* 23:1218–1225, 2007.

The femoral attachment of the ACL was studied histologically in seven human fetuses, arthroscopically in 60 ACL surgeries, and grossly in 16 cadaveric knees. Two different osseous landmarks were detected: the lateral intercondylar ridge (present in 100%) and the lateral bifurcate ridge (present in 80%).

Hewett TE, Myer GD, Ford KR, et al: Biomechanical measures of neuromuscular control and valgus loading of the knee predict anterior cruciate ligament injury risk in female athletes: A prospective study. *Am J Sports Med* 33:492–501, 2005.

Female soccer, basketball, and volleyball athletes were prospectively measured for neuromuscular control during a jump-landing task. Of the female athletes who subsequently sustained ACL ruptures, greater knee abduction angles at landing and higher ground reaction forces were observed. (Level II evidence)

Hussein M, van Eck CF, Cretnik A, et al: Prospective randomized clinical evaluation of conventional single-bundle, anatomic single-bundle, and anatomic double-bundle anterior cruciate ligament reconstruction: 281 cases with 3- to 5-year followup. *Am J Sports Med* 40:512–520, 2012.

ACL reconstruction patients were prospectively randomized into three groups: anatomic double bundle (ADB), anatomic single bundle (ASB), and conventional (transtibial) single bundle (CSB). ADB and ASB reconstructions were significantly superior to CSB reconstructions in terms of AP and rotational stability. ADB was also more stable than ASB, but these differences were small and may not be clinically relevant. (Level I evidence)

Hwang MD, Piefer JW, Lubowitz JH: Anterior cruciate ligament tibial footprint anatomy: Systematic review of the 21st century literature. *Arthroscopy* 28:728–734, 2012.

This systematic review examined 17 original articles published between 2000 and 2010 which described the ACL tibial footprint. They concluded that the anatomic center of the ACL tibial footprint was 15 mm anterior to the PCL (the most consistent arthroscopic landmark) and two-fifths the medial-lateral width of the interspinous distance.

Kopf S, Musahl V, Tashman S, et al: A systematic review of the femoral origin and tibial insertion morphology of the ACL. *Knee Surg Sports Traumatol Arthrosc* 17:213–219, 2009.

This systematic review examined 20 studies published before 2009 which described the anatomy of the ACL. They found a high diversity in size, shape, origin, and insertion of the ACL. They concluded that the use of anatomical landmarks and remnant tissue were the most reliable means of assessing anatomic origins.

Mandelbaum BR, Silvers HJ, Watanabe DS, et al: Effectiveness of a neuromuscular and proprioceptive training program in preventing anterior cruciate ligament injuries in female athletes: 2-year follow-up. *Am J Sports Med* 33:1003–1010, 2005.

Female soccer players between 14 and 18 years old underwent a neuromuscular and proprioceptive sport-specific training program and were compared to a control group. The intervention group had a 74% to 88% reduction in anterior cruciate ligament injuries compared to the control group. (Level II evidence)

Prodromos CC, Han Y, Rogowski J, et al: A metaanalysis of the incidence of anterior cruciate ligament tears as a function of gender, sport, and a knee injury-reduction regimen. *Arthroscopy* 23:1320–1325, 2007.

This metaanalysis examined ACL injury rates as a function of gender, sport, and prior injury-reduction training. Female/male ACL tear incidence ratios were as follows: basketball, 3:5; soccer, 2:67; lacrosse, 1:18; and Alpine skiing, 1:0. Injury-reduction programs were shown to be effective for soccer but not basketball. (Level IV evidence)

Multiple-Choice Questions

QUESTION 1. What is the most common mechanism for an ACL rupture?

A. Noncontact hyper-extension injury
B. Direct, lateral-sided injury
C. Noncontact valgus rotational injury
D. Direct anterior injury

QUESTION 2. In patients with ACL injuries, which other ligament of the knee has the highest rate of concomitant injury?

A. Medial patellofemoral ligament
B. Posterior cruciate ligament
C. Lateral collateral ligament
D. Medial collateral ligament

QUESTION 3. Which of the following increases an athlete's risk of rupturing their ACL?

A. Being a 37-year-old basketball player
B. Being a male ice hockey player
C. Returning to play after a high ankle sprain
D. Playing sports on modern artificial turf (infill surfaces)

QUESTION 4. Which of the following is commonly found in patients with acute ACL ruptures?

A. Inability to hold the leg extended against gravity
B. Painless arc of motion
C. Lack of effusion
D. Inability to recall a specific injury

QUESTION 5. Which of the following is LEAST helpful in making the diagnosis of an ACL rupture?

A. Magnetic resonance imaging
B. Radiographs
C. Physical examination
D. Computed tomography

Answer Key

QUESTION 1. Correct answer: **C** (see Epidemiology)

QUESTION 2. Correct answer: **D** (see Pathophysiology)

QUESTION 3. Correct answer: **C** (see Epidemiology and Pathophysiology)

QUESTION 4. Correct answer: **B** (see Clinical Presentation)

QUESTION 5. Correct answer: **D** (see Clinical Presentation)

NONOPERATIVE AND PREOPERATIVE REHABILITATION OF ANTERIOR CRUCIATE LIGAMENT INJURIES

David Logerstedt, PT, PhD, MPT, MA, SCS, Kathleen White, PT, PhD, DPT, Michael J. Axe, MD, and Lynn Snyder-Mackler, PT, ScD, SCS, ATC, FAPTA

GUIDING PRINCIPLES OF NONOPERATIVE REHABILITATION

- Rehabilitation should be progressed based on clinical milestones (time frames are included to guide progression)
- Rehabilitation strives to restore clinical and functional limb-to-limb symmetry
- Patients can return to previous levels of activity for short periods of time upon completion of rehabilitation that includes perturbation training

Phase I (weeks 0 to 3)

Protection

- Isolated ACL injuries do not require bracing for performance of ADLs and acute traditional isolated treatment.
- Execution of dynamic weight-bearing tasks, such as hopping tasks and agility drills, are often completed with a brace. Variations with this are often surgeon preference.

TIMELINE 32-1: Nonoperative and Preoperative Rehabilitation of Anterior Cruciate Ligament Injuries

PHASE I (weeks 0 to 3)	PHASE II (weeks 4 to 8)	PHASE III (weeks 9 to 12)
• Crutches: DC when ambulating with normal gait pattern • Brace • ROM through full range equal to contralateral knee • Manual therapy techniques • Stretching • ROM exercises • Quadriceps muscle activation • NMES if QI < 80% • OKC/CKC exercises • Functional exercises • TLS activities as recommended and tolerated	• Brace • Stretching • Quadriceps muscle activation • NMES if QI < 80% • OKC/CKC exercises • Perturbation training • Functional exercises • Agility training • TLS activities as recommended and tolerated	• Brace • Stretching • OKC/CKC exercises • Functional exercises • Walk/jog running progression • Sport-specific exercises

- Crutches may be used initially to assist with a normalized gait patterns after initial injury as well as to control knee-joint effusion.
- In patients with multiligamentous injuries and/or chondral deficiencies, bracing may be indicated.
- Individuals with potential repairable meniscal injuries are not recommended to participate in hopping activities as this puts them at higher risk for an extension of their initial injury.

Management of Pain and Swelling

- Effusion management is critical for these patients in the acute stage of rehabilitation. The modified stroke technique is used to objectively measures effusion.[1] This technique has substantial agreement between raters (interrater reliability).
- Effusion should be evaluated at every session, and treatment programs should be modified accordingly. For example, if a patient has an increase in effusion grades after a rigorous therapy session, then the treatment should not be progressed until the effusion has decreased.
- The modified stroke technique measures effusion on a 5-point scale (Table 32-1). Fluid must be pushed out of the medial sulcus of the knee superiorly followed by an inferior sweep of the lateral knee. The amount of fluid that refills the medial sulcus is used to determine the grade of effusion; 3+ effusion is the inability to move the fluid out of the medial sulcus. If fluid is moved out of the medial sulcus and then spontaneously refills the space, this is graded 2+ effusion. If the lateral stroke is completed and a large amount of fluid refills the medial sulcus, this is graded 1+ effusion. If only a small amount of fluid refills the medial sulcus, this is graded trace effusion. If the lateral sweep is completed and no fluid refills the medial sulcus, this is graded a zero-grade effusion.
- Increased effusion is a limiting factor for progression through rehabilitation. It is essential for patients to take steps on their own, as well as in the clinic, to manage knee-joint effusion.
- Patients should be instructed to ice the knee while the leg is elevated above the level of the heart with increased compression around the joint. Patients should be instructed to ice and elevate after activities and at the end of the day.

Table 32-1 Effusion Grades

Grade	Description
3+	Unable to move the fluid out of the medial sulcus
2+	Fluid is pushed out of the medial sulcus but immediately refills without the lateral stroke
1+	Large amount of fluid refills the medial sulcus with the lateral stroke
Trace	Small amount of fluid refills the medial sulcus with the lateral stroke
Zero	No fluid is present with the lateral stroke

(From Sturgill LP, Snyder-Mackler L, Manal T, Axe MJ: Interrater reliability of a clinical scale to assess knee joint effusion. J Orthop Sports Phys Ther 39, 846, 2009.)

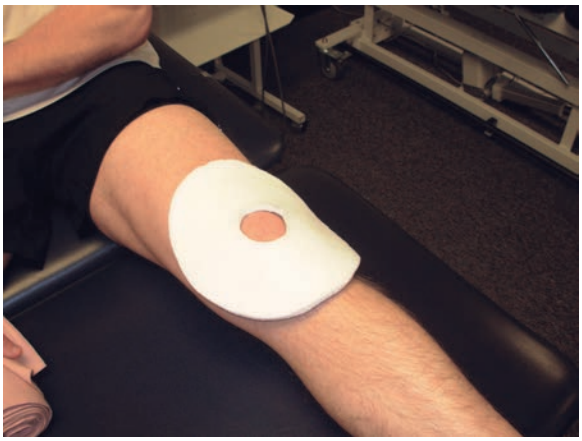

FIGURE 32-5. Donut for controlling knee effusion.

- If the patient continues to have persistent effusion, an additional donut is used to provide additional compression while the patient is completing daily tasks throughout the day in a dependent position. The donut is an oval shape with the inner most part removed as this space is made for the patella (Figure 32-5). This should be applied to the knee and then an additional wrap or bandage is used to hold it in place.
- This additional compression around the knee will assist in limiting increases in knee-joint effusion throughout the day. If patients are compliant with this method, it is effective in reducing the knee-joint effusion.
- Complaints of pain are most prominent in Phase I of rehabilitation. Pain can be resolved with the use of medications and modalities, such as ice, TENS, and noxious stimulation.
- Noxious stimulation (50 pulses per second, 12 seconds on, 8 seconds off, 2 seconds ramp) should be used for isolated areas of irritation to noncontractile tissues, such as fat pad irritation, patellar tendon inflammation, and joint line pain.

Techniques for Progressive Increase in Range of Motion

Manual Therapy Techniques

- To assist with knee-joint effusion management, retrograde massage can be performed by providing effleurage massage techniques from distal to proximal to move to fluid out of the affected area. This should be performed in addition to effusion management techniques listed above.
- For deficits with range of motion, manual techniques should be used.
- Overpressure to the tibiofemoral joint at end ranges of motion in both flexion and extension can be performed to increase knee range of motion.
- Mobility of the patella should also be evaluated to assist with a proper superior and inferior glides of the patella. Good mobility of the patella in the superior direction will allow for improved quadriceps contraction, while good patellar mobility in the inferior direction is essential for achieving full knee flexion range of motion.

Stretching and Flexibility Techniques for the Musculotendinous Unit

- Often, limitations in range of motion are caused by soft tissue musculotendinous restrictions.
- Flexibility of muscles that cross the knee joint should be evaluated and stretching should be completed where limitations exist.
- Flexibility limitations often occur in to the hamstrings, quadriceps, and triceps surae muscles. Stretching of these muscles should be done daily to improve and maintain flexibility after injury. Stretches can be held for 30 seconds and repeated at least 3 times. Additional stretching may be needed for some patients, and patient's tolerance should be considered.

Other Therapeutic Exercises

- Stationary cycling
- Classification screening
- Within 6 months of initial injury, classification of the patients with ACL deficiency should be performed using objective measures.
- A screening classification system has been developed to determine which active individuals with an ACL injury have a good probability of returning to high level of functioning without operative management for short periods of time, such as to complete a sports season.[2]
- Athletes classified as potential copers who received perturbation training are more likely to return to high-level activities in the short term than those who received standard training.[3]
- Noncopers have the potential to return to their previous activity level but only after undergoing lengthy rehabilitation.[4]
- The screening examination[2] consists of 6-meter timed hop[5]; patient reported outcome measures with the knee outcome survey, activities of daily living scale (KOS-ADLS)[6] and global rating scale of perceived function[2] and the number of episodes of giving way.
- For patients to be eligible to complete the screening exam, they must demonstrate less than 1+ knee-joint effusion, normalized knee range of motion, quadriceps strength measure 70% or greater compared to the contralateral limb with maximal voluntary isometric contraction with a central activation ratio of 95% or more with burst superimposition test[7] and no complaints of pain with single-legged hopping. The burst superimposition test[8] is completed with an electromechanical dynamometer with patients seated in an upright position and their hip and knee flexed to 90°. A supramaximal burst of electrical stimulation is given to the patient while they are actively contracting their quadriceps. If the patient is able to give a true maximal contraction, then no increase in force from the stimulation will be produced. This is reported as the central activation ratio and should be 95% or greater.[7]
- Potential copers are classified based on the following criteria: one or less episode of giving way, 80% or more on 6-meter timed hop test compared to the contralateral limb, 80% or more on KOS-ADLS, and 60% or more on global rating score (Table 32-2). Failure to meet any of these criteria will classify the patient as a noncoper.[2]

Table 32-2 Screening Classification[2]

	Potential Coper	Noncoper
Episodes of giving way	≤ 1	Failure to meet any of these criteria
6-m hop test	≥ 80% timed	
KOS-ADLS score	≥ 80%	
Global rating score	≥ 60%	

Activation of Primary Muscles Involved

- Quadriceps activation deficits are most prominent in Phase I of rehabilitation. Neuromuscular electrical stimulation may be used as an effective tool to improve quadriceps activation. High intensity setting (2500 Hz, alternating current at 75 burst per second, 10 to 15 seconds on with 50 second rest period) should be performed isometrically, with the knee flexed to 90° for 10 repetitions, 3 to 5 times per week.[9,10]
- This can also be used with active quadriceps contraction during a quadriceps setting exercise[11] or straight leg raise.
- Isotonic exercises, such as open chain knee extension exercises, may be used to increase quadriceps muscle activation.
- Additionally, isokinetic strength training has been found to increase quadriceps strength.[12]

Range of Motion Exercises

- Range of motion limitations are addressed using several techniques. Along with manual techniques, additional exercises can be completed by the patient to improve range of motion deficits.
- Knee extension:
  - Prone passive hangs with weight around ankle
  - Seated knee extension hangs with weight on knee joint
- Knee flexion:
  - Supine heel slides with heel on the table or the wall
  - Prone knee flexion stretching
  - Seated knee flexion stretching in closed chain

Open and Closed Kinetic Chain Exercises[13]

- Open Kinetic Chain (OKC)
  - Quadriceps setting: Quadriceps setting should be initiated with the patient in long sitting. Verbal and tactile cueing can be given from the rehabilitation specialist to isolate the quadriceps muscle and limit cocontraction of the hamstrings, quadriceps, and gastrocnemius. Patients should be instructed to perform 50 repetitions of quadriceps sets up to 5 to 10 times a day. This exercise can be progressed to standing to provide an additional weight-bearing component.
  - Straight leg raise (SLR): The SLR exercise can be completed with the quadriceps setting exercise. Patients should complete a quadriceps set first and then complete the SLR. A sign of quadriceps weakness is a quadriceps lag while the patient is completing the SLR exercise. Patients can complete 3 sets of

10 repetitions. This can be progressed with the addition of ankle weights as well as sets and repetitions.
  - Seated knee extension (long arc quadriceps (LAQ)): Unilateral LAQs can be completed with the patient seated at 90° of hip and knee flexion. Patients should be encouraged to complete the exercise through the entire range of motion since at this phase of rehabilitation, no range of motion restrictions are present. Patients can complete 3 sets of 10 repetitions and progression of resistance and volume should be done to challenge the patient. If patients complain of anterior knee pain with this exercise, knee extension can be initiated at 60° of flexion or a pain-free range. This exercise should be discontinued if patients report a worsening of knee symptoms, and the rehabilitation specialist should reassess for additional impairments.
- Closed Kinetic Chain (CKC)
  - Sit-to-stand activities: Sit-to-stand activities should be performed in front of a mirror for visual feedback. If one is not available, verbal and tactile feedback can be given by the rehabilitation specialist. Patients should be able to complete this task with symmetrical weight through the lower extremities and minimal trunk shifting. Patients can begin with 1 set of 10 repetitions and progress to 3 sets of 10 to 15 repetitions. The height of the sit-to-stand surface can also be lowered to provide an additional challenge to the patient.
  - Leg press: The leg press should be completed with the involved limb only if tolerated by the patient. Assist from the uninvolved limb may be needed if the patient is affected shortly after injury. Patients can complete this exercises with 3 sets of 10 to 15 repetitions. Resistance and volume can be increased to progress the exercise.
  - Isometric wall sits: Wall slides should be completed with the patient's back against the wall and feet shoulder-width apart. The patient should begin by sliding down the wall until their knees are flexed to 90°. This exercise can be held for 10 seconds for 5 repetitions and can progress to be held for 30 to 60 seconds for 10 repetitions.

Techniques to Increase Muscle Strength, Power, and Endurance

- After initial injury, quadriceps strength and activation deficits exist.
- Open chain exercises, such as quadriceps setting, straight leg raises (SLR), and unweighted, seated knee extension long arc quadriceps (LAQ), can be performed to strengthen the quadriceps muscles.
- Progression towards weight-bearing (closed kinetic chain) exercises should be initiated once the patient demonstrates improved quadriceps strength with open chain exercises, such as the absence of a quadriceps lag with a straight leg raise (SLR).

Functional Exercises

- Altered movement patterns during gait are present in noncopers with ACL deficiency and differ based on gender.[14-17]
- After ACL injury, noncopers demonstrate increased cocontraction of quadriceps and hamstrings musculature throughout gait.[15,18]
- Limitations in knee-joint range of motion, quadriceps strength measures, and patient's complaints of pain may contribute to gait deviations.
- In addition to resolving these impairments, gait training should be performed in the clinic with verbal, tactile, and visual cuing. Emphasis should be placed on heel strike at initial contact with quadriceps muscle contraction as well as symmetrical stance time between limbs.
- Interventions in the later phases of rehabilitation (perturbation training) have been suggested to abate these asymmetrical movement patterns in male and female noncopers.[14,15]

Milestones for Progression to the Next Phase

- 1+ effusion or less using the modified stoke technique[1]
- Symmetrical passive knee extension and flexion to the contralateral limb should be measured with a goniometer. Knee extension should be symmetrical to the uninvolved limb. If the uninvolved limb demonstrates hyperextension, the involved limb should demonstrate at least 0° of extension. Knee flexion range of motion should be within 5° to the contralateral side.
- No complaints of additional pathology (e.g., patellar tendon irritation, joint line pain, tibial tuberosity pain)

Phase II (weeks 4 to 8)

Protection

- Patients are required to wear a functional knee brace during the agility component of this phase.

Management of Pain and Swelling

- Soreness rules and effusion are used to determine progression through this phase.[1,19]
- The criteria for progression using the soreness rules are found in Figure 32-6.
- Knee-joint effusion is assessed using the modified stroke test (Table 32-1).[1] If effusion is 2+ or greater, the patient does not advance in the rehabilitation program.
- Effusion and pain in the knee joint are treated using cryotherapy, compression, elevation, and antiinflammatory medications as needed. In addition, retrograde massage of the knee is used for effusion management.

Techniques for Progressive Increase in Range of Motion

- To progress into this phase, full passive knee extension and flexion range of motion equal to the contralateral side must be present.[2,20]

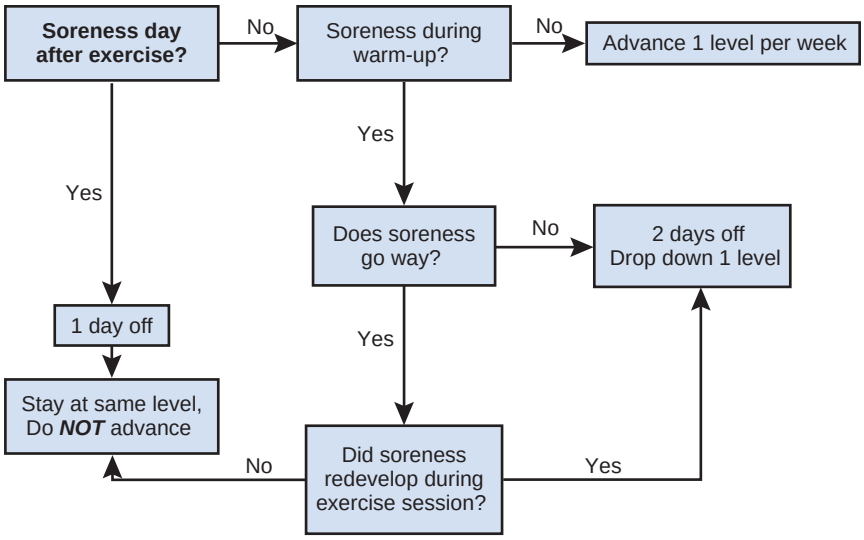

FIGURE 32-6. Soreness rules.[19]

Manual Therapy Techniques

- Tibiofemoral mobilization with rotation are used to regain full passive knee flexion.

Stretching and Flexibility Techniques for the Musculotendinous Unit

Stretching should be done to improve and maintain flexibility. The following stretches below are recommended after ACL injury. Stretches should be held for 30 seconds and repeated at a minimum of 3 times. Additional repetitions may be needed for some patients.

- Quadriceps stretch
- Hamstring stretch
- Iliotibial band (ITB) stretch
- Gastrocnemius/soleus stretch

Other Therapeutic Exercises

The type of cardiovascular training should be related to the patient's sport or occupational activity. A graded program should be initiated for 5 to 10 minutes using the soreness rules and effusion grades to determine progression.[1,19] When patients can perform the activity for 15 to 20 minutes without pain or swelling, they can progress to road or track-related activities.[20]

Stationary cycling: Should be used to improve endurance. Resistance and time can be increased as per patient's response.

- Elliptical machine: Reduces body weight to approximately 75%, so this should be initiated until patients can tolerate full weight bearing, pain-free. Progressive resistance should be added to improve endurance.
- Stair climber can be used as an additional form of cardiovascular training. Only when full, pain-free weight bearing can be tolerated should patients complete this form of cardiovascular exercise.

Activation of Primary Muscles Involved

- If quadriceps index is less than 80%, neuromuscular electrical stimulation to the quadriceps muscles is used to augment quadriceps strengthening exercises.
- Neuromuscular stimulation may improve quadriceps strength if applied in a high-intensity setting.[9-11,21]

Open and Closed Kinetic Chain Exercises

- The implementation of nonweightbearing (open kinetic chain) and weightbearing (closed kinetic chain) quadriceps strengthening exercises has been demonstrated to improve muscle strength and functional outcomes in patients with ACL injury.[3,21-23] Quadriceps muscles strength training involves the use of high-intensity, low-repetition, nonweightbearing and weightbearing quadriceps strengthening exercises to the involved limb (60% to 70% of 1-repetition maximum for 8 to 12 repetitions for 1 to 3 sets, with progression to 80% to 100% of 1-repetition maximum to maximize strength).[24]
- Nonweightbearing quadriceps strengthening exercises include knee extension exercises and isokinetic exercises on an electromechanical dynamometer.[13,15]
- Weightbearing exercises included resisted leg press and lateral and forward step-downs. Step-downs were performed initially on a 10.16 cm (4 inches) step and subjects were progressed in step height when they demonstrated adequate performance and proper technique.[13,15]

Techniques to Increase Muscle Strength, Power, and Endurance

- Open Kinetic Chain (OKC):
  - Resisted knee-extension exercises: seated knee extension should be completed with progressive weights. Unilateral strengthening and eccentric strengthening will improve quadriceps strength deficits of the involved limb. Low repetitions with high intensity are recommended for making improvements in strength deficits. To determine initial resistance, a resistance of approximately 75% of the patients' 1-repetition maximum should be used. It is recommended that 3 to 5 sets of 6 to 8 repetitions at this resistance is completed.[13]

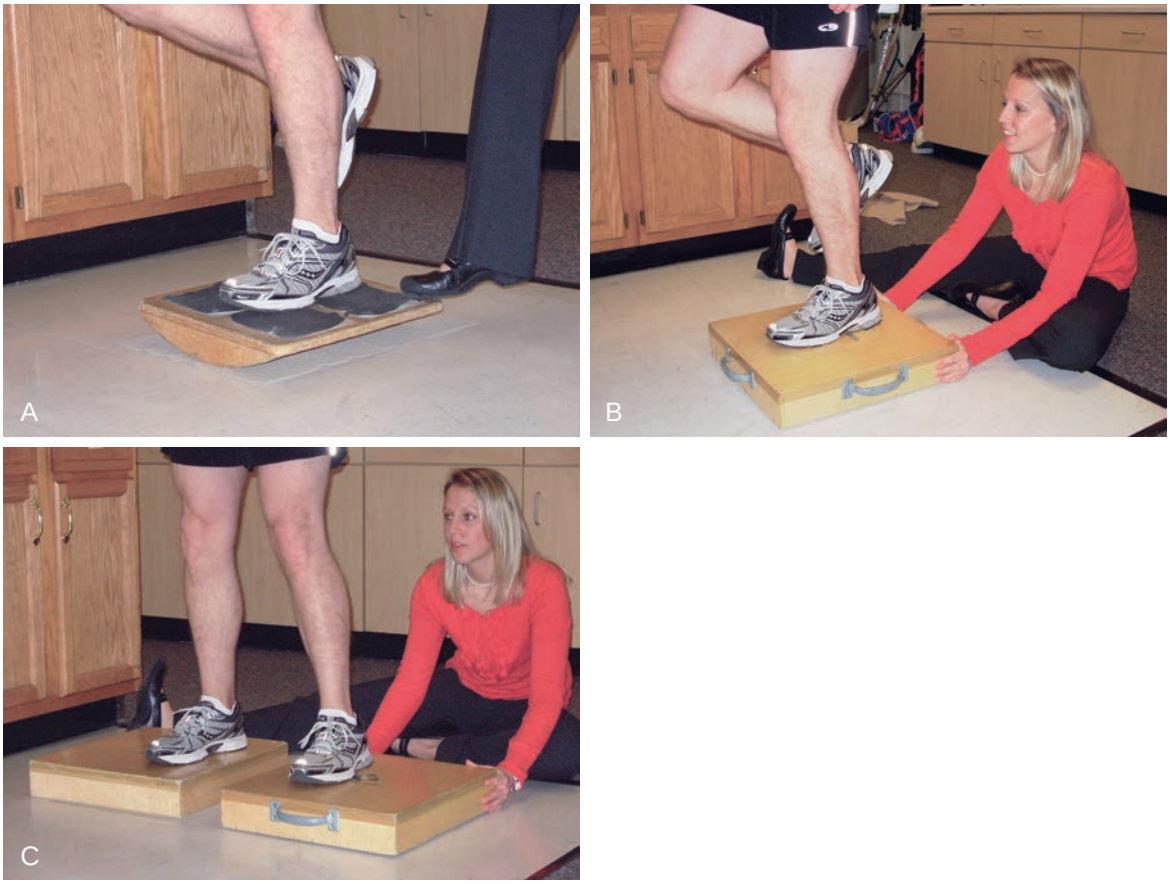

FIGURE 32-7. A, Perturbation training on rocker board. **B,** Perturbation training on roller board. **C,** Perturbation training on roller board and platform.

  - Isokinetic exercises on electromechanical dynamometer at various speeds: This strengthening protocol includes concentric and eccentric resistance of the knee extensors during active knee flexion and extension. Isokinetic strengthening can be completed using an isokinetic dynamometer at speeds beginning at 60°/s and progress to 180°/s at 30°/s increments.[13]
- Closed Kinetic Chain (CKC):
  - Resisted leg press: Both unilateral and eccentric leg press exercises are recommended to improve strength deficits. Similar to knee-extension exercises, low repetitions at 75% of the patient's 1-repetition maximum are recommended; 3 to 5 sets of 6 to 8 repetitions are suggested.[13]
  - Lateral and forward step-downs: These exercises are recommended for functional benefits and must be completed with proper form. The rehabilitation specialist should monitor the patient's mechanics, observing a level pelvis and that the patient keeps the knee alignment correctly over the foot. The height of the step should be chosen based on the highest height that the patient can properly maintain their form; 3 sets of 10 repetitions are recommended, and the height of the box is progressed as per patient's tolerance.[13]

Neuromuscular Dynamic Stability Exercises

- Perturbation training is a specialized neuromuscular training technique designed to encourage compensatory muscle strategies in patients with ACL deficiency[3,20,25]
- The proposed mechanisms for increasing dynamic knee stability with perturbation training is based on increasing the heightened sensitivity of muscle spindles to facilitate antagonist muscle activation to respond to perturbations (length feedback) and reciprocal inhibition of agonist muscles mediated by Golgi tendon organs (force feedback).[3,26-28]
- Perturbation training involves the destabilization of the lower extremity in a systematic progressive manner with translatory and rotary perturbations on support surfaces to elicit selective muscle activation without gross muscle cocontraction.[3,20,25]
- Perturbation training consists of 3 specific techniques to facilitate joint stability (Figure 32-7) (A) rocker board perturbations, (B) multiplanar roller board perturbations, and (C) multiplanar roller board perturbations with a stationary platform.
- For the rocker-board and roller-board techniques, initially all patients begin the first session in a double limb support stance. If the patient exhibits good balance reaction without loss of balance, they progress to single limb support stance for the remainder of the sessions.

- For the roller board/stationary platform condition, the subject placed the involved limb on either the roller board or the stationary platform and after the completion of 3 sets, the limbs were alternated and the treatment was repeated.
- The goal for this condition was to have the subject resist the speed and magnitude of the perturbation force applied by the therapist without anticipatory muscle contraction or rigid cocontraction. Subjects were given verbal commands: "Meet my force, don't beat my force," "Don't overpower me," "Soften your knees," and "Relax between perturbations".
- The objective was to either resist the force or to reestablish a balanced posture after the perturbation was applied by the therapist.
- For the first 2 to 5 sessions, the patient is informed with verbal cues of the direction and timing of perturbation movement. Verbal and tactile cues are used to inform the patient to avoid cocontractions at the knee.
- Subsequent sessions progressed from expected to random directions and timing of the perturbation, increasing intensity and magnitude of the force, and decreasing verbal cues.
- Progression of perturbations is individualized depending on the subject's ability to apply appropriate directional and counter-resistive force, selective muscle activation patterns, and reduction in loss of balance.
- During the last 5 sessions, a sports- or activity-specific task was introduced to distract the subject's attention to increase difficulty of the task.
- The progression of perturbation training is detailed in Table 32-3.

Functional Exercises

- Agility training is designed to expose the lower extremities to rapid body movement and directional changes of the limbs.[20]
- Clinicians should observe the patient's willingness to use and rely on the operated lower limb. We recommend the use of functional knee braces during agility training.
- Side shuffles and carioca drills are used to expose the involved limb to quick changes of direction in the lateral direction.
- Shuttle runs are used to promote rapid acceleration and deceleration.

Table 32-3 Perturbation Exercises and Progression Guidelines[20]

	Early (Estimated Treatment 1–3)	Middle (Estimated Treatment 4–7)	Late (Estimated Treatment 8–10)
Roller Board	Position: Patient on board (bilateral 1st treatment, progress to unilateral) Application: Slow application of force, low magnitude, Straight plane of movement (do all A/P reps before you begin M/L) Observe: Cue patient to avoid massive cocontraction at knee. Do not overstress beyond limit of stability (do not induce fall)	Position: Unilateral Application: Unexpected forces with rapid increasing magnitude force application with added rotatory and diagonal motions Distraction: Add distraction (ball toss, stick work) Observe: Observe difficulty with recovery but few to no falls	Position: Unilateral Application: Increased magnitude of force application with random direction movements Distraction: Increase speed and magnitude of distraction in sport specific positions Observe: Look for disassociation of hip, knee, and ankle
Rocker Board	Position: Begin bilateral, progress to unilateral Application: Slow application of force, low magnitude with less force medial than lateral Observe: Cue patient to maintain equal weight bearing bilaterally and avoid massive cocontraction at the knee	Position: Unilateral Application: Unexpected forces with rapid increasing magnitude force application Distraction: Add distraction (ball toss, stick work) Observe: Look for a rapid return to a stable base after perturbation	Position: Unilateral with foot on a diagonal Application: Increased magnitude force application with random direction movements Distraction: Increase speed and magnitude of distraction in sport specific positions Observe: Look for minimal sway from stable stance at rest or following any perturbation
Roller-board and Stationary Platform	Position: One foot on the roller board, one on the platform with equal weightbearing on both lower extremities Application: Slow application of force, low magnitude in all directions Observe: Cue patient to maintain equal weightbearing bilaterally (watch for unweighting of the involved limb as level of difficulty increases). Do not overpower the patient. Patient should match therapist's forces without excessive movement of roller board	Position: One foot on the roller board, one on the platform with equal weight bearing on both lower extremities Application: Unexpected forces with rapid increasing magnitude force application with added combined movements Distraction: Add distraction (ball toss, stick work) Observe: Cue patient to maintain equal weightbearing bilaterally. Cue patient to react as you remove force (avoid rebound board movement)	Position: One foot on the roller board, one on the platform with equal weightbearing on both lower extremities Application: Increased magnitude force application with random direction movements Distraction: Increase speed and magnitude of distraction with added diagonal/sport specific stance (forward split, backward split) Observe: Cue patient to maintain equal weight bearing bilaterally. Cue patient to react as you remove force (avoid rebound board movement)
Time: 3 sets of 1 minute of each with 30 to 60 seconds rest periods Phases: 10 treatments total			

Courtesy of Tara Jo Manal, University of Delaware Physical Therapy Clinic.

- Cutting and pivoting drills are incorporated to expose the patient to more sport-specific movements. The drills are initiated at half-speed and progress to full speed based on the knee's response to the training by using the soreness and effusion criteria for progression.
- Progression of the distance and the incorporation of unexpected direction changes and sports equipment into the drill is based on the patient's apprehension, pain, and swelling.

Sport-Specific Exercises

- Sport-specific skills and movements are gradually incorporated into the perturbation and agility training programs.[20]
- Patients must be able to perform the agility training without pain, swelling, or apprehension.

Milestones for Progression to the Next Phase

- This phase of the rehabilitation program is a minimum of 10 training sessions.
- The perturbation training is 10 sessions.
- To progress to the next phase, patients must pass a battery of tests to determine readiness for return to sports (RTS criteria).[2]
  - No pain using a visual analog scale (VAS) or numeric pain rating scale (NPRS)
  - No effusion measured with the modified stroke test[1]
  - Full passive knee extension and flexion ROM
  - Quadriceps index of 90% or greater measured with a maximal voluntary contraction (MVIC with the burst superimposition test or peak torque with isokinetic testing)
  - Single-leg hop symmetry index of 90% or greater
    - Single hop for distance
    - Triple crossover hop for distance
    - Triple hop for distance
    - 6-m timed hop
  - Knee Outcome Survey, Activities of Daily Living Scale (KOS-ADLS) of 90% or more
  - Global rating scale (GRS) of perceived knee function question of 90% or more

Phase III (weeks 9 to 12)

Protection

- Patients are required to wear a functional knee brace during the sport-specific drills and return to sports.

Management of Pain and Swelling

- Soreness rules and effusion grades are used to determine progression through this phase with the same criteria for progression as stated in Phase I and Phase II.[1,19]
- Effusion and pain in the knee joint are treated using cryotherapy, compression, elevation, and antiinflammatory medications as needed. Additionally, retrograde massage of the knee is used for effusion management.

Techniques for Progressive Increase in Range of Motion

- Patients must have full passive knee extension and flexion ROM before initiation of this phase.

Stretching and Flexibility Techniques for the Musculotendinous Unit

Stretching should be maintained as part of a home exercises program in this phase of rehabilitation. If flexibility restrictions remain in this phase, manual stretching by the therapist may be required. The stretches below are recommended, holding for 30 seconds for 3 repetitions.

- Quadriceps stretch
- Hamstring stretch
- Iliotibial band (ITB) stretch
- Gastrocnemius/soleus stretch

Other Therapeutic Exercises

All exercises should be completed as per patient's response to activity. An increase in knee-joint effusion or knee symptoms may occur, therefore, these exercises should not be progressed and symptoms should be treated and monitored.[1,19]

- Stationary cycling: Recommended at this phase to continue to improve endurance. Progressive resistance with interval training will increase endurance and strength, with progression to 20 to 30 minutes.
- Elliptical machine: Progressive resistance and increased incline can be added at this phase to improve endurance and strength with progression to 20 to 30 minutes. This can be completed both forward and backward as well as in a squat position to increase strengthening.
- Stair climber: Should be increased in resistance to improve endurance and increase strength with progression to 20 to 30 minutes.

Activation of Primary Muscles Involved

- The burst superimposition test should be used to determine muscle activation.[7,8] Patients should demonstrate less than 5% quadriceps inhibition.[7] This is measured as the force exerted by the patient volitionally divided by the force exerted with the burst super imposition multiplied by 100. This should be performed bilaterally.

Open and Closed Kinetic Chain Exercises

Muscle strength training involves the use of high-intensity, low-repetition, nonweightbearing and weightbearing muscle-strengthening exercises to the involved limb as recommended by the American College of Sports Medicine position on progression models in resistance training for healthy adults (60% to 70% of 1-repetition maximum, for 8 to 12 repetitions, for 1 to 3 sets; with progression to 80% to 100% of 1-repetition maximum to maximize strength).[24]

- Open Kinetic Chain (OKC):
  - Resisted knee-extension exercises: Similar to exercises in Phase II, these exercises can be competed with increased resistance. Unilateral and eccentric exercises can be used to increase strength of the involved limb knee extensors.

- Resisted knee flexion exercises: Hamstring weakness relative to quadriceps strength is linked to a higher rate of injury.[29] A hamstring to quadriceps ratio of at least 55% is recommended.[30]
- Isokinetic exercises on electromechanical dynamometer at various speeds: Concentric and eccentric resistance of the knee extensors can be completed with an isokinetic dynamometer. Similar to recommendations in Phase II, increased resistance can be added to challenge the patient.

- Closed Kinetic Chain (CKC):
  - Resisted leg press: Unilateral and eccentric exercises will improve quadriceps strength. Progressive resistance should be increased from the recommendations in Phase II.
  - Lateral and forward step-downs: Repetitions and height of the box should be progressed from Phase II without resulting in poor mechanics. Proper mechanics should be maintained with this exercise.
  - Squats: Can be completed both bilaterally and unilaterally with proper mechanics. Similar to step-downs, patients should maintain a level pelvis and correct knee alignment over the foot. This can be progressed to unstable surfaces, such as foam or a BOSU ball.
  - Lunges: Should be completed as long as patients are free of pain. Lunges can be repeated or alternating to improve quadriceps and hip extensor muscle strength. This can be progressed to holding weights or lunging on unstable surfaces, such as foam.
  - Heel raises: Can be completed bilateral or unilateral and can be progressed with the addition of weights.

Techniques to Increase Muscle Strength, Power, and Endurance

- See OKC and CKC exercises

Functional Exercises

- Walk/jog running progression for the benefit of unilateral lower limb strengthening and increased force generation and attenuation during a dynamic running task (Table 32-4).

Sport-Specific Exercises

- The demands and performance characteristics of the athlete's sport will dictate the necessary performance enhancement techniques.[31,32]

Milestones for Progression to Advanced Sport-Specific Training and Conditioning

All activities in this progression should be pain-free, measured with soreness rules, and no knee-joint effusion, measured with effusion grades via the modified stroke test.[1,19]

Before beginning agilities, patients should be able to hop without pain, effusion, or apprehension/hesitation

- Full-speed agilities without pain, effusion, or apprehension/hesitation.[1,19,20]
- Unopposed practice of sport-specific skills without pain, effusion, or apprehension/hesitation.[1,19,20]

Table 32-4 Walk/Jog Running Progression

	Running Progression	
	Treadmill	*Track*
Level 1	0.1-mile walk/0.1-mile jog repeat 10 times	Jog straights/walk curves (2 miles)
Level 2	Alternate 0.1-mile walk/0.2-mile jog (2 miles)	Jog straights/Jog 1 curve every other lap (2 miles)
Level 3	Alternate 0.1-mile walk/0.3-mile jog (2 miles)	Jog straights/Jog 1 curve every lap (2 miles)
Level 4	Alternate 0.1-mile walk/0.4-mile jog (2 miles)	Jog 1¾ lap/Walk curve (2 miles)
Level 5	Jog full 2 miles	Jog all laps (2 miles)
Level 6	Increase workout to 2.5 miles	Increase workout to 2.5 miles
Level 7	Increase workout to 3 miles	Increase workout to 3 miles
Level 8	Alternate between running/jogging every 0.25 miles	Increase speed on straights/jog curves

Criteria for Abandoning Nonoperative Treatment and Proceeding to Surgery or More Intensive Intervention

- Any giving way episode with pain and swelling during or after the completion of Phase II
- Patient unable to return to preferred level of activity

Tips and Guidelines for Transitioning to Performance Enhancement

- The transition from rehabilitation program to performance enhancement progresses from recovery of the sports injury in which the physical impairments and functional limitations are largely resolved to allow return to sports participation.
- A balance between the ability of the healing tissue to handle the progressive loading while increasing the intensity and volume of the training program to meet the high physical demands of returning to sports.[33]
- It is at this time period when the athlete can incorporate strategies and techniques to enhance performance. General guidelines to transition to this stage include:
  - No signs of joint inflammation.
    - No pain using a visual analog scale (VAS) or numeric pain rating scale (NPRS).
    - No effusion measured with the modified stroke test[1].
  - Normal limb-to-limb symmetry in:[20]
    - Full passive knee extension and flexion ROM
    - Quadriceps index of 90% or more measured with a maximal voluntary contraction (MVIC with the burst superimposition test or peak torque with isokinetic testing)

  - Single-legged hop symmetry index of 90% or greater
  - Single hop for distance
  - Triple crossover hop for distance
  - Triple hop for distance
  - 6-meter timed hop
- Knee outcome survey, activities of daily living scale (KOS-ADLS) of 90% or more
- Global rating of perceived knee function (GRS) question of 90% or more

Performance Enhancement and Beyond Rehabilitation: Training/Trainer and Optimization of Athletic Performance

- Athlete is transitioned back to sports with the assistance of athletic trainers and strength and conditioning specialists/coaches.
- The demands and performance characteristics of the athlete's sport will dictate the necessary performance enhancement techniques.[31]
- Components of performance training will include enhancement of strength, power, speed, agility, endurance, and metabolic system specificity.

Specific Criteria for Return to Sports Participation: Tests and Measurements

- Patients must pass a battery of tests to determine readiness for return to sports (RTS criteria).[2,20]
  - No signs of joint inflammation
    - No pain using a visual analog scale (VAS) or numeric pain rating scale (NPRS).
    - No effusion measured with the modified stroke test[1].
  - Normal limb-to-limb symmetry in:[20]
    - Full passive knee extension and flexion ROM
    - Quadriceps index of 90% or more measured with a maximal voluntary contraction (MVIC with the burst superimposition test or peak torque with isokinetic testing)
    - Single-legged hop symmetry index of 90% or greater
  - Single hop for distance
  - Triple crossover hop for distance
  - Triple hop for distance
  - 6-meter timed hop
  - Knee outcome survey, activities of daily living Scale (KOS-ADLS) of 90% or more
  - Global rating of perceived knee function (GRS) question of 90% or more
- One-on-one opposed practice of sport-specific skills without pain, effusion, or apprehension[20]
- Return to full practice in individual sports or with team without pain, effusion, or apprehension[20]

Evidence

Chmielewski TL, Hurd WJ, Rudolph KS, et al: Perturbation training improves knee kinematics and reduces muscle cocontraction after complete unilateral anterior cruciate ligament rupture. *Phys Ther* 85:740–749, Discussion 50–54, 2005.

This prospective, comparative cohort study of 17 potential copers following perturbation training compared with 17 healthy control on muscle cocontraction and knee kinematics. After perturbation training, muscle cocontractions were reduced and knee kinematics were normalized in potential copers. (Level III evidence)

Chmielewski TL, Rudolph KS, Snyder-Mackler L: Development of dynamic knee stability after acute ACL injury. *J Electromyogr Kinesiol* 12:267–274, 2002.

This prospective, cohort study of 9 potential copers evaluated the effect of perturbation training on muscle activation and function. Vastus lateralis muscle activation increased during walking and was dependent on lateral hamstrings and soleus activation. Patient-reported knee function improved and all subjects returned to preinjury activities without episodes of instability. (Level III evidence)

Eitzen I, Moksnes H, Snyder-Mackler L, et al: A progressive 5-week exercise therapy program leads to significant improvement in knee function early after anterior cruciate ligament injury. *J Orthop Sports Phys Ther* 40:705–721, 2010.

This prospective, cohort study of 100 patients evaluated changes in knee function after the completion of a rehabilitation program for patients with ACL injury. The progressive 5-week rehabilitation program resulted in significant improvements in thigh muscle strength and single-leg hop performance. (Level III evidence)

Fitzgerald GK, Axe MJ, Snyder-Mackler L: A decision-making scheme for returning patients to high-level activity with nonoperative treatment after anterior cruciate ligament rupture. *Knee Surg Sports Traumatol Arthrosc* 8:76–82, 2002.

This prospective, cohort study of 93 patients described the development of a screening examination for selecting patients most likely to achieve successful return to high-level physical activity with nonoperative management of an ACL injury. Of the 28 patients who were rehabilitation candidates, 79% were able to return to previous levels of activity without giving way episode of the knee. Those who successfully returned to preinjury level had higher scores in the knee outcome survey, sports activity scale, global ratings of knee function, and 6-meter timed hop indexes than those who failed. (Level III evidence)

Fitzgerald GK, Axe MJ, Snyder-Mackler L: The efficacy of perturbation training in nonoperative anterior cruciate ligament rehabilitation programs for physical active individuals. *Phys Ther* 80:128–140, 2000.

This prospective, randomized study of 26 rehabilitation candidates compared standard nonoperative rehabilitation versus standard rehabilitation augmented with perturbation training. The perturbation training group were more likely to have successful rehabilitation and greater long-term success than the standard group. (Level II evidence)

Hartigan E, Axe MJ, Snyder-Mackler L: Perturbation training prior to ACL reconstruction improves gait asymmetries in noncopers. *J Orthop Res* 27:724–729, 2009.

This prospective, randomized study of 19 noncopers who underwent ACL reconstruction compared preoperative

rehabilitation with aggressive quadriceps strengthening versus aggressive quadriceps strengthening augmented with perturbation training. Quadriceps strength improved similarly in both groups. The perturbation training group had greater knee excursions at mid-stance after training, whereas the strengthening group continued to have smaller knee excursions at mid-stance after training. (Level II evidence)

Hurd WJ, Axe MJ, Snyder-Mackler L: A 10-year prospective trial of a patient management algorithm and screening examination for highly active individuals with anterior cruciate ligament injury: Part 2, determinants of dynamic knee stability. *Am J Sports Med* 36:48–56, 2008.

This prospective, cohort study of 345 consecutive patients evaluated outcomes between potential copers and noncopers. No differences were seen in outcomes between the groups. Quadriceps strength influenced hop test performance more than preinjury activity level and anterior knee laxity. Self-reported global function was influenced by the 6-meter timed hop performance. (Level III evidence)

Multiple-Choice Questions

QUESTION 1. Perturbation training is a specialized neuromuscular training program that incorporates the use of which of the following conditions?

A. Roller board and a platform
B. Rocker board
C. Roller board
D. All of the above

QUESTION 2. Athletes can progress to Phase III when:

A. They are 6 weeks from the initial injury
B. They meet the clinical milestones outlined
C. They have 85% strength and hop performance on the involved limb compared to the uninvolved limb
D. They have full knee extension and flexion range of motion

QUESTION 3. Athletes should consider operative management if:

A. They have any giving way episode with pain and swelling during or after the completion of Phase II
B. They are unable to return to preferred level of activity
C. Both A and B
D. Neither A nor B

QUESTION 4. Using the modified stroke technique, when a small amount of fluid moves into the medial sulcus after a lateral stroke, this is graded as:

A. 2+ effusion
B. 1+ effusion
C. Trace effusion
D. No effusion

QUESTION 5. A subject can be classified as a potential coper if:

A. ≤ 1 episode of giving way and ≥ 60% global rating score
B. ≥ 80% timed hop score and KOS-ADLS score
C. All of the above
D. None of the above

Answer Key

QUESTION 1. Correct answer: **D** (see Phase II)

QUESTION 2. Correct answer: **B** (see Phase II)

QUESTION 3. Correct answer: **C** (see Phase III)

QUESTION 4. Correct answer: **C** (see Phase I)

QUESTION 5. Correct answer: **C** (see Phase I)

POSTOPERATIVE REHABILITATION AFTER BONE-PATELLAR TENDON-BONE ANTERIOR CRUCIATE LIGAMENT RECONSTRUCTION (AUTOGRAFT AND ALLOGRAFT)

Donna Williams, PT, MHS, Mark Allen Jordan, MD, and Geoffrey S. Van Thiel, MD, MBA

Indications for Surgical Treatment

Although there are no absolute criteria for delineating candidates for nonoperative management versus surgical reconstruction, the following are general indications for ACL reconstruction:

- High demand and high risk lifestyles (athletes)
- Concomitant injuries to other ligaments and/or menisci
- Generalized ligamentous laxity
- Repeated episodes of giving way despite rehabilitation
- Recurrent instability with activities of daily living

Brief Summary of Surgical Treatment

Major Surgical Steps

- Physical exam under general anesthesia with the patient in the supine position
  - Lachman and pivot shift tests
- Harvest and preparation of autograft from middle-third of patellar tendon/thawing of allograft
- Diagnostic and therapeutic arthroscopy for concomitant pathology (meniscectomy, debridement, etc.)
- Debridement of remnant ACL down to tibial stump
- Tibial tunnel creation
- Femoral tunnel creation
- Graft passage through tibial and femoral tunnels
- Fixation of the ACL graft in femoral tunnel
- Fixation of ACL graft in tibial tunnel
- Wound closure

Factors that may Affect Rehabilitation

Anesthetic

- Femoral nerve block usually provides excellent pain relief for the first 8 to 24 hours postoperatively. After wearing off, however, other methods will likely need to be employed including nonsteroidal antiinflammatories and cryotherapy.
- Patients using cryotherapy postoperatively have been demonstrated to require less narcotic analgesics for pain control.

Surgical

- Surgical
  - Concomitant knee pathology:
    - Preoperatively or during diagnostic arthroscopy, concomitant pathology (tendinous injuries, cartilage lesions, meniscal, and ligamentous tears) are often identified. These may dictate alteration to the rehabilitative protocol, and thus make it important to identify, before rehabilitation, which other lesions are present or procedures were performed.
  - Bone-patellar tendon-bone (B-PT-B) autograft versus allograft:
    - Patellar tendon grafts can be obtained either from the patient's own knee (autograft) or from a cadaver source (allograft). A goal of rehabilitation is to gain quadriceps strength, because this has been demonstrated to decrease following ACL injury. Current literature suggests that this extensor weakness is caused by the ACL injury itself rather than surgery or graft choice; thus, progressive gains in quad strength should be a goal of rehabilitation regardless of graft choice.
    - Patients with autograft experience graft site morbidity which may need to be addressed including patellar tendonitis and patellofemoral syndrome.
    - As patients with allograft tend to experience less postoperative pain, they may be prone to putting early excess stress on their grafts. In addition, allografts have been demonstrated to take longer to incorporate caused by their foreign origin. Thus, some authorities suggest using less aggressive rehabilitative programs for those with allografts, although this is not a consensus opinion.
    - Because allografts are foreign tissue, there is an increased (albeit rare) incidence of prolonged sterile inflammation.
  - Graft type and graft fixation
    - Bone-patellar tendon-bone autograft is considered the gold standard of ACL reconstruction caused by its demonstrated track record of strength; however, occasional anterior knee pain is considered its major drawback.
    - Bone to bone healing takes approximately 8 weeks to complete in the majority of cases, whereas soft tissue to bone healing takes approximately 12 weeks.

Before Surgery: Overview of Goals, Milestones, and Guidelines[1]

Goals

Patients with an ACL injury initially present with a swollen, painful knee. While patient's comfort is an issue in its own right, this acute inflammation can also lead to postoperative arthrofibrosis if surgery is undertaken before return of normal range of motion. As such, preoperative management aims to decrease pain and swelling, increase strength, increase range of motion back to preinjury level, and to begin early therapy training. These parameters should be the factors by which a patient is judged ready for surgery, rather than setting absolute time limits from the injury. The following are tools in achieving these goals:

- Management of swelling
  - Cryo/compression devices: there are multiple commercially available devices useful in both the pre- and postoperative period. These devices have been demonstrated to be superior to icepacks in analgesia most likely caused by their compression effect and the ability to use during ambulation
  - Regardless of the method, the knee should be iced, compressed, and elevated at least 3 to 4 times per day until swelling is eliminated.
- Restoration of normal knee range of motion (symmetry with contralateral knee)
  - Patients are restricted from competitive sports, but full weightbearing and range of motion are encouraged, and normal daily activities can be completed as tolerated.
  - The affected leg should be placed with a small roll under the ankle with nothing underneath the knee to encourage full extension.
  - The following exercises may be used both pre- and postoperatively:
    - Towel stretches (for extension): a towel looped around the midfoot is used to extend the knee and lift the heel, while the opposite hand holds the thigh down

    An advancement of this exercise is contract the quadriceps while releasing the towel to hold the heel off the ground.
    - Wall and heel slides (for flexion): laying supine with the affected leg's foot against a wall, the foot is slid into flexion with assistance from the opposite leg as needed
    - Quad sets and straight leg raises
  - The stationary bike and elliptical machine are good choices for maintaining physical activity

GUIDING PRINCIPLES OF POSTOPERATIVE REHABILITATION

- Early emphasis on obtaining full passive extension, progress knee flexion, and patellar mobility
- Early initiation of quadriceps and hamstring activity
- Control of swelling and pain to reduce muscle atrophy and inhibition
- Restoring neuromuscular control and proprioception
- Stepped progression based on achievement of specific therapeutic goals
- Functional testing and sport-specific training before return to play

[1] *Prehabilitation, if appropriate, is described in the Nonoperative Rehabilitation section of this chapter.*

Phase I: Immediate Postoperative Period (days 0 to 28)

Clinical Pearls

A frequent complication encountered following ACL reconstruction is the loss of full knee extension (extension lag), sometimes leading to a flexion contracture. Loss of extension often causes additional joint contact stresses, difficulty with quadriceps activation, and excessive muscular fatigue. During the first week postoperatively, a drop lock brace locked in extension during ambulation and sleeping can help prevent loss of extension.

Goals

- Protecting the graft
- Reducing joint swelling and pain
- Restoring patellar mobility and normal passive knee extension
- Progressively improving knee flexion
- Reestablishing voluntary quadriceps control
- Progressing towards independent ambulation

Protection

- Weight bearing as tolerated
- For the first week postoperatively, a drop lock knee extension brace is locked in full extension for ambulation and sleeping
- During weeks 1 to 4 (after the first postoperative visit), the brace is unlocked for ambulation and locked in extension for sleep
- If a concomitant meniscus repair/transplantation or articular cartilage procedure was performed, weight bearing parameters will be altered during this period

Management of Pain and Swelling

Treatment for pain/analgesia

- Pain causes reflex inhibition of muscle activity and can inhibit completion of strength and range of motion exercises.
- In additional to narcotic and/or antiinflammatory oral analgesics, cryotherapy and compression can be helpful in alleviating pain.
- Cryotherapy can be accomplished in a variety of ways including ice packs, ice baths, and continuous-flow cooling devices. A cryotherapy apparatus, consisting of a cooling apparatus and a wrap, can be useful during this period

Decrease swelling

- Swelling must be aggressively managed in the postoperative period as effusion can cause muscle inhibition.
- Cryotherapy and joint compression with a knee sleeve, ace wrap, or compression device are the most frequently used modalities.
- Cryotherapy can be done for 20 minutes hourly with the leg elevated.
- Muscle activities, such as quad sets and ankle pumps (active dorsi/plantar-flexion of ankle), can help reduce swelling by increasing venous return.

Techniques for Progressive Increase in Range of Motion

- As tolerated
- Early passive range of motion can be augmented by use of a continuous passive motion machine.
- In general, the patient should achieve full passive extension soon after surgery. This is facilitated by bracing in extension during ambulation and sleeping.

TIMELINE 32-2: **Postoperative Rehabilitation After Bone-Patellar Tendon-Bone ACL Reconstruction (Autograft and Allograft)**

PHASE I (weeks 1 to 4)	PHASE II (weeks 4 to 6)
• Knee extension brace locked in full extension for ambulation and sleeping • Crutches for comfort, WBAT • ROM: full passive knee extension and flexion as tolerated (goal of 90°) • Patellar mobilization • Ankle pumps, SLR, quad/ham sets, gastroc-soleus stretches in a nonweightbearing position • *After week 1, unlock brace for ambulation and remove for sleeping	• Gradually discontinue brace and crutches (brace off when no extension lag) • Continue self-performed ROM exercises 4 to 5 times daily • Overpressure into full knee extension • AROM from 0° to 115° flexion by the end of the phase • Continue patellar mobility • Bicycle, SLR • Isometric quad and hamstring sets • Begin closed chain extension (partial ROM squat, leg press, etc.) • Front and side lunges • Lateral step ups • Front step ups • Hamstring curls • Calf raises • Begin balance training (bilateral stance on tilt board and medicine ball throws) • Perturbation training

- Patellar mobilizations
  - Pushing up on the patella, hold the patella superiorly for 5 seconds for 10 repetitions. Repeat for the inferior, medial, and lateral positions.
- Initiate scar mobilizations as needed.

Other Therapeutic Exercises

- Heel slides (see Before Surgery section)
- Quadriceps/hamstring sets
  - Quad sets: Sitting on the floor with affected leg in front of body, tighten quadriceps by pressing the posterior knee flat to the floor. Hold for 10 seconds, and repeat. Neuromuscular electrical stimulation can be used to facilitate the quad contraction.
  - Hamstring sets: Laying on back with knees partially flexed and heels resting against the ground, press heels against the ground and isometrically contract hamstrings (no sliding). Hold for 10 seconds, and repeat
- Gastrocnemius/soleus stretching in a nonweightbearing position
  - Sitting with affected leg out in front of body, wrap a towel around ball of foot and pull back and hold until moderate tension is achieved in calf.
- Straight leg raise in flexion, extension, abduction, and adduction with brace in full extension until quad strength prevents extension lag (Figure 32-8)
- Prone hangs: Lie prone with legs hanging with the edge of the table at the thighs
- Gait training emphasizing full extension and quad activation
- Stationary bike, half to full revolutions without resistance to facilitate flexion

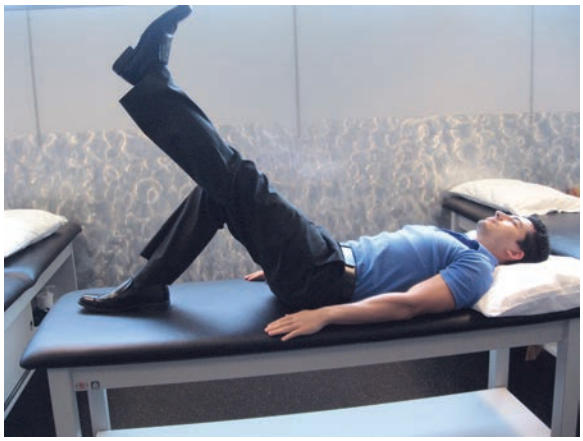

FIGURE 32-8. Straight leg raise (flexion, extension, abduction, and adduction).

Activation of Primary Muscles Involved in Injury Area or Surgical Structures

- Quad and hamstring sets
- Straight leg raise with brace in full extension until quad strength prevents extension lag (hip flexion, abduction, adduction, extension)

Milestones for Progression to the Next Phase

- Adequate wound healing
- Straight leg raise with or without extension lag
- Ability to put weight on affected limb
- Minimal knee swelling
- Good patellar mobility

TIMELINE 32-2: Postoperative Rehabilitation After Bone-Patellar Tendon-Bone ACL Reconstruction (Autograft and Allograft) (Continued)

PHASE III (week 6 to 4 months)	PHASE IV (months 4 to 6)	PHASE V (months 6+)
• No brace or crutches (gait should become normal without assistance) • PT modalities as needed • PROM-full, continue self-performed ROM exercises 4 to 5 times daily • Bicycle, stair stepper, NordicTrack, straight ahead running • Resisted SLR • Advance close chain exercises (leg press, squat, etc.) • Hamstring curl with band • Progress isometric strength program • Unilateral balance training on tilt board and with medicine ball throws • Lunge exercises • Wall squats, vertical squats, calf raises • Perturbation training • Biodex Stability System	• PT modalities as needed • Consider a functional brace in certain patient populations • PROM-full • Continue ROM exercises 4 to 5 times daily • Patient should have quiet knee (minimal to no swelling or pain) • SLR, hamstring curls and variations, leg press, squats, lunges • Continue and progress endurance work • Progress isometric strengthening programs • Perturbation training on a single leg • Continue balance training with medicine ball and tilt board • Continue Biodex Stability System • Initiate plyometric leg press and jumping exercises (observe and correct landing) • Initiate sport-specific exercises (cone drills, side shuffles, cariocas, cutting) • Backward/forward running	• PROM-maintain full motion • Gradual return to unrestricted sport • SLR, hamstring curls and variations, single-leg squats, lunges, and leg press • Continue and advance endurance training (consider interval training) • Increase cutting maneuvers • Progress isometric strengthening programs • Perturbation training on a single leg • Biodex Stability System • Progress plyometric leg press and sport-specific plyometric drills • Continue sport-specific exercises (sudden start/stops, cone drills, agility drills) • Sport-specific skill training (e.g., coming out of 3-point stance for football lineman) • After return to sport, encourage maintenance program for strength/endurance

Phase II (weeks 4 to 6)

Clinical Pearls

To facilitate discontinuation of crutches, it is useful to have the patient use a single crutch for 3 or 4 days to ease the transition.

Goals

- Maintain range of motion (particularly full passive knee extension) and patellar mobility established in previous phase
- Progressively increase knee flexion
- Discontinuation of brace once patient can perform straight leg raise without extension lag
- Discontinuation of crutches
- Initiate muscle strength, proprioception, and balance training

Protection

- During this phase, patient should progress to ambulation without brace or crutch use
- The brace should be discontinued once patient can perform a straight leg raise without extension lag
- The graft is at its weakest point from weeks 4 to 8

Management of Pain and Swelling

Treatment for pain/analgesia
- In addition to oral analgesics and cryotherapy, electrical stimulation and transcutaneous electrical neuromuscular stimulation (TENS) devices may be useful

Decrease swelling
- Cryotherapy and joint compression with a knee sleeve or ace wrap are the most frequently used modalities
- For cryotherapy the patient can ice for 20 minutes hourly and elevate the lower extremity

Techniques for Progressive Increase in Range of Motion

- Maintain full extension gained during previous phase
- Self-performed range of motion exercises should be done 4 to 5 times per day
- Continue to increase active and passive flexion, with a rough goal being 115° of flexion by the end of this phase
- Continue patellar mobility
- Perform scar mobility work as needed

Other Therapeutic Exercises

- Continue heel slides, quad and hamstring sets, and straight leg raises as in Phase I
- Progress to weightbearing gastrocnemius/soleus stretch (with towel)
- Begin standing heel raises (knees in extension)
- Begin closed chain extension exercises (see below)
- Begin balance and proprioception exercises (see below)
- Hamstring curls (begin with standing and no resistance)
- Stationary bike

Clinical Pearls

Closed chain extension exercises, such as partial squats, which cocontract the hamstrings along with the quadriceps while compressing the knee joint, place less strain on the ACL than open chain extension exercises (e.g., leg extension machine). Open chain flexion exercises (e.g., hamstring curls) put comparatively less strain on the ACL as well. With patellar tendon grafts, closed chain extension exercises and open chain flexion exercises are both appropriate and useful during this period. Due to applying a significant shearing force on the ACL, open chain extension exercises (leg extensions) are not used early in most protocols.

Activation of Primary Muscles Involved in Injury Area or Surgical Structures

- Isometric quadriceps and hamstring sets
- Straight leg raises
- Leg press and squats (partial range of motion)
- Hamstring curls (standing)
- Calf raises (in extension and with knees at 90°)

Sensorimotor Exercises

- Begin balance training with bilateral stance on a tilt board and medicine ball throws
- Single-leg balance with emphasis on full extension

Open and Closed Kinetic Chain Exercises

- Partial squats
- Leg press (Figure 32-9)
- Weight shifts
- Front and side lunges
- Lateral step-ups
- Front step-ups
- Standing terminal knee extensions with resistance

Techniques to Increase Muscle Strength, Power, and Endurance

Stationary bicycle for endurance

Neuromuscular Dynamic Stability Exercises

- Begin perturbation training
  - Roller-board translations
  - Tilt board perturbation
  - Roller board and stationary platform perturbation

Milestones for Progression to the Next Phase

- Active range of motion from 0° to 115° for knee flexion
- Discontinuation of brace along and full active extension without lag
- Single stance on affected leg with upper extremity assist
- Lack of knee effusion

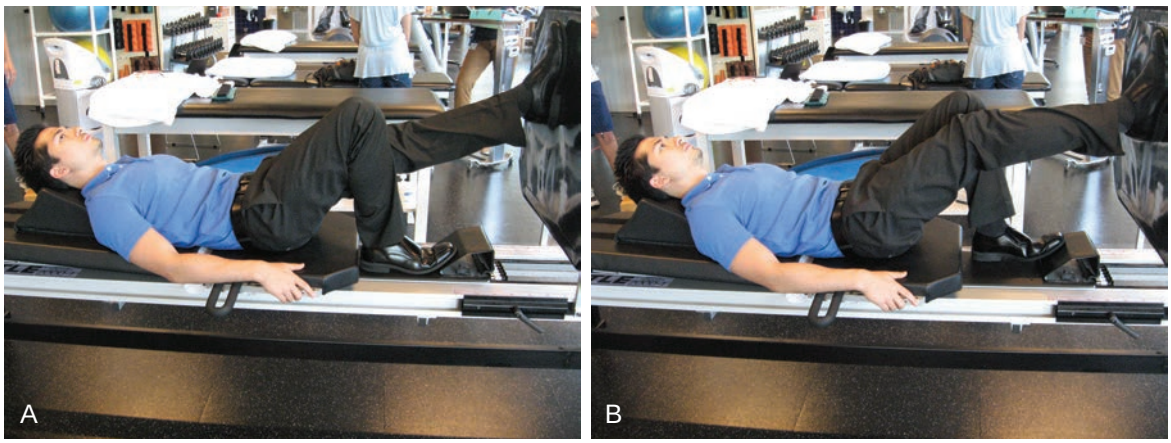

FIGURE 32-9. A, B, Leg press.

Phase III (week 6 to 4 months)

Clinical Pearls

At weeks 4 to 8, the graft is at its weakest point of the postoperative period. Accordingly, high-graft stress activities, such as jumping, squatting below 60°, pivoting, and cutting should be avoided. Scar tissue also sometimes becomes an issue at this point and may necessitate soft tissue mobilizations.

Goals

- Continue to increase strength, proprioception, balance, and neuromuscular control
- Gain full pain-free range of motion equal to nonsurgical knee
- Achieve normal gait without assistance device
- Improve endurance
- Improve limb confidence

Protection

- The graft is at its weakest point during the postoperative period from weeks 4 to 8
- Early in Phase III, avoid activities that place high stress on the graft (see Clinical Pearls above)
- Conditioning activities which avoid shifting and pivoting
  - Stair stepper/NordicTrack, and straight ahead running may be started at week 12

Management of Pain and Swelling

Treatment for pain/analgesia
- Narcotic analgesics should be discontinued by the start of week 4 and thus should be avoided in Phase III if possible.
- Cryotherapy, electrical stimulation, and transcutaneous electrical neuromuscular stimulation (TENS) devices may be continued, but pain should become minimal to nonexistent during this phase

Decrease swelling
- Continue the joint compression with a knee sleeve or ace wrap as needed
- Ice the knee for 20 minutes hourly and elevate lower extremity as needed
- Joint sleeve may be discontinued when swelling is no longer an issue, but some feel psychologically more comfortable with the sleeve

Techniques for Progressive Increase in Range of Motion

- Continue range of motion exercises 4 to 5 times per day focusing on maintaining full extension and increasing flexion. During this phase, flexion should become equal to unaffected leg.

Other Therapeutic Exercises

- Continue and progress on flexibility and isometric strength work
- Continue stationary bicycle
- Stair stepper/NordicTrack starting at week 12
- Straight ahead running starting at week 12
- Advance closed chain exercises (see below)
- Advance hamstring curls (add band resistance)
- Advance balance/proprioceptive training (see below)

Activation of Primary Muscles Involved in Injury Area or Surgical Structures

- Advancement of isometric strength program (quad sets, hamstring sets, straight leg raises, etc.)
- Advance hamstring exercises
  - Hamstring curls with band resistance
  - Swiss ball hamstring curls (Figure 32-10)
- Advance close chain strengthening (see below)

Sensorimotor Exercises

- Balance training on a tilt board (bilateral to unilateral, eyes open/closed)
- Balance training with medicine ball throws

Open and Closed Kinetic Chain Exercises

- Lateral lunge step-overs
- Front and side lunges

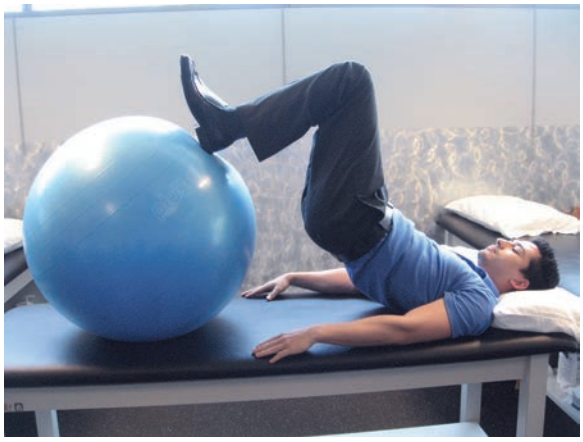

FIGURE 32-10. Chair walk. Sitting in a rolling desk chair with the unaffected foot off the ground, reach the foot of the injured forward and flex at knee to move the chair forward.

- Lateral step-downs
- Front step-downs
- Wall squats
- Vertical squats
- Calf raises
- Stair stepper machine
- Lateral side stepping

Techniques to Increase Muscle Strength, Power, and Endurance

- Stair stepper/NordicTrack
- Stationary bicycle
- Walking program
- Straight ahead running

Neuromuscular Dynamic Stability Exercises

- Biodex Stability system
- Perturbation training
  - Roller-board translations
  - Tilt-board perturbation
  - Roller board and stationary platform perturbation

Milestones for Progression to the Next Phase

- Active range of motion equal in both knees
- No joint effusion
- Normal gait without assistance
- Single-leg stance without assistance
- Understanding of precautions with regard to state of graft healing

Phase IV (4 to 6 months)

Clinical Pearls

This phase sometimes presents an issue with athletes being overly eager to resume sport-specific training. Many patients need to be reminded that as with Phases I and III, progression is necessary and commitment to the process and protocol is key.

Goals

- Return leg strength to normal
- Improve muscular power and endurance
- Enhance neuromuscular control
- Gradual incorporation of higher stress movements, such as cutting and pivoting
- Initiate plyometric program and sport-specific drills

Protection

- Most patients do not require crutches or a brace by this point
- Some patients, such as downhill skiers or football lineman, may benefit from functional bracing to decrease the chance of injury recurrence

Management of Pain and Swelling

Treatment for pain/analgesia
- Patient should have a quiet knee by this point (minimal to no pain and minimal swelling with activity)
- Narcotic analgesics should not be necessary at this point in time
- Cryotherapy, electrical stimulation, and transcutaneous electrical neuromuscular stimulation (TENS) devices can be used when necessary

Decrease swelling
- If swelling is still an issue, joint compression with a knee sleeve or ace wrap is useful.
- Ice for 20 minutes hourly and elevate lower extremity as needed.

Clinical Pearls
